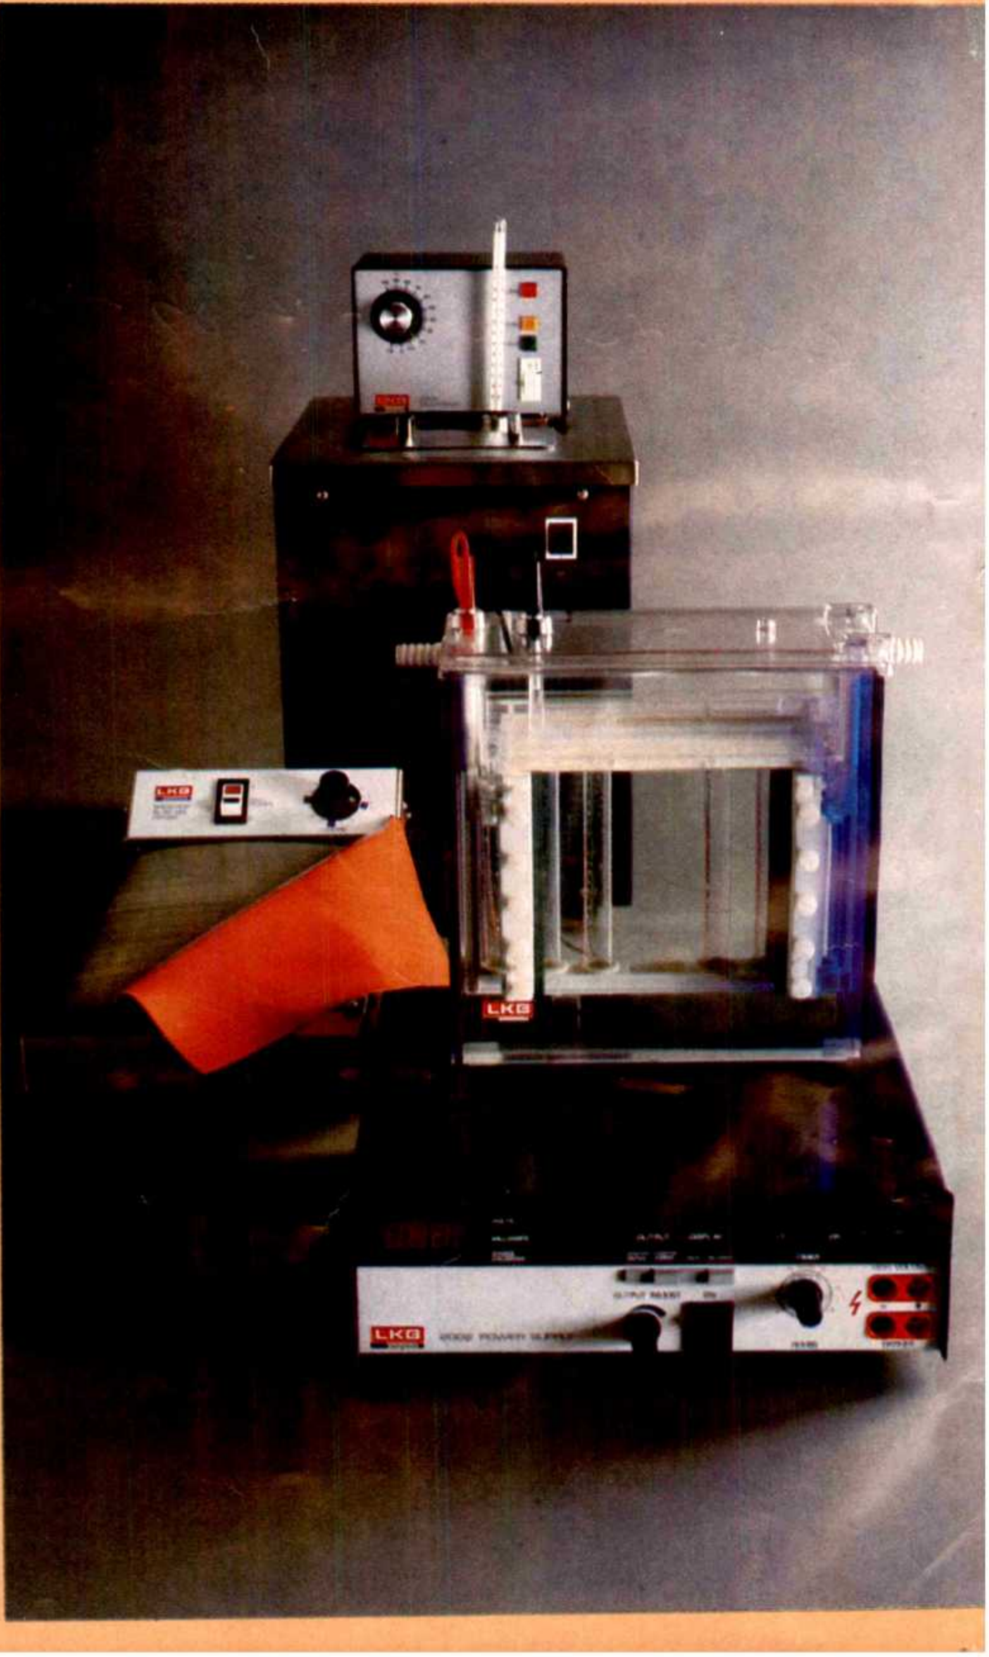
GEOLOGY OF EUROPA

The new LKB Vertical Electrophoresis System.

Obtain superior electrophoretic separations routinely, with the new vertical electrophoresis instruments from LKB.



LKB 2001 Vertical Electrophoresis Unit
Cast gels without leaking and without messy grease, tape, or agar seals. You can run any of the most widely used polyacrylamide or agarose techniques: SDS, disc, or gradient gels. Perform simple two dimensional separations with our built-in 2-D trough. Circulate buffer, if you wish. Handle heavy workloads with optional twenty well combs and dual slab capability.

LKB 2002 Power Supply
Digital display makes this 500 volt power supply easy to set, and easy to read even from across the lab. A built-in timer assures you reproducible run times and results which are easy to compare.

LKB 2003 Gel Dryer
Preserve your results safely, by drying them onto paper or between cellophane sheets. Accurate temperature control and easy sealing vacuum mean that even hard to handle gradient gels can be dried without cracking.

LKB 2009 MultiTemp Cooling Circulator
Remove the heat produced during electrophoresis to eliminate band skewing and curved migration fronts. The circulating flow of coolant and efficient heat exchanger of the vertical electrophoresis unit permit dependable results, year round, with reduced running times and without wasting water.

Surprisingly low price
You will be pleasantly surprised at how little it costs to acquire the Complete Vertical Electrophoresis System. For full details, call or write to your local LKB office or to the address listed below.

Style that counts

~~R514~~ R415

We've introduced some remarkable features into our new Colony Counter, each aimed at improving an often long and unrewarding but very necessary task.

The compact case styling, simple control layout and improved counter trigger system have resulted in a design which reduces fatigue during prolonged counting operations and requires no special probes or markers.

The counter is simply triggered by depressing the Petri dish. An unobtrusive audible tone increases counting speed by giving an immediate indication of each count action, rendering visual confirmation unnecessary.

Uniform, glare-free illumination of the dish holder minimizes eye strain and clearly defines even small or uncoloured colonies against light or dark backgrounds.

A dishweight sensitivity control is provided to suit each individual's preferred operating pressure and type or size of Petri dish. The unit has three other controls comprising a power on/off switch, a manual reset of the digital display and an audible tone on/off switch.

A no-compromise solution to scanning electron microscopy

The increasing use of scanning electron microscopy in industrial research and product development calls for higher standards and degrees of quantification and improved operational versatility.

Until now however, positional geometry within the specimen environment, along with the many detectors that have to be placed around the specimen, has required an SEM (scanning electron microscope) detector compromise that often produces poor performance in at least one of the operating modes.

So Philips developed a 'no-compromise' scanning electron microscope – the SEM 505 – in which a revolutionary, fibre-optics based, Multi-Function Detector (MFD) interfaces the detecting elements with a photomultiplier/pre-amplifier assembly that can be placed outside of the specimen chamber; thus permitting high flexibility in detector placement. The result? Optimum detection performance in all modes because detection geometry is no longer limited by fixed construction or precise port location.

Aims and Scope:

This quarterly journal will be the official publication of the newly formed International Society of Cerebral Blood Flow and Metabolism. It will gather, in one publication, new information on experimental, theoretical, and clinical aspects of brain circulation and metabolism. It will be of relevance to neurologists, neurochemists, physiologists, pharmacologists, anesthesiologists, neuroradiologists, neuropathologists and neuroscientists in general. Papers will be reviewed by a distinguished editorial board and carefully chosen experts in various fields. Reviewing will be rigorous in order to attain the highest standards of scholarship.

Features:

The following types of material will appear on a regular basis:

- *Original articles* on all fields relating to cerebral blood flow and metabolism including experimental physiological, pharmacological, and biochemical studies, methodological and theoretical papers, and clinical reports.
- *Short communications* reporting concise pieces of work that lead to positive conclusions. These communications should not normally exceed 1500 words and should not contain more than 2 figures.
- *Reviews* on important aspects from invited contributors.
- *Editorials* on subjects of a timely nature.
- Announcements of scientific meetings related to the field.
- Book reviews of new books of interest to the readership.

Circle No.04 on Reader Enquiry Card.

Call for Papers:

The submission of suitable articles for editorial review is welcomed. Articles must be in English and three copies should be submitted. References in the text should be cited by names of authors and year of publication. They should be listed in alphabetical order at the end of the text. Journal titles should be abbreviated in accordance with Index Medicus. A detailed list of instructions to contributors can be obtained from the Publisher or the Editor-in-Chief. The format of the journal will permit high quality reproduction of plates with minimal reduction. Articles should be sent directly to the Editor-in-Chief: Dr. A. M. Harper, M.D., University of Glasgow, Wellcome Surgical Institute, Garscube Estate, Bearsden Road, Bearsden, Glasgow G61 1QH, Scotland.

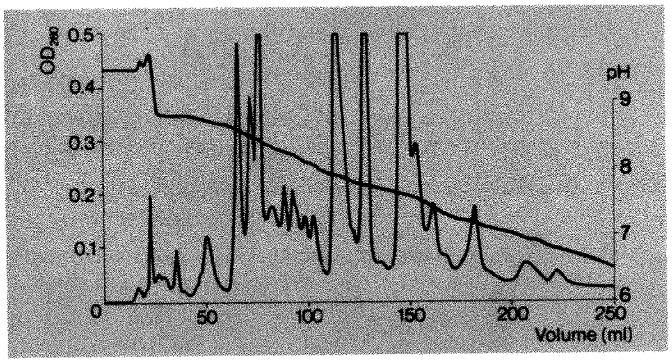
PRODUCT REVIEW This week's product review (page xix) covers chromatography.

CHROMATOFOCUSING. A NEW HIGH RESOLUTION TECHNIQUE FOR PROTEIN SEPARATION.

If you think chromatofocusing sounds like an interesting combination of two well known techniques, you're right. But if you think its probably only half as good as either of them you're wrong. Chromatofocusing gives you the best of both.



Separation of proteins from mammalian muscle by chromatofocusing.

Separations according to pI

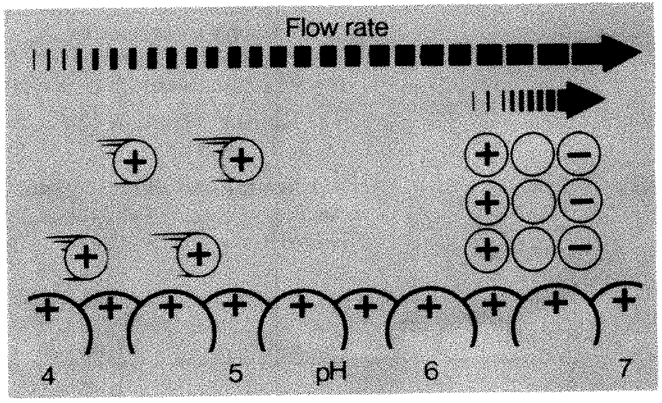
As you've probably guessed, chromatofocusing separates proteins according to isoelectric point. All you need is a column, and the new products Polybuffer™ and Polybuffer exchangers. All you do is equilibrate and pack your column with Polybuffer exchanger, and elute at a lower pH with Polybuffer.

High resolution, high capacity

What you get is a highly selective preparative method for purifying proteins. In addition, focusing effects ensure that samples elute as sharp zones.

Column chromatography with focusing effects

When protein is applied to a column of Polybuffer exchanger below its pI, it migrates downwards in the pH gradient until pH = pI. Beyond this point it binds to the gel. However, as more Polybuffer is added to the column, the pH decreases and the protein elutes according to its pI. Zones are focused since molecules below their pI are repelled from the gel and so catch up with the leading edge of the zone.



Self-generated pH gradients

Chromatofocusing works because Polybuffer exchangers are substituted with basic buffering groups. When these groups are titrated with Polybuffer, at a lower pH, a linear pH gradient forms automatically in the column.

Easy to use Chromatofocusing kit

Two gels and three buffers cover the range pH 11–4. If you're starting from scratch, you should order the Chromatofocusing kit (order no. 17-0520-01), which contains full instructions for use and sufficient material to cover the range pH 9-4.

More information is available in the booklet "Chromatofocusing with Polybuffer and Polybuffer exchangers" so remember to request it when you place an order for the Chromatofocusing kit. We'll accept your order by phone or by post. Once you've tried chromatofocusing you'll wonder how you managed without it.

Spiders

E.O. Wilson: Let me remind you that people everywhere, a large percent of the population, at a very early age have already developed a deep horror at the sight of snakes or spiders with nothing more than gentle nudging from their parents, if that. Yet, in spite of the fact that parents constantly reinforce their children against going near electric sockets, automobiles, knives and the like, phobias against such objects rarely develop.

Marvin Harris: Let's go back again to the possibility that these phobias are genetically programmed – which I'm willing to grant. The overwhelming bulk of the socially conditioned response repertories of different human societies consists, by your own admission, of culturally determined rather than genetically determined traits. Then it seems to me that when one offers a cogent culturological explanation of these

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership Many reviews are invited, but submitted articles may also be accepted, it is advisable to consult us before writing a review article
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables), they are reports of major research developments
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible

Manuscripts may be submitted either to London or New York Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced The title should be brief and informative Pages should be numbered References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends Units should be identified in the margin on their first appearance Equations should occupy single lines if possible exp (x) is preferred to e^x if 'x' is more than one character

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials Most figures are reduced to one column width so originals should be about as wide as a page of *Nature* To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted We are always glad to see artwork for possible use on the cover, but cannot guarantee its return

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

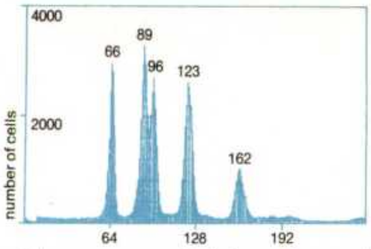
Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov (1976)

The Ortho ICP 22A Flow Cytometer utilizes a high power mercury arc lamp in combination with a Kohler optical system to achieve extraordinary precision and wide versatility. The capabilities of this instrument are best evaluated from the standpoint of the results it can provide. Examine the actual fluorescence histograms presented.

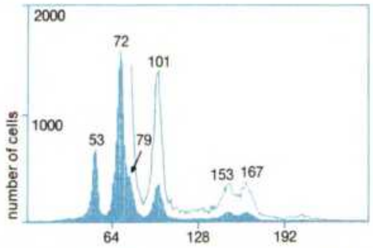
The high resolution of the instrument is complemented by its dual channel fluorescence detectors, which allow correlated measurements of two different dyes. Thus, the ICP 22A can provide simultaneous measurement of per cell DNA and protein content. Because of its Kohler illumination system it can even measure the DNA content of cells in which the DNA is irregularly distributed. Given the range of specific stoichiometric dyes available, its versatility is almost unmatched. To enhance that versatility still further, the ICP 22A will soon offer electronic cell volume measurement in addition to the other parameters (available September 1980).

Therapy monitoring by flow cytometric analysis

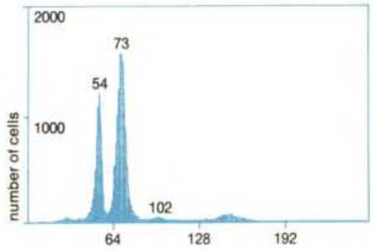
1. DNA histograms show a multiclonal tumor with four distinct tumor cell lines. Left peak in all histograms is normal cells. During three month chemotherapy with bleomycin and DTIC, the three higher ploidy tumor lines disappeared leaving only the more resistant lowest ploidy line. This biopsy series shows the different sensitivities of tumor cell lines in the same patient.



1a. At commencement of chemotherapy, the DNA histogram shows four cell lines with different ploidy stages. Left peak is normal diploid cells.



1b. After two months the DNA histogram shows suppression of three of the tumor cell lines.



1c. One month later, the DNA histogram shows the disappearance of higher ploidy tumor cell lines and the resistance of lower ploidy tumor cell line to chemotherapy.

In order to provide customers with complete support, Ortho maintains an Applications Laboratory that is available for confirmation and consultation services. Additionally, an international network of service technicians is ready to aid customers should calibration or repairs ever be required.

The Ortho ICP 22A offers remarkable precision and versatility at an exceptionally affordable price. We invite you to contact the Research Instruments Division of Ortho to find out more about the ICP Flow Cytometer. It's available either as a stand alone flow cytometric analyzer or as part of an Ortho System 40 or 60, with dual laser illumination.

Protocols No. 28 and 29

Two new Protocols; *One step Ethidium Bromide DNA/Cell Staining Procedure* and *DNA analysis using D.A.P.I.* are available from Ortho. Write or call for your complimentary copies. (617) 329-6100

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

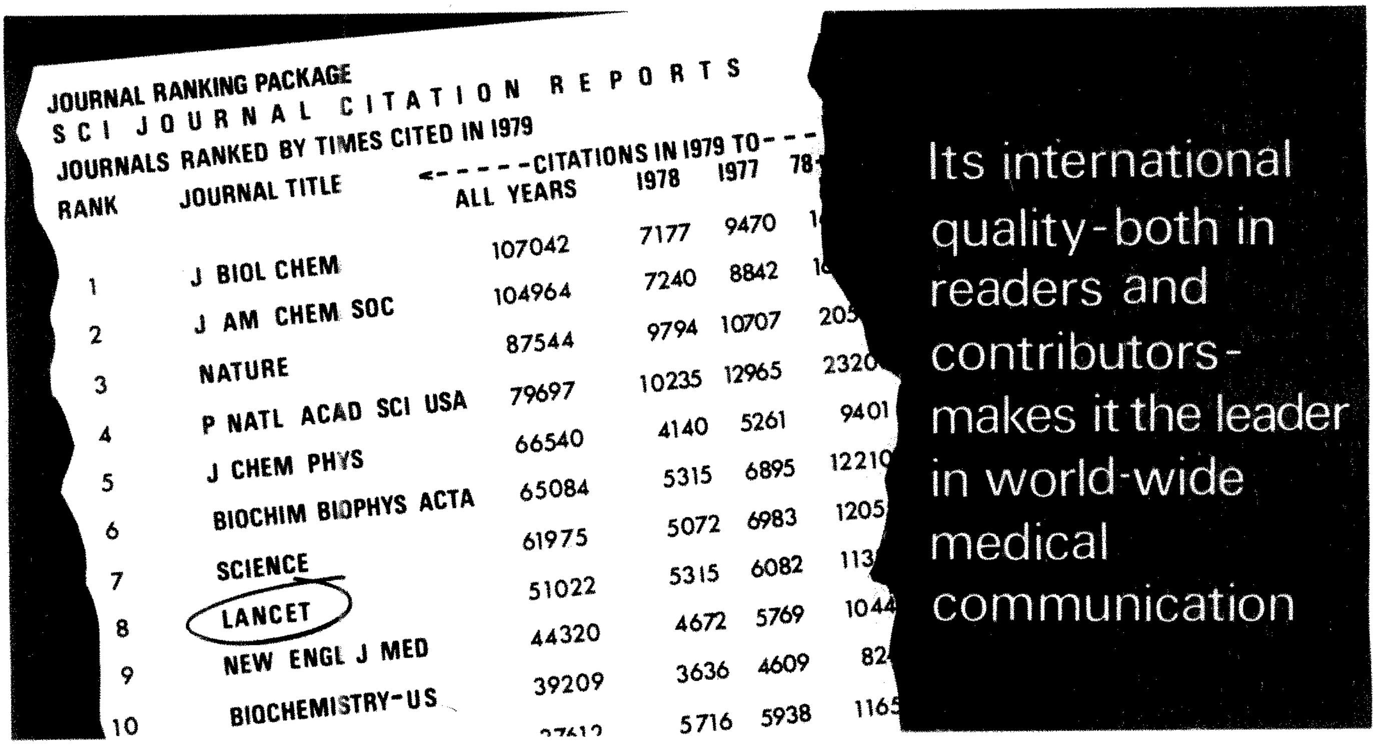
In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

THE LANCET

On the frontiers of medical and scientific knowledge THE LANCET is not only the last word - it's the first!

Consistently ranked by the Institute of Scientific Information as the most cited medical journal in the world.



JOURNAL RANKING PACKAGE

Contents continued overleaf

Cover: A leech ganglion stained with the monoclonal antibody Lan3-2 and rhodamine-labelled second antibody. The fluorescence micrograph shows the nociceptive cell bodies and processes stained. Zipser and McKay report on page 549 the use of monoclonal antibodies to distinguish identifiable neurones as well as numerous unidentified cells in the leech nervous system.

Raven Press

New Titles in Neurosciences

The Primary Acoustic Nuclei

Rafael Lorente de Nó

Written by one of the world's most outstanding neuroanatomists, this monograph contains reproductions of nearly 100 original drawings prepared from Golgi or Golgi-Cox sections, as well as microphotographs of 19 myelin-stained sections that present the locations of the various subdivisions of the acoustic nuclei and the courses of the main association tracts. **200 pp., 8½ x 11 inches, 129 figures, $25.00 (1981) ISBN 0-89004-318-3**

Kuru: Early Letters and Field-Notes from the Collection of D. Carleton Gajdusek

Editors: Judith Farquhar and D. Carleton Gajdusek

This volume is a collection of D. Carleton Gajdusek's writings during the first year of his medical investigation of Kuru. The investigation of this fatal disease provides illuminating insights into the scientific method and the history and philosophy of science, as well as valuable leads for future work on slow virus infections and chronic and heredofamilial degenerative diseases of man's central nervous system.
366 pp., $32.00 (1981) ISBN 0-89004-359-0

Amino Acid Neurotransmitters

Editors: Francis V. DeFeudis and Paul Mandel

This volume places particular emphasis on roles of amino acid in integrated central nervous system functions and behavior, receptor pharmacology at both *in vivo* (electrophysiological) and *in vitro* (ligand-binding) levels, amino acid uptake and release, enzymology metabolism, and autoradiographic studies.
600 pp., $54.00 (1981) ISBN 0-89004-595-X
ISBN 0-89004-595-X

Psychobiology of Aggression and Violence

Editor: Luigi Valzelli

This monograph by an internationally renowned neuroscientist integrates findings from animal and human studies to provide insights into the physiology and pathology of aggression, and to formulate potential controls for individuals and groups.
265 pp., $24.00 (1981) ISBN 0-89004-403-1

GABA and Benzodiazepine Receptors

Advances in Biochemical Psychopharmacology, Vol. 26

Editors: E. Costa, Gaetano Di Chiara, and G. L. Gessa

This book examines GABA participation in the action of benzodiazepines: the structure of the GABA receptor and the benzodiazepine binding site, the localization of these receptors within specific brain regions, structure-activity relationships with agonists, and the involvement of GABA receptors in specific functional pathways.
321 pp., $36.00 (1981) ISBN 0-89004-530-5

Glutamate as a Neurotransmitter

Advances in Biochemical Psychopharmacology, Vol. 27

Editors: G. Di Chiara and G. L. Gessa

Basic neurobiological evidence, as well as the pharmacological and clinical implications of the role of glutamate as transmitter are broadly and systematically treated, from the anatomy, biochemistry, and electrophysiology of glutamatergic synapses and receptors to the role of glutamate analogs, particularly kainic acid, in neuropathology. **464 pp., $41.00 (1981) ISBN 0-89004-420-1**

Neurosecretion and Brain Peptides: Implications for Brain Function and Neurological Disease

Advances in Biochemical Psychopharmacology, Vol. 28

Editors: Joseph B. Martin, Seymour Reichlin, and Katherine L. Bick

This volume presents the most recent findings regarding the synthesis, anatomic distribution, and function of neuropeptides and provides a critical evaluation of their importance for the understanding of the pathogenesis of neurologic disease.
725 pp., $58.00 (1981) ISBN 0-89004-535-6

Journal of Cerebral Blood Flow and Metabolism

Quarterly, Vol.1 (1981) ISSN-0271-678X
Subscription rates: Personal subscriptions-$85.00, U.S.A.;$95.00 elsewhere.
Library and institutional subscription-$95.00, U.S.A.; $105.00 elsewhere.
This quarterly journal is the official publication of the newly formed International Society of Cerebral Blood Flow and Metabolism. This publication offers new information on experimental, theoretical, and clinical aspects of brain circulation and metabolism.

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^{a} if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

NICK TRANSLATION KIT

5′ NICK$_{OH}$ TRANSLATION KIT 3′

3′ 5′

Now from Amersham

Tritium Nick Translation Kit TRK.700

A new kit for the preparation of DNA labelled with tritium to the specific activity of your choice.
Recommended protocols give 5×10^6–4×10^7 dpm/μg DNA
The kit comprises a set of non-radioactive reagents + 1 mCi [1′, 2′, 5-^{3}H]dCTP.

Already available from stock

PB.5100 non-radioactive reagents + 1 mCi [α-^{32}P]dCTP
PB.5025 non-radioactive reagents + 250 μCi [α-^{32}P]dCTP
for the preparation of DNA labelled with ^{32}P at up to 4×10^8 dpm/μg DNA

N.5000 non-radioactive reagents only

for the preparation of DNA labelled with the nucleotide of your choice.

Full details of the kit and protocols are available on request.

Cover: An Augergraph depicting the microchemistry of a grain boundary at the crack front of a steel failing by stress corrosion. The analysis is made by Auger electron spectroscopy which monitors a depth of only one or two atom layers. The yellow represents oxygen, cyan represents iron and the zone in between is tin segregated to the grain boundary and delineating the failure path. The role of grain boundary microchemistry in stress corrosion failure is described on page 663.

This issue also contains a review supplement devoted to textbooks published during the past eighteen months.

ENVIRONMENTAL SCIENCE & TECHNOLOGY

ES&T

Environmental Science & Technology—The premier research journal in the environmental field

Environmental science continues to be one of the fastest growing fields. And ES&T has grown right along with it!

ES&T continues to give you the practical, hard facts you need on this science...covering research, techniques, feasibility, products and services.

Essential reading for environmental scientists both in the business and academic world...ES&T has increased its emphasis on peer-reviewed research dealing with water, air, and waste chemistry in addition to adding critical discussions of important environmental science issues—all relevant to understanding the management of our natural environment. Also included is analysis of governmental regulations, current environmental research lab activities, and much more!

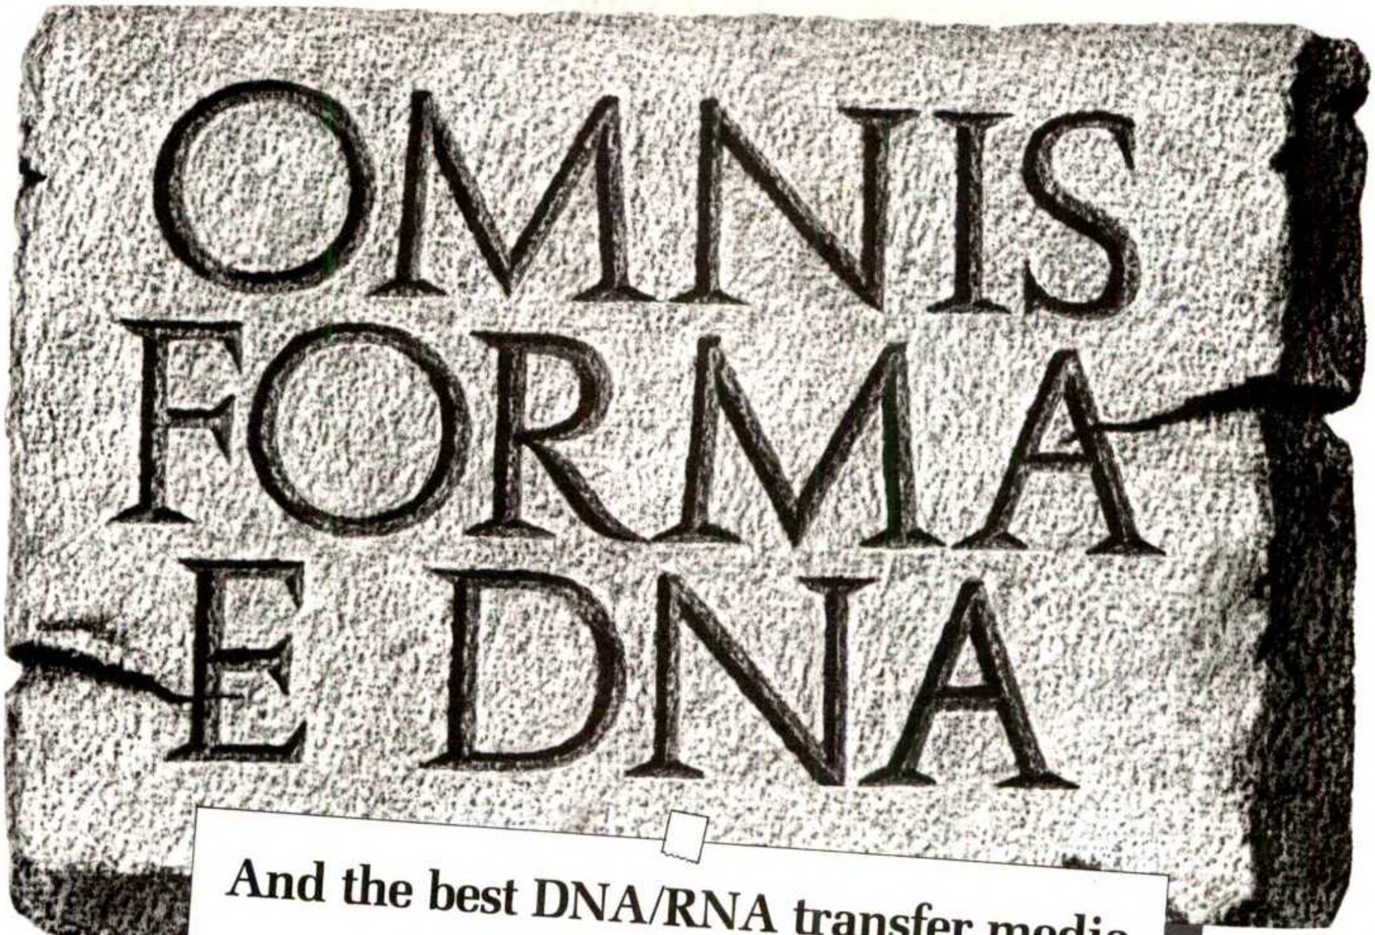
PRODUCT REVIEW This week's product review (page xxi) covers microbiological products



And the best DNA/RNA transfer media come from S&S.

S&S transfer media are established as the products of choice for "Southerns," "Northerns," "Westerns," "shotgunning," "plaque lifts" and "blitz-blotting"—because they do the job.

Pure nitrocellulose—the proven standard

Because S&S nitrocellulose is *pure* nitrocellulose, it effects a high degree of DNA transfer from gels, bacterial and plaque lawns. Maximum levels of hybridization can be achieved, resulting in more intense bands or spots. S&S nitrocellulose is available in whatever form you need: 12-0.025 μm pore size, gridded, in circles, squares, strips, rolls or full sheets.

Transa-Bind™—universally accepted medium for "Northern" transfers

Schleicher & Schuell Transa-Bind medium has found wide use in DNA, RNA and protein transfers because the fragments are covalently bound to the medium. Available in NBM (nitro) form and ABM (amino) form to suit your needs. Packaged in nitrogen-filled opaque bags to extend shelf life.

New S&S products in development for genetic researchers

S&S enjoys an earned reputation for working with researchers in developing new products to meet their specific needs. Be on the alert for new S&S transfer media soon to be introduced. Contact S&S for any information or technical help you might need.

Signs of grace (and opposite) for 1981

All new years are important. This, 1981, will be crucially so. By next December, it should be clear how several influential governments are tackling the problems which now confront them. For the time being, the most absorbing question is whether Mr Ronald Reagan will live up to his election promises — and threats. Before the year is up, however, there should be a new government in the Soviet Union, Even when the fear that change means danger is as deeply ingrained as in Moscow, it is unthinkable that Mr Brezhnev will be kept on as president much longer. In Western Europe, the chances are that the same old governments will have to battle with the same old problems, but with a sense of mounting despair. If the problems of economic stagnation coupled with inflation appear as obdurate by the end of the year as they seem now, people will begin to behave as if these problems have come to stay. So what are the signs to look for in the months ahead?

Economic problems matter because they determine the resources available for existing, cherished, institutions and for innovation. The industrialized democracies now all suffer to some degree from the disease pioneered first by Italy and then by Britain — rapid inflation born of democratic voters' convictions that living standards must inexorably rise, even when productivity is falling or when resources are transferred in substantial amounts to OPEC oil producers. The consequences are all too clear — industrial investment and research and development are starved of resources, productivity falls still further, the pool of wealth for sharing out diminishes and the dole queues lengthen. One of the first tests of Mr Reagan's temperament in office rather than on the hustings will be the fine print that will no doubt accompany his promised tax-cut. The promise is too fresh in people's minds to be forgotten, but a tax-cut unrequited by reduced federal expenditure would be inflationary. So will the offsetting cuts be intelligent (housing subsidies, pointless environmental protection, excessive solar energy research), stupid (education, research and development) or — horror — non-existent? Other governments in industrialized countries are likely to take their cue from Washington. If Mr Reagan ducks the economic issues, many other governments will know that there is no point in their struggling separately against inflation.

The Soviet economic problem, outwardly different, is as worrying — and not exclusively for Soviet citizens. In the whole Soviet bloc, there is less wealth to share than the managers of the economy would like. Inflation is, by definition, not a problem. Whatever people's hopes, their shares of what is to be shared are determined by the system of allocation. One consequence is the grinding deprivation of much of the Soviet system, partly the cause of troubles such as those with which Poland has recently been beset. The question which the anonymous electors of Mr Brezhnev's successor will have to face is whether the new Soviet government should risk some relaxation of the domestic system for the benefits that would ultimately accrue in improved economic performance. Probably they will shrink from taking such a step on the grounds that the risks of relaxation would be immediate and the benefits delayed. That will be bad news both for citizens of the Soviet bloc and for the rest of us. The needless economic privations of Eastern Europe and beyond are not simply cruel to those who bear the brunt of them but part of the cause of continuing trouble between East and West.

The irony, both in the West and the East, is that the ingredients of continuing technical change and economic improvement are clearly apparent. The cost of petroleum has become a burden, but nuclear power stations are partially a substitute. The new computer technologies, wildly oversimplified though they may have been, are gathering dust for lack of investment capital and sufficiently skilled manpower. Communications technology, physical and electronic, is held back by lack of capital but also by regulatory bumbledom. Agriculture, surprisingly the great success of the industrialized West in recent decades, languishes elsewhere. The outstanding challenge for most governments in 1981 will be to make a fresh start on using these ingredients of prosperity to enable their people to feed, clothe and house themselves decently, and to have something left over to do what they like with. For many Western governments, but especially for the American, this will require something of a battle with the powerful lobbies which have grown up in the past decade and which appear, after all, to think that there is such a thing as a free lunch — the benefits of technology but no generating plants within sight or the benefits of new drugs but no experiments with animals please. Mr Reagan's reputation suggests that he might throw himself cheerfully into such a fight, but only time will tell.

Two other issues will be bellwethers for the coming year, with policies on defence and arms control most vividly in people's minds. Mr Reagan seems to be committed to winning the arms race, whatever that may mean. Nobody, not even the Soviet Union, will be surprised if the Pentagon's budget now grows again. People in Europe will bite their nails. The danger is that one side or the other will be tempted to check whether it is really winning by pressing all the buttons. The chances are, however, that the arms race of the 1980s will not be very different from that of the 1950s — the modern equivalent of sabre rattling, a diversion of resources from more constructive purposes but adventitiously a source of further technological innovation. What matters much more, especially where Mr Reagan is concerned, is whether he will have the wit and the courage (for a Republican) to seize the opportunity in arms control with which he has been presented. The new administration is committed to reopening Salt II, but Mr Reagan is not the out-and-out abrogator who began the election campaign. As Inauguration Day approaches, he will be made increasingly aware of the advantages, philosophical and political, from balancing his part in the arms race with an open-minded view of what package might replace Salt II. The Comprehensive Test-Ban Treaty, nearly ready for signature though it is, is probably too much of a pill for the Republican Senate and General Alexander Haig to swallow. There is more room for manoeuvre on what are called theatre nuclear weapons — the missiles that must worry the West Germans but also, no doubt, Soviet military planners as well.

A less obvious sign of the way the wind is blowing in 1981 will be the way in which governments, but especially those of industrialized countries, shape in their dealings with the developing world. Mr Reagan's reputation is not encouraging but, to be fair, his position on the recommendations of the Brandt Report (as on many other issues) is not all that explicit. Again, the new president has the appearance of a conservative who may be pushed in liberal directions by events or even arguments. The obvious difficulty is that the months ahead are likely to see still more occasions on which developing countries act uppishly towards the United States (provoking pressure to put them in their place), but that there is no powerful political constituency for the decently self-interested policy of adequate assistance, technical and financial. In the long run, however, there will be no point in beating inflation or surviving the arms race ahead if the world that is left remains as dangerously divided into rich and poor.

0028-0836/81/010001-01$01.00

Beating a retreat from Rothschild

British governments have long experience of saying one thing and doing another, and the skills thus acquired are now being applied to the management of civil science. Less than ten years have passed since a previous Conservative government (Mr Edward Heath's) embraced Lord Rothschild's then radical notion that government departments seeking benefits from applied research should pay for it out of their own budgets. For most of the 1970s, the British government was devoted to this principle, with the result that government departments (called "customers") and research councils (called "contractors") have been locked in almost perpetual negotiation about the terms on which specific research projects should be carried out. When the Rothschild era began, the research councils affected were deeply offended, and for a time it seemed as if the then president of the Royal Society, Sir Alan Hodgkin, would join them on the barricades. In the event, it seems that the anti-Rothschild forces need not have bothered. They could have counted on the unwillingness of government departments to change their ways.

A few weeks ago, it became clear that the Medical Research Council had won its decade-long battle with the Department of Health, and had won back the share of its budget filched by the department with effect from 1973 (see *Nature* 23 October). Now, the Agricultural Research Council's relationship with its principal "customer", the Ministry of Agriculture, Fisheries and Food, is being changed but in a different direction — the ministry seems likely to have a more direct say in what the council does (see *Nature* 11 December).

This turn of events has an obscure origin — a report of the Public Accounts Committee of the House of Commons published in July 1979 dealing with the cost of storing skimmed milk and potatoes as well as with the affairs of the two research councils. The proceedings, nevertheless, have an arcane interest. Dr James Gowans, the secretary of the Medical Research Council, gave the committee a winsome account of the importance of good luck in the conduct of medical research. The steps in medical research in the past twenty years that "have made the greatest impact. . . have all been made by accident", and as a consequence there is nothing that a research council can do but back "good ideas and good people". Customer-directed research is, in other words, impossible.

The committee, known to the popular newspapers in Britain as the "watchdog" over public expenditure, softened to putty, swallowed the line taken by Dr Gowans and the Department of Health that it was "impracticable" for the ministry to control the research it had commissioned, and recommended that for medical research the government should abandon the Rothschild principle. Both parties have lost no time, and the arrangement has indeed been unscrambled.

With agriculture, similar arguments appear to have led the Public Accounts Committee to the opposite conclusion. The committee seems to have been bamboozled into believing that the Agricultural Research Council supported research intended to yield practical benefits (plant-breeding, for example) with funds left untouched by the Rothschild transfer to the ministry. The committee, evidently ignorant of the council's terms of reference, kept asking why. And why should there have been so little change in the pattern of the council's work since 1972? Surely the only explanation is that the ministry's influence was too remote, and the only possible remedy that the ministry should have a more direct say in what the council does? The ministry has leapt at the chance. It may not be long before the Agricultural Research Council is indistinguishable from a government department.

This is an odd way in which to tackle an issue of principle. The Public Accounts Committee of the House of Commons, for all its virtues, is neither experienced nor competent in fields like this. Its cursory inquiry into the workings of the Rothschild principle was hardly searching enough to give the two ministries the licence that they have so eagerly assumed. The conclusion may be correct that the Rothschild arrangement has not functioned well in medical and agricultural research, but the explanations given are spurious. Dr Gowans's doctrine of investment in "good ideas and good people" is a necessary but not a sufficient condition for success — and applies in other fields than medical research. And if neither the medical nor the agricultural research programmes have been changed in pattern since 1972, the explanation may simply be the indolence, incompetence or neglect of the ministries concerned. The unhappy tale of how the Department of Health set out to act as a customer by setting up a network of committees whose meetings were as often cancelled as held has been vividly documented in Professor Maurice Kogan's study (with Nancy Korman and Mary Henkel) *Government's commissioning of research* (Department of Government, Brunel University). The wonder is not that the system failed to work, but that its designers thought it might.

Before the rot goes too far, the British government must decide what it is trying to accomplish. Lackadaisical support for supposedly autonomous research councils is demoralizing, and probably wasteful of public money as well. The plain truth is that three of the research councils (agriculture, medicine and natural environment) are geared to basic research relevant to the practice of technology (*pace* physicians). Their autonomy is an historical accident, going back to the First World War and Lord Haldane's doctrine that government departments should not be allowed to control basic research because they would not understand it. Government departments may not be much better now, but times have changed. The Advisory Board for the Research Councils should be the forum in which the research councils make their priorities explicit. In practice, the board seems to be yet another device for making sure that no research council is disappointed in its share of the collective budget. How could it be otherwise, when the chief executives of the councils dominate the proceedings?

The truth is that the five research councils are different animals. The Science Research Council is an essential adjunct of higher education. The Social Science Research Council was set up both to encourage academic social science and to apply the social sciences to the solution of practical problems; it has been only a modest success, but these are early days. All five research councils, together with the Royal Society and the scientific museums, share in the annual cake-cutting ceremonies of the advisory board. (There is even talk that the British Academy, responsible for research in the humanities, should be included.) The result is that the question of how much of the civil research budget should be spent in or on universities, and how much on basic research relevant to technology, is never openly considered.

So what should the British government do? The simple response is to say that there should be yet another inquiry into the organization of civil science. The interval since Rothschild has been longer than any other period since the Second World War when some mammoth reorganization has not taken place. Such a decision, however, would be disastrous. The outcome would be another reorganization which, in the end, would be eroded by the unwillingness of those concerned to change their ways. The solution, which is being forced on the Thatcher government by its unthinking retreat from Rothschild, is a return to the arrangements of the early 1960s, when civil science was the responsibility of a part-time minister. The immediate benefit would be that there would be machinery in being for making policy as the need arose; as things are, nothing is dicided between agonized reappraisals. Such a development would have the extra benefit of separating the administration of civil science from that of education (for which Lord Todd was asking in his valedictory anniversary address to the Royal Society in November and will now no doubt be urging on the House of Lords Select Committee on Science and Technology). How much longer will it be before the government recognizes that its neglect of the past few months now predicates such a course?

AAAS plans pressure on education

Dismay at proposed NSF budget cut

Toronto

The American Association for the Advancement of Science (AAAS) has decided to devote a substantial proportion of its efforts over the next decade to reversing what the US Department of Education has recently described as a growing tide of "scientific illiteracy".

Concerned about the growing gap between scientists and technologists on the one hand and the public and congressional decision-makers on the other, the association plans a series of programmes aimed, in particular, at raising the general level of scientific and mathematics education in the nation's primary and secondary schools.

The announcement was made during the AAAS's 147th annual meeting in Toronto this week. On Sunday, the association's board passed a resolution pledging the AAAS to work with its affiliated science and engineering societies to reverse what it called a "damaging decline" of science and engineering education in the United States.

Mr William Carey, the association's executive secretary, later said that the Carter Administration's apparent intent to cut back expenditure on science education by the National Science Foundation (NSF) was "a severe malfunctioning of the bureacracy".

This cut was occurring, he said, only two months after the NSF and the Education Department had delivered a report to the President which concluded that there had been a 15-year decline in the national commitment to excellence and international leadership in science, mathematics and engineering.

Mr Carey added that as a result of the Administration's decision to absorb cuts in the NSF budget by focusing in particular on its science education programmes, under the terms of the budget proposals which the President will present to Congress next week, science education would be reduced to only 7.5 per cent of NSF's efforts — the lowest figure for 30 years.

What concerns AAAS is not so much the quantity or quality of university science graduates — the department's report found little problem here, and suggested that where there were shortages or deficiences, these would probably be corrected by market forces — but evidence of declining educational standards in schools.

Dr Allan Bromley, professor of physics at Yale and next year's president of AAAS, said that it had been a "dismal mistake" to leave things in the hands of "professional educators". He cited, in particular, national surveys of educational achievement which demonstrated a general decline in scientific and mathematical abilities among high school students, as well as widespread evidence of the remedial action which universities and colleges were having to take with undergraduates enrolled in science classes.

"A whole generation of students is being short-changed" Dr Bromley said. "In physics, if you look at undergraduate curricula across the country, the first year is being increasingly devoted to teaching subjects that you would not have had to worry about 10 or 15 years ago."

Other AAAS officers were slightly less harsh in their criticisms. Current president Dr Frederick Mosteller of the Harvard School of Public Health pointed out that many subjects, such as calculus, were now widely taught in schools where they had been missing a generation ago. Retiring president Dr Kenneth Boulding spoke up in support of less conventional teaching methods, arguing that "education is becoming less important as a means of learning".

However, what Dr Bromley described as a "severe crisis" in science education has spurred the AAAS into convening a conference of the heads of its affiliated societies to look at the health and priority needs of science and engineering education in the United States in the 1980s — and to make educational excellence in these areas a major theme of next year's meeting.

The association also intends to use its new monthly magazine, now called *Science 81*, to produce teaching materials for use in secondary schools, and it announced that Dr F. James Rutherford, previously associate director of NSF responsible for science education, and at present assistant secretary of the Department of Education, will join AAAS as adviser on science education to the board of directors after leaving office on 20 January.

"The AAAS cannot solve the problems on its own, but if we don't get busy, things will get worse" said Dr Mosteller, adding that both federal agencies and private industry would probably be approached to support the association's proposed activities.

David Dickson

Slow progress on Greek reforms

As Greece enters the European Community (from 1 January) the universities are still in the throes of reorganization, with student unrest at some institutions. But the new Science Research and Technology Agency is in good shape, with two years of constructive work behind it, although the threat of its becoming ensnared in Greek bureacracy remains. The hope is that the influence of the community will strengthen the recent tendency to reform.

The government's first attempt at university reform (see *Nature* 2 February 1978) met with strong opposition and the enforcement of some of the provisions of the new Law 815 had to be postponed. A committee was set up to make new proposals and these have now been presented to the government. The success of the committee, representing the fourteen university-level institutions in Greece, owes much to the way in which its chairman, Professor F. Mitsis, enjoys the confidence of all sides.

Much deadwood was painlessly removed from the academic profession by the provisions in Law 815 for voluntary retirement — in one department of the University of Athens only three out of twelve are still in post. Now there are many openings to be filled using new selection procedures.

The new draft bill would abolish the unpopular system of "chairs", in which professors were surrounded by a mixed bag of assistants. Instead subject "sectors" would be introduced, each consisting of at least seven academics at three grades: lecturers, associate professors and professors. The short-term appointment of assistants, usually working for higher degrees, would also be allowed. Undergraduates are granted 20 per cent participation in all university bodies under the proposed law.

Examination regulations are being drafted separately, amid protests from student associations that as long as general conditions in the universities leave so much to be desired, students cannot be expected to attain high standards. At the Technological University at Athens there was a prolonged sit-in to protest against the system of semesters, considered unduly onerous by many students. And at the University of Athens chemistry students have been striking against the alleged harshness of a particular professor.

Greece's newest university, in Crete, remains in a critical state. Facilities are makeshift and most of the teaching depends on visiting lecturers from abroad. Permanent senior appointments are being blocked by the Athens-based administration committee, perhaps under the influence of the old establishment. Fotis Kafatos of Harvard is no longer a member.

For research, the outlook is more cheerful. More than two years ago the government invited Dr George Argyropoulos back from the United States to head the new Science Research and Technology Agency (see *Nature* 23 February 1978). The main achievement of the agency has been the introduction of

0028-0836/81/010003-02$01.00

project grants on the pattern of the British research councils, instead of state subsidies for the overall budgets of institutions.

Following wide consultations, the agency prepared a list of nine priority areas of research, approved by a ministerial committee in June 1979. By October 1980 436 grant applications had been received and some 70 approved projects were already under way. Applications are being dealt with speedily, the process taking an average of seven months including the time required for three referees (at least one from abroad) to report.

Other achievements include eighteen international agreements for joint projects. Solar energy plants are to be built with Germany and France, and a geothermal plant constructed on the island of Melos in cooperation with the European Economic Community.

There are some clouds on the horizon, however. The law setting up the Science Research and Technology Agency sought to exempt it from the notoriously bureacratic public accounts regulations, but the Ministry of Finance nevertheless managed to block payments of grants for "technical reasons". The Committee of Ministers which oversees the work of the agency has reaffirmed its confidence in it. One hopes that it will now be allowed to function unhindered. **E. M. Pantelouris**

UK space policy

Year of decision

Last year was a busy one for makers of British space policy. By November, a committee of the Central Policy Review Staff, the think tank, had submitted to the Cabinet its study of Britain's efforts in space applications; and an interdepartmental committee, under the Department of Industry, had been created to coordinate space policy more effectively and to discuss the think tank's deliberations. The Home Office was also busy preparing a report on direct broadcast television by satellite.

The sudden interest in space seems to have been stimulated by the fear that Britain might miss out on the profits that could be made from selling space technologies, especially telecommunications satellites. The think tank's report is to remain confidential for commercial reasons. The gist of the recommendations is that there is a demand for space applications satellites which British industry should be encouraged to meet.

One important question is whether Britain should try to build up its industry alone or whether it should continue, perhaps at an increased level, in the space applications programmes of the European Space Agency (ESA) which France and Germany, in particular, have used more effectively than Britain to boost their own industries. The most likely outcome is that Britain will continue at more or less the same level in ESA's telecommunications programmes, but that greater efforts will be made to transfer the results of ESA's research and development to industry.

The government is unlikely to rush to pour money into the industry, seeking rather to encourage private investment. A central issue in the telecommunications field will be the government's attitude to the monopolies held in television broadcasting by the broadcasting authorities and in satellite communications by the telecommunications division of the Post Office, British Telecom. A bill to dilute British Telecom's monopoly is now before Parliament, and could be used by the Department of Industry to liberalize access to satellite communications, leaving the way open for private operators, in particular, of small satellites for business communications. If greater incentives are given to satellite operators, the next question will be the ability of British Aerospace (which not everyone is convinced could withstand open competition) and other UK manufacturers of satellite components to meet the demand.

A government announcement on the subject is expected soon and it may seem rather bland, leaving the question of monopolies at least until the Home Office has reported on direct broadcasting by satellite. A decision will have to be taken fairly shortly, however, on the scale of Britain's effort in another space application — remote sensing — if it is not to miss the opportunity of cooperating in ESA's next programme. This year promises to be a vital one for Britain's space industry.

Judy Redfearn

Herbicide safety

Bill of health

The herbicide 2,4,5-T has been given a cautious but clean bill of health by two recently published reports. One*, by the Advisory Committee on Pesticides of the UK Ministry of Agriculture, Fisheries and Food, says that there is no sound medical or scientific evidence that herbicides based on 2,4,5-T are harmful to humans, animals or the environment in general. The second, by the European Community's Advisory Committee for Safety, Hygiene and Health Protection at Work, says there is no conclusive evidence that 2,4,5-T causes cancer, but asks for further evaluation of the long-term risks.

The British pesticides committee, essentially the licensing body for pesticides and herbicides, has reviewed 2,4,5-T nine times since 1970. Its latest review was undertaken at the request of the Minister of Agriculture after the National Union of Agricultural and Allied Workers claimed, in March 1980, that 2,4,5-T was harmful.

The union reviewed the scientific literature on 2,4,5-T and referred to 20 cases where it was alleged to have harmed humans or farm animals. The advisory committee says, however, that the union's evidence does not indicate that 2,4,5-T is a health risk.

Concern about 2,4,5-T has centred mainly on the presence of a contaminant, 2,3,7,8-tetrachlorodibenzodioxin (dioxin), a teratogen and carcinogen in some animal species. The committee now believes that this concern may have been misplaced and that the risks posed "by dioxin contamination in 2,4,5-T formulations may hitherto have been overestimated".

First, the committee says, dioxin contamination of 2,4,5-T formulations sold in the United Kingdom is now at the low level of 0.01 p.p.m. Second, the committee says that new studies enable it to identify for the first time "a daily level of intake below which effects on reproduction do not occur in the rat", that is 0.001 μg kg^{-1} day^{-1}.

In the circumstances, the committee considers that 2,4,5-T itself would present a problem before its dioxin contaminant, but that there is no convincing evidence that any effects caused by 2,4,5-T will be passed on to succeeding generations "on an heritable basis". The committee also notes that the WHO/FAO authorities have set a "no effect level" for 2,4,5-T in animals at 3 mg kg^{-1}. Employing a thousandfold safety margin, WHO/FAO have set a "temporary acceptable daily intake" for a man at 3 μg kg^{-1} for 2,4,5-T containing 0.1 p.p.m. dioxin.

The committee does, however, accept the union's claim that workers using 2,4,5-T are not always adequately protected. It suggests that exposure to the herbicide should in future be measured in urinary excretion.

On the question of alternatives to 2,4,5-T, the committee is doubtful. Much less is known about their toxicity and the committee, in continuing to allow 2,4,5-T to be used, is relying on the maxim "Better the devil you know . . .".

All of the twenty cases where 2,4,5-T exposure is alleged to have caused health problems are discussed in the report. The advisory committee has harsh things to say about coverage of alleged 2,4,5-T incidents and accuses the press of causing needless distress by publicizing cases without the consent of the individuals involved. The committee may have been unwise in making this accusation, given that most of the individuals referered to in the report seem to have sought out journalists.

Although the committee has given 2,4,5-T herbicides a clean bill of health, it does ask for prospective epidemiological studies of the risk from exposure to herbicides in general. Professor Robert Kilpatrick, chairman of the advisory committee and dean of the school of medicine at the University of Leicester,

---

**Further review of the safety for use in the UK of the herbicide 2,4,5-T.* Available free of charge from Pesticides Branch, Ministry of Agriculture, Fisheries and Food, Room 678, Great Westminster House, Horseferry Road, London SW1P 2AE, UK.

0028-0836/81/010004-02$01.00

says that a prospective study is in the offing and that 2,4,5-T would almost certainly be one of the herbicides investigated.

The report ducks one issue, however, that of trade union involvement in its decisions. The unions would prefer the Health and Safety Executive (HSE) — where the unions are included on various committees — to be responsible for assessing herbicide safety. Kilpatrick says that this is a matter for ministers to decide. But it seems likely that the unions will be involved in planning the prospective epidemiological study on herbicides. It remains to be seen, however, whether participation on this *ad hoc* basis will satisfy them. Despite the reassuring conclusions of the advisory committee's report, the recent decision by the Trades Union Congress to instruct its members not to handle any 2,4,5-T imported into Britain stands for the time being. **Alastair Hay**

UK forestry policy

Research wanted

British policy on forestry research came in for a drubbing just before Christmas in a critical report from the House of Lords Select Committee on Science and Technology. And the annual report of the Forestry Commission, the public agency responsible for publicly-owned forests, did little to answer the criticisms when it appeared a few days later.

The select committee's chief complaint is that there is no coordinated policy on forestry research. The Forestry Commission is accused of being too concerned with wood production to bother promoting less obvious areas of research, so that the Natural Environment Research Council has been left to support "fundamental and strategic research" — a responsibility which it has shouldered "lightly", according to the committee.

The committee asks that the Forestry Commission should mend its ways by appointing a chief scientist, and that the Advisory Board for the Research Councils should decide which of the two obvious candidates — the Natural Environment Research Council and the Agricultural Research Council — should be responsible for longer-term research. The commission should also be urged to provide advisory services for the owners of private woodlands much in the spirit in which the Agricultural Advisory Services help private farmers to tackle agricultural problems.

The commission's own account of the past year (to March 1980) confirms a preoccupation with the production of wood and in this respect some of the results are impressive. Machinery and pesticides have made the planting of trees a more certain business, with obvious benefits to production costs. The development of local seed supplies, the search for more productive species and for the avoidance of damage by high winds and the control of pests and forest diseases remain the mainstays of the commission's research.

Lords look ahead

The House of Lords Select Committee on Science and Technology will study scientific advice to government in its next inquiry. The idea came from Lord Todd, chairman of the committee. The committee will consider whether the post of chief scientific adviser to the government, which was abandoned in 1974, should be reinstated and whether responsibility for science should be removed from the Department of Education and Science.

British forestry is a controversial business with the commission frequently pilloried for its preoccupation with conifer plantations. The select committee makes a case for the preservation and renewal of often ancient broad-leaved woodlands, suggesting local authorities as suitable custodians. There is a plea for research to throw light on the more effective planning of land use.

The implementation of many of the select committee's recommendations will cost money — both for reorganization and for an increase in volume of some areas of research. The current level of forestry research funding of just under £5 million for the past year is not generous when compared with the current value of the forest estate of £500 million. But recognizing that an increase in public funds is unlikely, the committee suggests that extra revenue could be created by a 0.1 per cent levy on imported timber and wood products, raising £2.75 million a year.

There is little prospect that extra funds could be found in the Forestry Commission's profits. The commission acknowledges that over the next three years it is unlikely to make the financial target of 3 per cent a year in real terms required of it by the British government. In this respect, the Forestry Commission has yet to make an effective response to the criticisim of its financial operations by the Treasury in 1972. **Judy Redfearn**

UK clinical research

Future not so rosy

Celebrating their fiftieth anniversary in London last month, members of the Medical Research Society were not altogether optimistic about the future. One of the principal fears, aired at the day-long symposium on the organization of medical research, was the declining ability of clinical departments to attract and train the people to keep them in the front line of research.

Part of the problem is to provide the money and status to keep non-clinical research workers in clinical laboratories, where their knowledge and expertise is essential. Dr J. L. Gowans, secretary of the Medical Research Council (MRC) pointed out that although MRC grants can sometimes cover the costs of such people, the universities should really be providing them with permanent jobs.

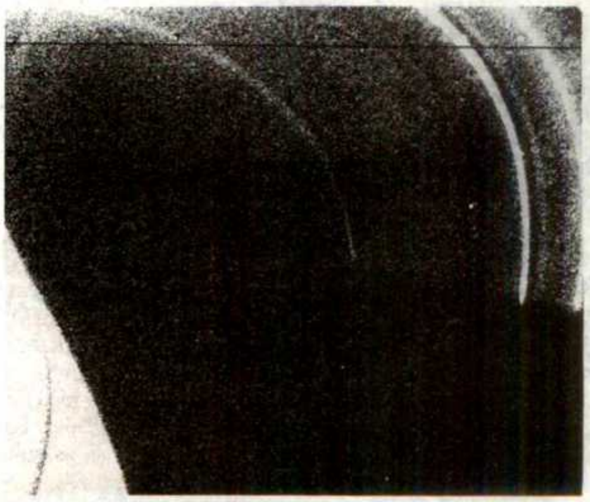
Professor W. S. Peart of St Mary's Hospital Medical School, London, said that in hard times, hard choices must be made in medical schools between technical staff and academic staff — it may be necessary to take on a new postdoctoral fellow rather than a lecturer.

The other side of the problem is the difficulty of providing high quality scientific training for medically qualified staff without disrupting the smooth course of their clinical careers. Professor Peart was disturbed by the lack of young people entering academic clinical research.

The continuing revolution in biology will increase the need to unite basic and applied research on man. Dr S. Brenner, director of the MRC Laboratory of Molecular Biology in Cambridge, pointed out that human molecular and cell biology, now in its infancy, will become the essential interface. In twenty-five years, he said, it will be as essential for researchers in pathology, cardiology and so on to have a thorough knowledge of cell and molecular biology as it is now for clinical endocrinologists to know their steroid chemistry. **Mary Lindley**

New rings for old

Claims from ground-based astronomers that Saturn has an innermost D ring, stretching from the bright C ring down to the planet's cloud tops, were apparently disproved by Pioneer 11 in 1979. But this image from Voyager 1, taken soon after its encounter with Saturn last November, reveals an inner ring, complete with fine structure, between the planet (bottom left) and the C ring (top right). Here, Saturn's shadow falls across the ring, which is apparently too faint to be detectable from Earth.



0028-0836/81/010005-01$01.00

UK universities

Feeling the pinch

Figures released by the Committee of Vice-Chancellors and Principals show that the number of overseas undergraduate and postgraduate students admitted to British universities in October 1980 was 90.7 per cent and 88.9 per cent respectively of the number admitted in October 1979. The intake of British undergraduates was 2.3 per cent higher than in 1979, an increase in line with the rise in the number of 18-year-olds in the population.

The shortfall in the number of overseas students was not as great as some had expected after the British government's decision earlier in the year to charge them the full economic fee for their education, averaging about £3,000 per year. But recent figures released by the Universities Central Council on Admissions (UCCA) indicate that a much greater shortfall may be expected this year. The number of applicants from overseas for admission in October 1981 is 33 per cent down on the number received at the same stage last year. One reason for the delayed reaction may be that governments had already committed themselves to paying for students to study in Britain this year before the increased charges were announced. Applications from British students for university places in 1981, however, continue to show a small increase, the number from men being up by 2 per cent and from women by 7 per cent.

Figures released at such an early stage in the academic year are not a reliable guide of what will happen next year. Nevertheless, many universities are worried. They will face a difficult decision in February and March when they have to fix their fees for 1981–82. With a considerably reduced income from overseas students, they will have to decide whether to compensate by increasing the fees of overseas students yet again at the risk of discouraging even more students from accepting places.

According to the vice-chancellors' committee, the increase in the number of home students only adds to the universities' problems because the government has set aside no extra funds to meet the growth. Well qualified home students could well be refused places because of a lack of cash to support them. The full effects of the increase in overseas students' fees will be felt in 1982–83 by which time government protection of overseas students who began their studies before October 1980 will have ceased. The government will then have effectively removed 10 per cent of universities' income from the recurrent grant.

The Committee of Directors of Polytechnics reports a similar but more marked trend for entry to full-time and sandwich courses in October 1980. Admissions of overseas students were down 29 per cent on 1979, but this was more than compensated for by a 7 per cent increase in home students, much of the growth being in science and technology courses.

Some polytechnics with a high percentage of overseas students, especially those near London, may be hit particularly badly. Others may only be able to offer those courses for which there is a buoyant demand. At Portsmouth Polytechnic, for example, the masters' course in fuel technology, the only one of its kind offered in Britain, is very popular. But courses offered by several institutions may suffer badly from increased competition.

polytechnics' advantage may, however, be that they can adapt their courses to changing demands more easily than the universities.

Few universities and polytechnics have yet analysed this year's intake in terms of subject area and students' nationalities. But general impressions are that students from South-East Asia are having more difficulty in raising fees than those from the Middle East and that science and engineering courses are suffering less than courses in the humanities.

Judy Redfearn

Poland freezes Antarctic research

Poland's Antarctic research programme for 1981 will include a "wide range of economy measures" according to a statement last month by Dr Maciej Zalewski, Secretary of the Polar Research Committee of the Polish Academy of Sciences. From now on, he said, research will concentrate on "strategic lines" of special importance to science and the economy.

The main saving, said Dr Zalewski, will be made by discontinuing large and expensive summer expeditions, and concentrating on small teams occupying a permanent base on a yearly shift system. Nevertheless, some summer activity will continue — such as the current joint expedition from the Academy of Sciences and the Marine Fisheries' Institute in Gdynia which is part of the international "Biomass" programme, as is the similar expedition planned for summer 1982–83.

Arctowski Station, King George Island.

What, then, is to be cut? According to Dr Stanislaw Rakusa-Suszczewski, of the academy's Institute of Ecology, very little of any significance. Antarctic programmes are planned by the three relevant institutes of the academy — geophysics, biology and ecology — and financed by the academy, and judging the proposed research entirely on its intrinsic merits, the arguments were so strong, he said, that the academy has decided to go ahead. Under the new programme, the main emphasis will be on marine biology and the study of whales, but in all disciplines there would be increased stress on fund a mental research.

This represents a significant change in research planning. Since the early 1970s, research in Poland has been target-oriented and financed on a project basis, within a complex hierarchy of "problems" of the national economy. (Fundamental research was still possible, but had to be formally associated with some specific "problem"). The new intellectual climate in Poland, with its emphasis on greater academic autonomy, described by Dr Rakusa-Suszczewski as a "very positive change", has clearly meant that, in reshaping the Antarctic programme to fit Poland's reduced economic circumstances, the planners of the academy have been able to make their decisions on basis of scientific value.

Vera Rich

Brazil's space programme

Aiming high

Saõ Paulo, December

Showing refreshing optimism at a time of unprecedented inflation, plans have been drawn up in Brazil for an ambitious space programme costing hundreds of millions of dollars over the next ten years. Remote sensing and meteorological satellites and the rockets to launch them are included in a plan approved in principle by the Brazilian government.

Meteorology and remote sensing have already attracted substantial interest and investment in Brazil, where the information they can provide on the physical conditions of little-known areas is especially valuable. The remote sensing programme, set up in the 1960s, was intended to help map the Amazon Basin. The programme has grown from the use of aerial survey to using Skylab and Landsat images. A Landsat receiving station was

0028-0836/81/010006-02$01.00

opened in Curitiba in 1975 and now provides 20,000 images a year to 1,100 users, many of them in other South American countries. The next step will be to upgrade the station, at a cost of about $6 million, to receive Landsat D images.

The meteorology programme involves the building of up to 100 data-collection platforms around the country. A prototype is being tried out in France and the first Brazilian platforms are expected to start operating early this year. Information from them will be relayed by the American TIROS N and GOES satellites. A major objective of the platforms is to provide accurate forecasts of drought in the impoverished north-east region.

According to Dr Jesus Parada, director of the civilian space research institute, INPE, previous cooperative ventures, mainly with America, have given Brazil the necessary expertise to go it alone.

The intention is to launch four satellites a year from 1986–87. INPE would develop the satellites and the launcher would be developed at the nearby military space institute. Total cost of the programme is estimated at more than $700 million, about two thirds of it for launcher development.

The first two satellites would take over from TIROS N and GOES by relaying information gathered by the meteorological data collection platforms to a national centre. And the number of platforms could be increased to several thousands if the new satellites are launched. A radiation budget experiment is also planned. The first satellite, weighing 150–200 kg, would be launched on the qualification flight of the rocket into an orbit of 25–30° at an altitude of 700 km.

The third and fourth satellites would be more complex, devoted to direct land imaging and weighing 250–300 kg. They would be placed in a near-polar orbit at an altitude of 650 km.

All four satellites would be launched from a site in Brazil, possibly the existing military launch pad near Natal. A major drawback of this site, however, is that large payloads would have to be launched into an unusual trajectory to minimize the threat to the city which is only a few kilometres away.

Ambitious though the new plans are, progress so far has been slow. With a budget of only $10 million for 1980, feasibility studies have not got as far as Dr Parada would have liked. But if the hoped-for budget of $40 million is forthcoming for 1981 the project can move on into the design phase.

In a country with grave social problems there are many areas where investment might provide a more obvious and immediate return than a venture into space. And a second space project, for Brazil's first telecommunications satellite, is also competing for funds. So the chances of Brazil's space programme are closely tied to the fate of Brazil's economy over the next few years.

Judy Redfearn

Nuclear waste

US Senate stalls

Washington

Hopes for new legislation establishing a national policy for the disposal of radioactive waste — eagerly sought by both the nuclear industry and the environmental movement — foundered in the Senate last month on disagreement over whether states should be involved in decisions about military waste from nuclear weapons construction.

Main responsibility seems to rest with Senator Henry Jackson, powerful chairman of the Senate Energy committee and a member of its Armed Services Committee.

Senator Jackson had previously supported a proposed nuclear waste bill that was passed in the Senate in July. This bill contained limited provisions for the involvement of states in siting decisions, which the Senator opposes, but it was sweetened by the inclusion of plans for "away-from-reactor" sites which the owners of nuclear reactors could use for the temporary relief of their own spent-fuel storage tanks.

The House of Representatives, after lengthy negotiations between pro-nuclear and anti-nuclear forces, passed a compromise bill last month. Like the Senate bill, it provided for a state to veto a siting decision, if it obtained support of one of the two congressional bodies.

However, the House bill did not include any mention of away-from-reactor storage, which the industry would like since it would keep spent fuel available for future reprocessing. And Senator Jackson made it clear that he did not support the bill, killing any chance of agreement by offering an amended version unacceptable to the House.

The storage of nuclear waste remains the Achilles' heel of the nuclear power industry, with several states currently refusing permission for further power-plant construction until adequate means for long-term storage are available.

The nuclear industry itself is keen to find more permanent storage for the 80,000 metric tons of spent fuel now lying in storage tanks next to reactors around the country. And the environmental movement wants a nuclear waste policy that is both ecologically acceptable and open as much as possible to local participation in decision-making.

In February, President Carter announced plans for a long-term waste disposal policy. Reiterating his previous opposition to reprocessing, this is based on the permanent storage of waste in deep geological formations — a technique considered both feasible and relatively safe by most of the scientific community.

Carter proposed that long-term studies of possible sites should be initiated, with the goal of having a permanent disposal facility in operation by 1995. But the Senate, acting under pressure from the nuclear industry, expressed impatience with this schedule, and the bill which it passed in July emphasized short-term waste storage procedures.

Sharp differences also occurred in the House of Representatives. Pro-nuclear forces, led by Congressman Mike McCormack of the Science and Technology Committee, supported a bill which would require the Department of Energy to construct technology demonstration facilities in various parts of the country, to serve as a basis for licensing a full-scale commercial waste facility.

In contrast, the chairman of the House Interior Committee, Congressman Morris Udall, supported a bill more closely modelled on the Administration's proposals, arguing that it was premature to rush into demonstration projects.

In the end a compromise was reached between the two committees and the House passed a joint bill, under which the Department of Energy would pick two possible burial sites by 1982 and two more by 1985; and by 1987, following an elaborate series of public hearings, the President would recommend to Congress the site or sites which he considered safe for the storage of waste.

Despite the faster schedule, this compromise proved unacceptable to the Senate. Stung by the omission of any provision for short-term away-from-reactor storage, Senator Jackson told the Senate that without a specific exemption for atomic defence repositories, the House bill as it stood infringed the jurisdiction of both House and Senate Armed Services Committees, and could conflict with existing clauses in the Atomic Energy Act.

Environmentalist groups are insistent that military wastes, amounting to up to 90 per cent of the nation's high-level radioactive waste, should also be covered in any national plan.

But the Senate's decision now means that the process of developing legislation must start over again when the new Congress convenes this month. In the Senate at least, recently-elected conservative legislators are likely to be more sympathetic to the nuclear industry.

Meanwhile, in line with the Carter Administration's long-term waste disposal policy, the Department of Energy has issued an environmental impact statement confirming its view that the best method of permanently disposing of radioactive wastes from nuclear power plants is to place them in mined depositories deep in geological formations.

According to the department, a typical repository would require about 2,000 acres underground, and above-ground facilities would occupy 500 to 750 acres. Access roads would take up another 30 acres. A total of 2,000 acres above ground would be needed for each facility, with consequent restrictions of mineral and surface rights.

CORRESPONDENCE

Badgers and TB

SIR — I refer to the letter by Dr Stephen Harris in your issue of 11 December 1980 (p.532) which, while critical of certain aspects of Lord Zuckerman's Report to the Minister of Agriculture on "Badgers, Cattle and Tuberculosis", agreed with his basic conclusion that the badger is a major reservoir of bovine tuberculosis (TB) in some areas of South-West England. The main criticism was that, while the reservoir constitutes a potential danger to cattle in limited areas, there is no "scientific evidence" to justify the deduction that the level of tuberculous infection in badgers in the South West is "dangerously high" and may result in spread of the disease to adjacent populations.

Since Dr Harris writes for and on behalf of the Mammal Society, it may be appropriate to ask whether all the interested members of that society would fail to be convinced by the evidence. More than 4,000 badgers were examined in connection with official investigations in the years 1971–79 and 14 per cent at least harboured *Mycobacterium bovis* (Report: para. 130). Of animals found dead since 1972 in fields, woods and farms in Gloucestershire, Avon and Wiltshire, 54/194 (28 per cent) were found to be tuberculous. Of those killed in Gloucestershire, predominantly on the roads and presumably by chance, during this period 1976–80, 21/232 (9 per cent) were tuberculous; this admittedly was the highest recorded prevalence by county but for the whole of the South West the figure was still 4.2 per cent (Report; Table 3).

These figures should be a cause for concern when dealing with a social animal which occupies, for much of the time, confined spaces underground and whose movements above ground favour between-group contacts. Bovine tuberculosis in badgers is sometimes a rapidly progressive, lethal disease, the causal organism probably being excreted by many routes in large numbers[1,2]. It has, therefore, ample opportunities for transfer and by any objective epidemiological standard the risk of spread to neighbouring badger populations must be considerable. The onus for showing that this is not a reasonable interpretation should rest on others.

The argument advanced by Dr Harris, that the recent decline in the incidence of tuberculosis in cattle in the South West is simply a reflection of a general downward trend in the figures for England as a whole, misses the point that the incidence of herd "breakdowns" in the South West, in the years 1974–80, has never been less than five times that for the rest of England (Report; Table 19).

Many anomalies in the data were highlighted in the Report, which pointed out the need for continuing investigation and research. In this connection it is difficult to see how the "subtle factors" twice mentioned by Dr Harris as significant in the spread of the disease from infected badgers, could be elucidated without extensive sampling on a statistically significant scale. In particular, continuous monitoring of badgers on the perimeter of heavily infected areas would be necessary to prove that the disease is *not* spreading (Report; para. 137). It is to be hoped that consideration will be given by interested bodies as to how this could be organized, if the necessary funds were provided.

From the Mammal Society:
In the letter from the Mammal Society on badgers and TB published on 11 December, the statements appear to be attributed to Stephen Harris. I wish to make it clear that the letter is a Mammal Society view and that Stephen Harris was only personally involved in the communication of the letter to the Editor.

Museum policy

SIR—The broader implications of cladism are not my special concern, but the study of human evolution is. Cladistics is a useful research tool, but I support L.B. Halstead's[1] objections to the way it is used in the new exhibit *Man's place in evolution* at the Natural History Museum.

Cladistic analysis is still a relatively untried method for expressing relationships between groups, and technical details of its application are still being debated. It was devised as a conceptual framework within which one aspect of the relationships between modern and fossil forms could be analysed. It relates groups solely on the basis of shared features, and rejects the notion that any ancestral relationship can be inferred from this evidence; such relationships are considered "unknowable". Proponents claim that only by adhering to these principles can palaeontologists frame testable hypotheses. The strengths of the method are its simplistic rigour, but therein also lie its weaknesses. In order to provide an unambiguous framework, certain assumptions have to be made. For example, speciation is recognized only as a dichotomous branching event, and more complex adaptive radiations, anagenesis and convergent evolution of morphological features are discounted. Such assumptions are unrealistic. The concept of "relatedness" enshrined in cladistics is therefore fundamentally different from the general one which implies a lineal relationship, and as used in the exhibit, it is likely to confuse, if not actually mislead, the visitors.

The contents of the exhibit also give cause for disquiet. The authors seem particularly confused about what constitutes the "habiline" and "australopithecine" groups of early hominids. Two important specimens "1470" and KNM-ER 1813, have been seriously misassigned. KNM-ER 1813 is consistently cited as an example of a "habiline" and "1470" as an "australopithecine". Yet, "1470" has a cranial capacity of around 775 cm^3 and is included in *Homo habilis* by many workers. The cranium KNM-ER 1813 is smaller overall, and it has a cranial capacity of between 500 and 550 cm^3. It has not yet been formally assigned to a taxon but its position is sufficiently enigmatic for it to have been compared, by some authors, to *Australopithecus africanus*, and by others, to early *Homo*. Howell[2] has attributed KNM-ER 1813 to *Homo habilis*, but he also includes "1470" in the same species.

The section which deals with *Homo erectus* also deserves comment. Recent, and well known, discoveries in Europe and Africa have demonstrated that a much wider range of cranial morphological features is subsumed into the "erectus" group than was previously believed. Several skulls shown an apparent mixture of classic "erectus" and archaic *Homo sapiens* features. These new finds strongly suggest a continuous gradation of morphology from "erectus" to "sapiens". The exhibit totally ignores this evidence.

To attribute important finds wrongly is careless; to ignore "uncomfortable" evidence is dubious academic practice, and to imply that cladism is an orthodox systematic approach is irresponsible. The contribution of the Natural History Museum to science and education is too important to be compromised in this way.

2. Howell, F.C. in *Evolution of African Mammals* (eds Maglio, V.J. & Cooke, H.B.S.) 154-248 (Harvard University Press, Cambridge, 1978).

SIR — In a recent letter to *Nature* (**288**, 208; 1980) L. B. Halstead states his convictions that human evolution was gradual, that its gene pool of the past had certain knowable characteristics, and that the ancestry of a living species can be determined with deadly accuracy. Halstead's convictions arise from his discovery of a new form of *doubt*, such that he can contend that "there is not any serious doubts about *Homo erectus* being directly ancestral to *Homo sapiens*". This is certainly the news Biology has waited for, the moment when the Truth can at last be known so that all this difficult and extremely tiresome theory can be dispensed with. Until now my colleagues and I had always imagined that to doubt something was "to be uncertain as to a truth or fact" and the notion that distinguishes science from, say, politics is that in science uncertainty about the truth must remain or progress ends. Halstead's discovery can only mean that he has in hand a new form of truth — a kind of truth that can be known. Many of us puzzled over what kind it might be until it finally dawned on us that it emerges from false doubt and, to honour its discoverer, I call it *Halsteadian Truth*. If ever again we are troubled by some theoretical matter we need only consult the oracle in Reading. Now that Halsteadian Truth permits us to know at last the way in which evolution proceeds, what extinct gene pools were like, and exactly who was whose ancestor, I confess, with sadness for years misspent, that cladistics is indeed a waste of time.

This news about the emptiness of cladistics will have a profound effect on systematics, for

The ocean floor closely observed: will it subvert marine geology?

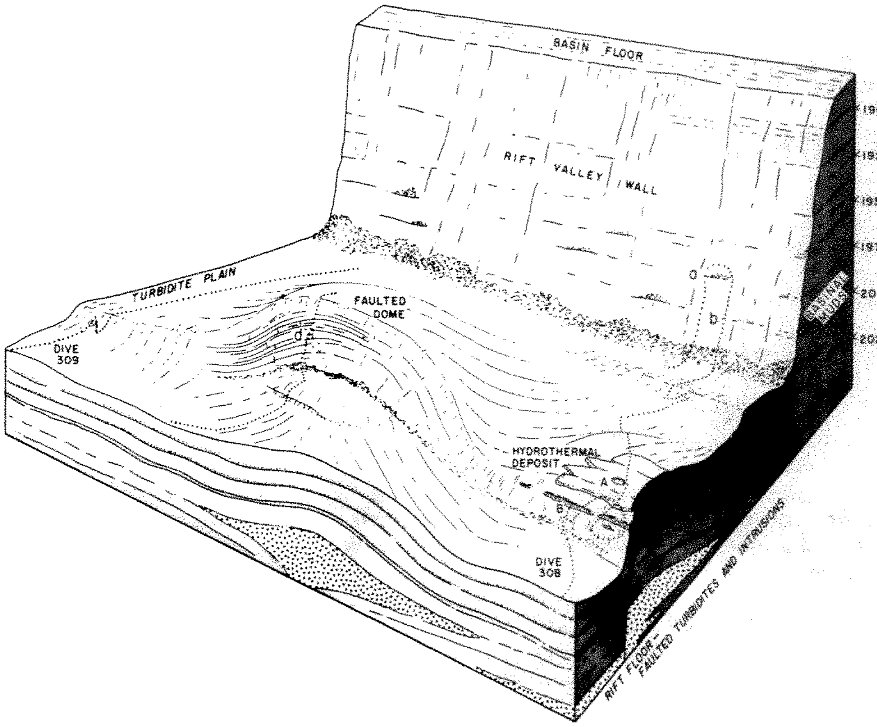
from Tjeerd H. van Andel

In a recent paper based on work with a deep-diving research submarine, fine-scale observations of the sea floor are ingeniously extrapolated to models of the events occuring at depth*. The paper is a good example of the geologist's method of using detailed observations on rock outcrops to yield grand interpretations of causes, and it is as such quite similar to the usual fare in geological journals except for an important difference — the observations were made 2,000 m below the sea surface rather than on a walk in the hills.

For a century, marine geologists have coped with severe limitations imposed by the vastness of their domain, by the filter applied to their observations by water depths of several kilometres, and by the difficulty of knowing where one is. The first of the constraints produced descriptions of entire ocean basins equivalent to a geological synthesis of Britain based on ten outcrops, while the second and third limited resolution to features tens or even hundreds of metres across. The traditional oceanic mapping scale is about 1:1,000,000, and in the 1960s a 'detailed' map was usually drawn to a scale of 1:250,000. We did, of course photograph the sea floor but the gap between a photo of a few square metres and a map representing the terrain at a scale of 2.5 km to the centimetre is near unbridgeable. We observed mid-ocean ridges and sand ripples but very little in between. Until a decade ago, the divergent plate boundary appeared as a V-shaped cleft on sounding records; now we know that it consists of vertical fault scarps, terraces, flat lava floors, rows of small but complex volcanoes and fascinating hot springs.

About a decade ago our ability to appreciate detail improved rather suddenly with the introduction of instrument vehicles towed near the ocean floor, manned submarines and, above all, with the means to determine positions within ten metres or so. Since 1970, large expeditions to several mid-ocean ridges have demonstrated the power of the new technology with numerous startling discoveries, and have introduced new ways of thinking about marine geology that are akin to traditional approaches in petrology and structural and sedimentary geology on land. At times the change has been disconcerting to marine geologists not accustomed to looking at their world on a fine scale, but the new opportunities clearly hold much promise.

The impact of this costly and logistically complex technology has not been restricted to scientific data and inferences. There has been some sense of discouragement. A decade of hard work has covered little territory at a high cost. Perhaps 0.01 per cent of the divergent plate boundary has now been studied in detail at a cost of much more than 10 million dollars. One wonder whether, at this rate, we shall ever be able to obtain a reasonable sample of the rest of the ocean floor. The work is also



A sketch of the undersea terrain near to the north west wall of Northern Trough, Guayanas Basin, Gulf of California from two dives made by Lonsdale and Lawver in the submersible *Sea Cliff.* The Gulf lies between two crustal plates that are drifting apart, in a position like that of the Mid-Atlantic Ridge between the American and the European and African plates. At mid-ocean ridges, as the plates separate, molten rock wells up from below to fill the rift and heal it, forming a string of small volcanoes. In the Gulf of California the same process occurs but is modified by a thick blanket of sediments shed from the nearby Continental margins. As a result the lava does not reach the surface but forms mushroom shaped intrusions within the sediment layer and deforms and domes the overlying deposits and sea floor.

---

cumbersome and improving the instrumentation is sometimes more challenging than using it. This is not without reason. The paper that provoked this discussion, based on minimal technology, suffers the weakness of a consequently much reduced precision.

Coupled with this image of an overwhelming task is a feeling of insecurity. Does any value, except crude geographic description, remain in the work done before? Are the sparse observational nets, the data of low resolution still useful? Does the image of the ocean floor obtained over the last century still hold up? Of course no one was ever wholly unaware of the shortcomings of our methods, but we coped with that by assuming that, somehow, the ocean floor was simpler than the land, the gradients of change more gentle, the processes not so variable in time and space. We thought subconsciously of the sea floor as having the gentle and smooth slopes of our sounding records and were startled by the discovery of vertical fault scarps and of open fissures. Similarly,the petrologists, having attributed to variations in the earth' mantle the subtle differences between basalts from various parts of the mid-ocean ridge, were surprised to find this entire range exhibited in a single 3 km long traverse across the volcanic axis, presumably as a result of ageing of the magma chamber. In a limited way, but we have no other means, we can test the value of the old data by inquiring after their impact on our present understanding of the geology of the mid-ocean rift. I submit that this impact is negligible and no reason for comfort.

It does not seem proper to retreat one step and say "Well, the mid-ocean ridge is an active and hence complicated place but, surely, elsewhere in the ocean things are much more uniform and do not need this sort of detail". This, then, suggests that we should ask whether the detailed, fine-scale, near-bottom approach is the way of the future, rendering obsolete most of the old ways that bemuse our colleagues on land but are second nature to us. Aware that I am putting it very strongly I propose that the answer is yes and that we should, the sooner the better, divert most of our resources to this approach and leave the large scale global mapping to organizations charged with mapping. I am willing to allow for numerous exceptions but it seems that we have gathered enough regional data now and must proceed with the methods that provide the best hope to answer fundamental questions of process and history. I do not truly believe that we shall soon see the last of the roaming marine geologist disappear but I think that we should attempt to hasten his demise in order to look at the ocean floor in the detailed, time-consuming, expensive and, alas, often tedious way that will give us the answers we need. □

Did retroviruses evolve from transposable elements?

from Andrew Flavell

RETROVIRUSES (formerly called RNA tumour viruses) have attracted much interest as they can cause cancer and are ubiquitous in a wide variety of vertebrates. It has long been known that DNA copies of these RNA-containing viruses are synthesized in infected cells and these copies are able to integrate into the cellular DNA, becoming part of the genetic complement of the cell. Recently the structures of the integrated 'provirus' DNA copies of several retroviruses have been studied by a combination of DNA cloning and sequencing methods (Shimotohno *et al. Nature* **285,** 550, 1980; Dhar *et al. Proc. natn. Acad. Sci. U.S.A.* **77,** 3937; 1980; Sutcliffe *et al. Proc. natn. Acad. Sci. U.S.A.* **77,** 3302; 1980; Majors *et al. Cold Spring Harb. Symp. quant. Biol.* **45,** 1980; Benz *et al. Nature* **288,** 665; 1980; Czernilofsky *et al. Nucleic Acids Res.* **8,** 2967; 1980). These results have shown that there exists a striking similarity between these structures and those of 'transposable genetic elements' from both prokaryotes and eukaryotes. Transposable elements themselves are a highly interesting class of sequences (see *Nature* **287,** 188; 1980). In bacteria these sequences are able to move around inside the host cell genome and can catalyse chromosomal deletions and rearrangements. In *Drosophila* they can probably act as insertional mutagens (Gehring and Paro *Cell* **19,** 897; 1980; Rubin and Bingham, personal communication). Furthermore, the generation of antibody diversity in mammals, the control of mating type in yeast and alteration in surface antigens in trypanosomes all occur via DNA rearrangements which may share features in common with those of transposable elements. Lastly, tumour progression is often accompanied by chromosomal rearrangements, though no evidence exists connecting such changes with transposable elements; indeed their presence has not yet been proven in vertebrates.

All eukaryotic transposable elements and retrovirus proviruses studied so far possess DNA sequence repeats a few hundred nucleotide pairs long at each end of the element (see the figure). This structure is also shared by some bacterial transposons although there seems to be a much broader spectrum of transposable structures in bacteria. It therefore seems tempting to postulate a familial relationship between all these various species. This idea has been leant further weight by DNA sequencing of several eukaryotic transposable elements and integrated retrovirus proviruses at the presumed key regions for transpositon, namely the ends of the elements. Here, the (so far) inviolable rule is the presence of the dinucleotides TG . . . . . CA at the ends of the element. This homology is much greater in several cases, notably that of the *Drosophila* element *copia* which shares with an avian retrovirus the sequence TGT . . . . . TACAAACA at it's ends (Levis *et al. Cell* **21,** 581, 1980; Shimotohno *et al. Nature* **285,** 550, 1980). Such similarities are very unlikely to be coincidental but cannot be regarded as proof of an interrelationship between these far-diverged species. Not surprisingly, some effort is being expended to relate these two fields by discovering whether eukaryotic transposable elements are really a special form of integrated retrovirus provirus or whether retroviruses are, in fact, transposable elements with an extra trick up their sleeves. The article in this week's *Nature* by Keshet and Shaul (see page 83) describes a family of DNA sequences in mice that may be both types of element simultaneously. Originally described by Howk *et al.* (*J. Virol* **25,** 115; 1978) these sequences (termed VL30 genes) were assumed to be retrovirus-related (although no sequence homology was detected with any retrovirus) by the ability of their RNA transcripts to be packaged into helper retrovirus virions which could be used to infect other cell types. Keshet and Shaul have now shown that those sequences possess direct DNA repeats at their ends. What is the relationship of this sequence family to the proviruses and transposable elements?

The generalized structure of a eukaryotic transposable element. The repeat units (>) are in the same orientation as the DNA and each repeat is itself bounded by small inverted repeats (|) of between 2 and 12 nucleotide pairs.

In 1970 Temin discussed in his protoviral hypothesis the possibility that retroviruses might have evolved from an ancestral gene by successive cycles of transcription, reverse transcription and reintegration (*Persp. Biol. Med.* **14,** 11; 1970), each cycle picking up extra genetic information. In this light, such sequences as the VL30 family and perhaps some defective retroviruses might be regarded as intermediates in this pathway. It also seems plausible that retrovirus evolution might have proceeded via DNA transposition,

---

0028-0836/81/010010-02$01.00

each new transpositional event adding to the repertoire of the element until its RNA transcript possessed the capsid and reverse transcriptase genes necessary for a successful sortie outside its home cell. Or possibly a combination of the two processes might be used. However, the answer to such crucial questions as 'Do RNA copies of the yeast and *Drosophila* elements ever leave their cells?', and 'Can retroviral proviruses move around their host genome without recourse to an RNA intermediate?' are as yet unknown. What is not in doubt, however, is that both types of species, by their ubiquity, sheer quantity (it has been estimated that 5 per cent of the *Drosophila* genome is composed of *copia*-like sequences) and intriguing properties are well worthy of further study. To prove that retroviruses and transposable elements can interconvert in either direction it will be important (and difficult!) to find examples of the 'missing links' between them, one of which may well be the V130 gene family described in this issue. □

In the beginning

from E G. Nisbet and C. T. Pillinger

Our exploration of Darwin's "warm little pond" in search of the origins of life on Earth has revealed but a few islands of fact. New and apparently firm ground slowly appears: sometimes it turns to quicksand. In this issue of *Nature*, Bridgwater *et al.* (see page 51) cast doubt upon earlier reports of evidence for life in 3,800-Myr old rocks from Isua, Greenland. Here we examine some of the new evidence concerning the existence of life in the early Precambrian, and discuss recent advances in the understanding of the nature of the early surface of the Earth.

When did life begin? In an earlier review, Nisbet (*Nature* **284**, 395; 1980) concluded that the oldest possible evidence of life was from Isua, the oldest probable evidence from 3,500-Myr old rocks in W. Australia and the oldest definite evidence from 2,700-Myr old strata. Much work has been done on the Isua rocks and three lines of evidence have emerged: Pflug and Jaeschke-Boyer (*Nature* **280**, 483; 1979) have described apparent 'microfossils'; hydrocarbons have been reported among chemical extracts (*Chemical Eng. News* **75**, 22; 1979); and isotopic studies on carbonates (Schidlowski *et al. Geochim. Cosmochim. Acta* **43**, 189; 1979) suggest biological controls on the carbon cycle.

Pflug and Jaeschke-Boyer detected cell-like inclusions in cherty layers from Isua. They investigated these by the innovative use of the Raman laser molecular microprobe, an excellent approach unifying the efforts of palaeontologists and organic geochemists. The microprobe showed spectral features indicative of aliphatic side chains and esters. From this and their petrographic study Pflug and Jaeschke-Boyer concluded that the inclusions were microfossils of a primitive organism which they termed *Isuasphera*. If so, this would be the oldest evidence of life.

Bridgwater *et al.* have examined duplicate samples of the same rocks. From morphological and petrographic studies and the known metamorphic history of the rocks, they conclude that *Isuasphera* are no more than fluid inclusions of secondary origin.

Much of the debate hinges on the metamorphism; Isua rocks may have reached temperatures as high as 500-600°C. Perhaps more important, oxygen isotopic data (Perry *et al. J. Geol.* **86**, 223; 1978) suggest minimum alteration temperatures of 390°C. Bridgwater *et al.* point out that high grade metamorphism does not entirely preclude the survival of microfossils. However, individual geolipids and esters could not be expected to remain intact after experiencing such conditions. In another paper querying Isua studies, Nagy *et al.* (this issue of *Nature* page 53) indicate the life expectancy of a straight chain aliphatic hydrocarbon at 600°C as about 10 seconds! In the oil industry it is well known that by 250°C everything that can be cracked will be cracked to give methane and graphite end products.

What then is the origin of Isua organics? Ponnamperuma (personal communication to C.T. Pillinger) has argued that hydrocarbons present in extracts of the acid resistant residues of Isua rocks must be contemporary because repeated and prolonged extraction of the intact rock matrix failed to release them (see also Barlow *Open Earth* **9**, 16; 1980 for a similar report). On the other hand Nagy *et al.* suggest that the extractables are no more than a few tens of thousands of years old and derive from encrusting lichens and cyanobacteria.

The lessons of contamination have been painfully learned by organic geochemists. Metamorphism may not be a problem of similar magnitude but it is noteworthy that Hayes *et al.* (Hayes, Kaplan and Wedeking, in preparation), from a painstaking study of H/C ratios in over 400 Precambrian samples, have concluded that all early Archaean samples investigated by them have been affected by thermal events. The H/C data suggest that if evidence of biological activity survives in early Archaean rocks, it must be within the kerogen (the cross-linked organic polymer) rather than extractable geolipids. Stable isotope studies by the same investigators on 50 samples, selected as worthy of kerogen isolation, should produce interesting results.

Thus recent work has thrown much doubt on the supposed evidence for life in Isua time. Nevertheless, there is carbonaceous matter, albeit graphite, in Isua rocks, and the third category of evidence, isotopic studies on the carbonates, remains intriguing. Schidlowski *et al.*'s work is not inconsistent with biological processes in a stabilised carbon cycle. The evidence remains 'possible'.

In slightly younger rocks, the information is becoming much more certain. There are three well-studied 3,500-Myr old terrains of low metamorphic grade — the Pilbara Block, Australia; the Barberton Mountain Land, South Africa; and parts of the Rhodesian Craton, Zimbabwe. In all three, a variety of sedimentary rocks exist, some of which are remarkably little deformed and metamorphosed, in contrast to the samples from Isua. In the Pilbara, new mapping, both by Hickman and Lipple (Geological Survey of W. Australia), and in the very important field program of the University of W. Australia, has led to the discovery of much evidence of 3,500-Myr life, especially in rocks collected by J. Dunlop and R. Buick (University of W. Australia). Dunlop *et al.* (*Nature* **274**, 676; 1978) found possible microfossils and Walter *et al.* (*Nature* **284**, 443; 1980) found a probable stromatolite structure. Significantly, important new discoveries have been made by Awramik, Walter, Schopf and co-workers in rocks from areas studied by Dunlop and Buick (*Geotimes* Sept, 1980). This work, "finding the first conceit of love there bred, where time and outward form would show it dead", is becoming accepted as sound evidence for early life. It may be that as early as 3,500-Myr ago there was an abundant, simple but diverse biological community in the seas.

So much for the islands of 'fact'. What of the warm pond of speculation? Recent modelling (often by Monte-Carlo methods) of early Archaean conditions is helping to place constraints on that pond. Frey (*Precamb. Res.* **10**, 195; 1980) and Grieve (*Precamb. Res.* **10**, 217; 1980) have suggested, though with different models, that late heavy bombardment of the Earth by asteroid sized bodies established a topographic dichotomy between 'continents' and 'oceans' by about 4,000-Myr ago. Former models proposing a global ocean, such as that of Hargraves (*Science* **193**, 363; 1976) appear unlikely; the process described in *Psalm* 104, 5-9 appears to have taken place very early indeed.

Models of the atmosphere have also

E. G. Nisbet and C. T. Pillinger are in the Department of Earth Sciences, University of Cambridge.

0028-0836/81/010011-02$01.00

improved. In recent years there has been a strong shift away from the traditional idea that the early atmosphere of the Earth consisted of a highly reduced mixture of methane, ammonia and hydrogen. If a reducing atmosphere did once exist, it would probably not have survived for long, ammonia being very rapidly converted by photolytic destruction to nitrogen. Hart (*Icarus* **33**, 23; 1978), Owen *et al.* (*Nature* **277**, 640; 1979) and Henderson-Sellers and Schwartz (*Nature* **287**, 526; 1980) have shown that the 'window of life' must have been rather narrow: if the atmosphere had had too much CO$_2$ or if temperatures had been slightly higher a Venus-like runaway greenhouse inferno would have developed; too little and Martian-like glaciation would have occurred. Perhaps only in a relatively short period around 4,000-Myr ago were surface conditions suitable for life to appear: once it had appeared, the CO$_2$ levels would be controlled and the danger of runaway averted. Henderson-Sellers and Schwartz also highlighted the ammonia 'problem' — there was probably very little in the atmosphere, except perhaps small quantities produced abiotically by photochemical reduction of N$_2$ catalysed by TiO$_2$ in desert sands. Consequently, those chemical evolutionaries who rely on the availability of ammonia may depend on the uncertain intervention of a *deus ex titania.* Life did appear, the warm pond was occupied, but it may have been a close-run thing. Perhaps the Earth is indeed a very rare place, perhaps there are few Gardens in Eden. □

Magic bullets

from Tony Davies

THE possibility of constructing Zauberkugeln — magic bullets — was first thought of by Paul Ehrlich in his inspired attempts to find new cures for a variety of human diseases. Magic bullets, he said, would have some of the properties of the antibodies then newly discovered by Behring and would be able to find and destroy a target in the body which was responsible for a particular disease.

At a recent meeting* (part of the *Quo Vadis?* series) progress towards the fulfilment of Ehrlich's dream was considered. The aim of the organisers was to assemble a group of membranologists and cancer chemotherapists, immunologists, experimentally orientated clinicians and toxinologists who might collectively constitute an engineering team to consider the numerous component problems of the overall design.

The basic philosophy is to have a carrier molecule, of which the function is selectively to bind to the target, covalently attached to a 'warhead' chosen to kill or modify the target cells. Carrier molecules could be antibodies, lectins, peptide hormones or any other molecule which tissues take up selectively but consideration was limited to the use of antibodies and, in particular, monoclonal antibodies.

There was agreement that the homogeneity afforded by monoclonality was advantageous but restriction of the number of sites to which such a highly specific antibody could bind was seen as a potential problem. Localisation is, however, fundamental to success and it was demonstrated by Mach that localisation of anti-CEA antibodies onto human colonic carcinomas in either mice or men could sometimes be demonstrated (Mach *et al. New Eng.J.Med.* **303**, 5; 1980). In well differentiated tumours it tended not to occur, presumably because of difficulties of access to the luminal (antigenic) surface of the malignant ductal epithelium. It is not known whether the larger molecular weight conjugates would do any better but common sense seems to indicate that they would not. The obstacle is not, however, insuperable in well delineated tumours as various devices could be employed to improve local blood flow or to promote extravasation. Neither is it impossible that IgE anti-tumour antibodies could be used as systemic promotors of extravasation. Alternatively IgA antibodies might be transported across the epithelial cells to the target surface as long as the mechanism for secretory piece recognition could operate.

Warheads so far utilised include small molecular weight standard chemotherapeutic drugs or high molecular weight toxins or their subunits. Enzymes have also been employed.

Toxic agents of small molecular weight have limited effects because relatively few molecules can be bound to the carriers without reducing their cell binding capacity. This problem might be circumvented by binding relatively large numbers of drug molecules to a macromolecule such as poly L-glutamate (Rowland *et al. Nature* **255**, 487; 1975) or dextran (Rowland *Eur.J.Cancer* **13**, 593; 1977; Hurwitz *et al. Int.J.Cancer* **21**, 747; 1978) and then attaching the complex to the carrier with target specificity. It emerged incidentally that merely binding daunomycin to dextran reduced the toxicity of the drug although without apparent loss of therapeutic potential. The mechanism involved here probably involves a slower release of the drug over a long period of time rather than an alteration in its pattern of distribution.

Excitement at the meeting was caused by the description of antibody-toxin conjugates or 'immunotoxins' as Jansen and his colleagues (Centre de Recherche Clin-Midy, Montpellier) call them. The toxins, exemplified by diphtheria toxin, abrin and ricin, consist of a B piece which has a receptor for the cell surface and which may mediate the transport into the cytoplasm of the A piece (Olsnes *et al. Nature* **249**, 627; 1974). The A pieces are inhibitors of protein synthesis which can in various ways interfere with messenger RNA translation in cell free systems and which are presumed to do the same in the cytoplasm of cells to which they gain entry (Pappenheimer *Ann.Rev.Biochem.* **46**, 69; 1977).

The means of linking together the toxin and carrier was discussed. Covalent binding of some sort seemed indicated and various chemical strategies for achieving this were considered. Gros (Clin-Midy) reported that a disulphide bond, such as exists naturally between A and B chains of toxins, was needed to link together ricin A chain and immunoglobulin in a form that could express cytotoxicity in tissue culture. The stability of the SS link *in vivo* was questioned and dissociation of the conjugate may explain the lack of impressive therapeutic results with A chain conjugates in animals. Edwards (Wellcome Foundation, London) reported that use of a disulphide bond to attach intact abrin to anti-lymphocyte globulin yielded a conjugate less capable of inducing immunosuppression in mice than a chlorambucil-linked conjugate.

The membranologists, particularly Blobel (Rockefeller University), were of the opinion that the only molecules that would be able to cross the membrane barrier would be those which had the appropriate translocation signals. The B pieces of toxin molecules have been widely regarded as possessing the signal for translocation of the A chain from outside the cell into the cytosol. This may also be true of diphtheria toxin since conjugates with the isolated A chain have lacked potency (see, for example, Gilliland *et al. Proc.natn.Acad.Sci. U.S.A.* **75**, 5319; 1978; Chang *et al. J.Biol.Chem.* **252**, 1515; 1977). But it seems from the work of Jansen (Jansen *et al. Immunol.Lett.* in the press) and Thorpe (Institue of Cancer Research, London) and others (Uchida *et al. J.Biol.Chem.* **255**, 6687; 1980; Yamaguchi *et al. J.Nat.Cancer Inst.* **62**, 1387; 1979) that conjugates with ricin A-chain or A-piece like materials such as gelonin (Stirpe *et al. J.Biol.Chem.* **255**, 6947; 1980) can also be profoundly and specifically cytotoxic. Antibody molecules, like many if not all other secreted proteins, are thought to lose their leader sequences at the time of their translocation into the vesicle from which they will be shed. Thus it must be considered that certain A pieces, with antibody-conferred capacity to bind to cells, may themselves have the additional information necessary to be translocated

---

*The meeting held in Montpellier, 17th July, 1980, was a satellite symposium of the International Congress of Immunology in Paris.

into the cytoplasm without a mediating B-piece.

The technology of antibody-toxin conjugates is developing at a time when our understanding of plasma membranes is increasing rapidly. At present we simply do not know exactly how or why toxins gain entry to cells although we can make informed guesses. The consequences of binding of antibody to cell surfaces are also only known in a limited number of circumstances, so it is very difficult to predict what will happen to an antibody molecule coupled to a toxin.

The overall impression was that the new breed of conjugate therapists should increase their efforts to attack targets *in vivo*, in experimental models, perhaps taking into account the pattern of potential clinical usage. The existing results are promising and the answer to the question 'Quo Vadis?' seems to be 'forward'. □

Macroevolution

from John Maynard Smith

In October 1980 a conference was held in Chicago on "macroevolution". At the meeting, some 150 palaeontologists, anatomists, taxonomists, embryologists and geneticists debated the claim that the large-scale features of evolution cannot be explained as a mere extension of the microevolutionary changes within populations which are studied by geneticists.

The main proponents of this view have been Niles Eldredge, Steven Gould and Steven Stanley. The minimum claim is an observational one, that the fossil record does not show a gradual transformation of populations, but instead shows 'stasis' — morphological constancy of species over millions of years — and 'punctuation' — the sudden appearance of new species.

To establish this assertion would require measurements of the distinguishing characteristics in populations from successive strata. An odd feature of the meeting was that no data of this kind were presented. Stanley's[1] book, *Macroevolution*, argues for punctuation mainly on the basis of data on the durations of taxonomic groups (species, genera etc.) in the fossil record. The trouble with this is that one does not know whether one is studying the habits of taxonomists or of evolving taxa. The morphometric data he presents (notably, Gingerich & Simons' data[2] on adapid mammals) show gradual transformation rather than stasis and punctuation. The claim, therefore, appears to rest on the strong impression felt by some, but by no means all, palaeontologists; it may be true, but needs to be shown to be true.

One study known to me which does support the punctuationist view is that of Williamson[3] on 21 species of fresh-water molluscs in the lake Turkana region of Africa. Over the last 5 million years population measurements show only small changes in 16 of the species. The other five change little for most of the time, but rapidly during a period of perhaps 50,000 years when the lake was isolated. The derived species later went extinct and were replaced by the original forms, presumably by immigration from outside. This example ilustrates a semantic difficulty which often confused the conference. A new species arising in 50,000 years (2m of sediment) is sudden to a palaeontologist but gradual to a geneticist. As a geneticist I was left with the impression that the 'sudden' appearance of new species called for no new explanations, but that stasis may do.

Punctuations have made a further deduction from the supposed pattern of stasis and sudden change. This is that long-term trends in evolution are the consequence of 'species selection'. According to the hypothesis of species selection, the species is the 'unit of selection', which either reproduces (that is splits into two species) or dies (that is goes extinct); this is in contrast to the more usual view, according to which the individual is the unit of selection. It is proposed that some lineages show greater speciation rates and/or lower extinction rates than others, and that therefore there is a trend towards those characteristics responsible for rapid speciation and low extinction. Some of the most interesting data presented concerned associations between species' traits (for example, sedentary versus planktonic larvae) and rates of speciation.

The deduction that species selection is the sole cause of trends rests, however, on the further assumption that punctuational changes are as likely to occur in a direction opposite to that of the trend as parallel to it. If this assumption is not true, then the overall trend of evolution would be the sum of the punctuational changes, each one of which would be the result of selection at the individual level within the populations. The punctuational patterns of change would then not imply any new evolutionary mechanism. It would merely show that evolution occurs not at a uniform but at a very varied rate. This would hardly be new; it was in fact the main theme stressed by G.G. Simpson, one of the founders of the 'modern synthesis'.

There is no evidence to show that the direction of punctuational changes is random with respect to major trends, and it seems implausible as a generalisation. It implies, for example, that in the evolution of mammals from reptiles, newly derived species, when compared to their ancestors, were as likely to have more outwardly directed femur and humerus than the opposite, and similarly a shorter secondary palate, a more complete dermal covering to the skull, more bones in the lower jaw, and so on for all the other trends.

Stasis, punctuation and species selection constitute the minimum claim of the new school. Further claims are that the reason for stasis lies in 'developmental constraints', that the origin of new species requires 'hopeful monsters' (large morphological changes arising from a simple genetic change) and/or 'genetic revolutions' (major reconstructions of the genome, perhaps occurring in a small population), and that the fundamental structures, or bauplans, of major taxa represent a set of possibilities constrained by the laws of development; in constrast, Darwin argued that the structures common to a taxon exist because they were present in the ancestors of that taxon, and that they arose in those ancestors as naturally-selected adaptations to particular ways of life.

Thus there are two possible ways of explaining stasis; normalising selection (that is, selection favouring the typical members of a population relative to the extremes) or developmental constraints. Species did not change either because deviants were weeded out, or because the developmental system prevented them from arising. Clearly both effects operate. The crucial test of their relative importance lies in a study of geographical variation in existing organisms. Thus it seems to be the case that species with a wide geographical distribution often display a range of forms such that the most extreme differ from one another as much as do sympatric species. If so, it is hard to see how developmental constraints can account for stasis. There is a clear need to compare patterns of spatial and temporal variation in the same groups.

Is there evidence that macromutations have been important in speciation? The best way to find out seems to be a genetic analysis of hybrids between morphologically distinct species. One example quoted in Chicago concerns hybrids between *Drosophila sylvestris* and *Drosophila heteroneura*[4,5]: the latter has projecting eyes which are among the most striking morphological variants in the genus. Analysis shows that the difference

in eye shape is caused by genes at at least eight loci. It seems that no macromutation was involved in this case. I know of no example pointing the other way, but shall not be surprised if one crops up.

Genetic analysis cannot, of course, be applied to the more extreme differences between bauplans, so it is still possible to argue that the origins of major taxa require special genetic events. However, no-one at the conference was prepared to challenge Stebbins's remark that the most striking morphological novelty among the higher plants was the flower head of *Zea mays*, which is largely the result of selective breeding under domestication and is known to be under the control of many genes with small effects.

It will be apparent that this report has been written by a geneticist, not a palaeontologist. Despite my reservations, I found the meeting immensely stimulating. It can only be good for evolutionary biology that people from such different disciplines should meet, talk and, occasionally, listen. It was only to be expected that there would be much misunderstanding, confusion and even indignation. I hope we shall meet again in a year or two, and that next time the confusion may be slightly diminished. □

Why is a plant where it is?

from Peter D. Moore

ONE of the simplest questions to ask, yet one of the most difficult to answer is why a particular individual of a given plant species should be found growing at a particular location. The answer may be sought in its physiological requirements and the degree to which they are satisfied by the physical framework of that spot; or in the complex of biological interactions with other organisms, competitors, predators, parasites, and so on; or in the tangled web of historical events which has moulded both of these former factors; or, finally, in the sheer chance which brought a propagule to that site and which left it untouched by random catastrophe. The interaction of all these forces permits no easy answer to the apparently simple question.

Any attempt must seek first to locate the physical environmental stress and physiological sensitivity which, in combination, allow the identification of a limiting factor. This factor can be regarded as a necessary resource in such short supply that any increase in its availability will result in an increase in the performance of the individual or density of the population. But the model, stated in these terms, needs to be flexible enough for such factors as temperature at specific times of day or year to be regarded as a resource.

One may examine any aspect of the plant's physiology, or any time in the plant's life history, to find where resource restriction meets the plant at its most vulnerable point and prevents further reproduction, growth, or even survival. Perhaps the most obvious place to start is at the beginning and to define those resource limitations which restrict the germination of the seed and thus determine whether the plant is to be given the opportunity to meet further tests. Thompson (*Ann. Bot.* **34**, 427; 1970) has approached from this direction in his studies of various species of Caryophyllaceae. He devised a metal bar along which a temperature gradient was maintained and observed the germination characteristics of each species in relation to temperature, and found that their requirements correlated well with the biogeographical characteristics of each species. For example, a species (*Silene secundiflora*) from the Mediterranean germinated at low temperature, this being advantageous to species in which autumn germination means a mild, damp period before meeting the unfavourable drought of the following summer. A more northerly species, on the other hand (*Lychnis flos-cuculi*), had a higher temperature germination requirement; it thus remains dormant through the winter after seed set and germinates in the spring.

Subsequently Thompson (*Ann. Bot.* **39**, 1; 1975) has examined in detail the geographical variation between populations of a single species, namely *Silene dioica*. He has found considerable variation both within and between populations and also a different response among after ripened seeds from those which were fresh. The populations from regions with milder winter contained more individuals which were capable of germination at low temperature, thus confirming the trend indicated by the previous experiments.

Silene dioica, the red campion, is a woodland herb, widespread in Europe, which, in the western, deciduous woods of Britain and northern France is often accompanied by the bluebell, *Hycaninthoides non-scriptus*. The seeds of this species were also subjected to the attentions of Thomson and Cox (*Ann. Bot.* **42**, 51; 1978), and on the basis of their experiments they propose that the seeds germinate naturally at about 11°C, in the late autumn and that they therefore overwinter as seedlings. This obviously leaves the species somewhat vulnerable to winter frost; its distribution appears to correlate well with the isotherm of the main daily maximum temperature of the coldest winter month at 0°C, and also with a mean daily maximum of the warmest summer month at 25°C. Its sensitivity to winter frost and summer drought account for its western distribution and its confinement to the woodland habitat, where it is protected from both. The survival of bluebells in open habitats in the extreme west of Britain (often as a relict of former woodland) may be a reflection of the mild, oceanic conditions prevailing there.

The examination of seed from one further woodland species, the wood millet grass, *Millium effusum*, has shown a rather more complex pattern of reaction. Thompson (*Ann. Bot.* **46**, 593; 1980) found that seed germinated immediately after harvesting had an optimum temperature requirement of 16°C but, after storage for 2.5 months, the optimum temperature for germination was 21°C and germination took place over a wider temperature range. The breadth of tolerance increased yet further after 10 months. Also, germination was faster after a period of storage but, rather surprisingly, a higher temperature (26°C) of storage reduced the subsequent germination rate. The ecological significance of this high temperature inhibition of the after ripening process is difficult to discern, but Thompson suggests that it could reduce the chances of an ill-advised, rapid response to mild conditions soon after shedding.

Millium effusum has a wide distribution in Europe and, in view of the late flowering and fruiting in the north of its range (late August in areas to the north of the Baltic), temperatures will already be below those needed for germination, which is thus delayed until spring. In the south (southern France and Iberia), seed is shed in early summer, so it experiences a hot, dry period followed by a warm, moist one. This results in the bulk of the seed germinating before winter arrives. In between these two extremes, the complex microclimatic variations caused by site factors (microtopography, aspect, etc.) and fluctuations in weather conditions, can result in a range of responses. Indeed, the plasticity of this species may be a key to its success.

Thompson's germination studies illustrate the possibilities which exist for pinpointing the limits of a plant's capacity to meet the stresses of the environment, but seed germination is only one of many critical phases in the plant's life cycle. Also, the fact that one factor may limit a species on a continental scale, does not preclude the possibility that other factors will limit its local distribution pattern. At the level of the individual one must still account for the part played by chance. At this scale is vegetation simply, in the words of Gleason, a "fortuitous juxtaposition of plant individuals"?

Galileo would have been pleased

from J. E. Guest

THE discovery that Io, the Moon-sized satellite of Jupiter, has active volcanoes throwing plumes as much as 270km above the satellite's surface was one of the exciting revelations made by the Voyagers I and II spacecraft as they sped past Jupiter and its attendant satellites in March and July 1979. The four largest satellites in the Jupiter system, named Io, Europa, Ganymede and Callisto, were discovered by Galileo in 1610. For three centuries after their discovery little more was found out about them but, during this century, it became abundantly clear, even from Earth-based astronomical observations, that each satellite has distinctive characteristics.

Although classified as satellites, the Galilean moons are planetary bodies in their own right and of similar size to the Moon and Mercury. Io, the innermost of the satellites, was thought to be the most peculiar. Its density (3,500kg m^{-3}) is similar to that of terrestrial rocks and its surface is characterised by high reflectivity and a striking reddish colour. Furthermore, Io is constantly emitting atoms from its surface, leaving a trail of ionised sulphur, potassium, hydrogen and sodium behind it to form a torus-shaped atmosphere in its orbital path. Telescopic observations of the next satellite outwards, Europa, showed that it too has a density (3,100kg m^{-3}) consistent with it being made primarily of rocks. Its density is slightly less than that of Io implying a higher water content. Whereas Io is somewhat larger than the Moon, Europa is almost the same size.

The way light is reflected from Europa and the next satellite out, Ganymede, suggests a covering of water ice on their surfaces. It is thought that Europa is between 50 and 100 percent frost and ice, and Ganymede between 20 and 60 percent covered by fresh ice. Ganymede has a much lower density than Io or Europa, (1,900kg m^{-3}) implying a high content of water and ice. Callisto, on the other hand, which is of comparable density (1,800kg m^{-3} from new Voyager data) to Ganymede, has a low albedo and any ice at the surface must be 'dirty' containing fragmental rocky material.

Thus from the limited pre-Voyager astronomical data it was clear that the internal structures and compositions, and the processes that had moulded the surfaces could be very different from those with which we have become familiar on the terrestrial planets. From previous studies of the Moon, Mars and Mercury, a familiar pattern of surface history for solid planetary bodies has emerged. The early surface history was dominated by impact craters, ranging from the minute to large basins of 13,000k diameter or more. The surface expressions of any other processes operating at the same time, such as volcanism, were destroyed. For the Moon at least, this period of bombardment ended around 4×10^9 years ago. There then followed for each of these planetary bodies a period when volcanism dominated to give on the Moon, for example, the extensive dark marial plains, consisting of vast sheets of lava. On Mars, the volcanic process was more varied giving large volcanic constructs such as the huge mountain of Olympus Mons. Tectonic processes produced patterns of faults, the most complex structures being on Mars. As well as these internal processes modifying the surface Mars was further modified by the effects of water and wind erosion as well as the effects of sub-surface ice. But even these processes occurred relatively early, the major events having been completed $2\text{–}3 \times 10^9$ years ago.

The pictures returned by the Voyager spacecraft show surfaces much stranger than had been predicted.

Whereas for bodies in the inner Solar System virtually the whole record of surface history has been preserved, the surfaces of the Galilean Satellites have each preserved different periods in their history and each is dominated by specific processes.

The outermost satellite, Callisto, has a surface dominated by impact craters and basins, and presumably has the oldest preserved surface of the Galilean satellites. The high content of ice and water suggests that there was little modification of the surface by internal activity following the period of impact bombardment. Ganymede on the other hand has a higher rocky content and as well as impact craters a complex pattern of tectonic features which have strongly modified the surface since the period of heavy bombardment can be seen. The evidence suggests that during the period of bombardment the mechanical crust of Ganymede was probably only a few tens of kilometres thick and there then followed a period of rapid thickening and stiffening of the crust resulting in the tectonic patterns now observed.

When we examine the surfaces of Europa and Io, we can see they have quite different histories. On Europa only a few impact craters have been identified suggesting that the present surface was formed after the period of intense bombardment; on Io, volcanic resurfacing has obliterated the craters formed earlier. Thus, although on Ganymede internal activity has been important, its effects on the surface were concluded early in its history, whereas for Europa and Io, internal mechanisms have continued, and, in the case of Io are still operating.

Models for the internal constitution and thermal history of the two inner Galilean satellites have concentrated on two energy sources, one deriving from tidal interaction between Jupiter and the satellites and the other involving decay of long lived isotopes within the rocky interiors. Models involving these two processes depend very much on the satellites' origin, the timing of events and the composition and degree of differentiation.

In their remarkably well timed paper, Peel *et al.* (*Science* **203**, 892; 1979) produced a model in which there was intense heating in the interior of Io by tidal dissipation, anticipating the Voyager results of active volcanism on Io just a few days before it was discovered. Likewise, tidal heating can have played a part in the thermal history of Europa and tidal deformation may explain some of the surface characteristics. The surface of Europa is generally smooth and bright with a strange pattern of intersecting linear features composed of shallow grooves, low ridges and albedo markings. The topographic relief on these features is small and only seen close to the terminator. These features are probably formed by stress in the surface materials, but their orientation has not so far been shown to be uniquely explicable in terms of a particular stress field. Previous models for the internal constitution of Europa suggested that early differentiation resulted in a silicate core surrounded by a liquid water mantle, crusted over by some tens of kilometres of water-ice. However, more recent calculations suggest that solid state convection in the crust probably caused progressive freezing of the liquid mantle and it now seems unlikely that tidal heating could have maintained the liquid state.

The Voyager discoveries have prompted a reconsideration of this type of model. It is possible that the six percent by weight water component (derived from density considerations) is not all taken up as free water or ice at the surface, is instead contained in hydrous silicates in the rocky part of the planet, leaving only a thin ice outer shell of a few kilometres thickness (Ransford, *et al.* this issue of *Nature* page 21). However, such a model imposes constraints on the time of formation of the surface ice. It appears that Europa's surface consists of relatively 'clean' ice, although in some areas a brownish hue to the surface may suggest contamination by rocky material. Assuming that Europa, like the outer Galilean satellites, was bombarded in its early history it is

---

0028-0836/81/010015-02$01.00

inevitable that, with a thin icy crust underlain by rock, impact excavation would have brought up rocky material, mixing it with the surface ice: the present ice layer must therefore have formed after the period of heavy bombardment. With a thicker ice (or water and ice) outer shell, impact need not have penetrated to the rocky layers and the effects of impact might have been removed by cold viscous flow in the ice crust. Alternatively, early formed craters might have been eroded by the sputtering effect of charged particles capable of removing tens of metres, or even kilometres, from the surface (Smith *et al. Science* **206**, 927; 1979). A thin icy crust must either have formed after the end of bombardment, or have remained in a liquid state, allowing denser silicate material to settle, until after the bombardment period.

The origin of the linear pattern on Europa is particularly enigmatic. Various proposals have been put forward including crustal expansion owing to freezing of an early ocean, global expansion as a result of dehydration of the interior, and tidal deformation. The complexity of the pattern made up of features of different morphology is difficult to interpret in terms of mechanism and indeed more than one process may have contributed to the surface features. At present, interpretation of the surface of Europa is model-dependent; a situation which is perhaps not surprising on a planet whose geology is unlike anything in our previous experience. □

Finding nitrogen fixation genes

from John E. Beringer

THE enzymic conversion of atmospheric nitrogen to ammonia is carried out only by prokaryotic microorganisms. The structure and properties of the enzyme complex used, nitrogenase, are very similar in all species that have been studied.

Nitrogenase consists of two main components. One is an iron protein, composed of two identical subunits; it binds MgATP and transfers electrons to the other component which reduces the substrate. The second component is a molybdenum-iron enzyme containing four proteins which can be separated into two distinct sub-units, giving the enzyme an $\alpha_2\beta_2$ type of structure. All these proteins are irreversibly denatured by oxygen. A further striking similarity between nitrogenases is that a functional enzyme can be constructed by mixing iron and iron-molybdenum proteins from different genera; for example *Klebsiella* and *Azotobacter*, though some combinations such as *Klebsiella* and *Clostridium* are inactive.

Over the last few years there have been dramatic advances in our understanding of the genetics of nitrogen fixation (Nif). This has been due largely to the fortunate finding that *Klebsiella pneumoniae nif* genes are linked to each other and could be manipulated in *Escherichia coli*. As a result of extensive mutant and complementation studies we know that there are 17 *nif* genes in seven or eight operons. Three genes code for nitrogenase proteins; *nif* H for the iron protein and K and D for the different subunits of the molybdenum-iron enzyme. Functions have yet to be assigned to some of the other genes.

Parallel genetic studies of *nif* genes in other nitrogen fixing species have been restricted by limitations in our ability to do the necessary genetic manipulations or, in the case of the genetically amenable *Rhizobium* species, our inability to obtain nitrogen fixation in pure culture. However, using *Rhizobium meliloti* as an example, Ruvkun and Ausubel in this issue of *Nature* (see page 85) have shown that one can take advantage of the conservation in DNA sequence of *nif* genes to promote site-directed mutagenesis and localized mapping in prokaryotes.

In 1979 Nuti *et al.* (*Nature* **282**, 533) reported that DNA encoding the *K. pneumoniae* iron and molybdenum-iron proteins hybridized with plasmid DNA from *Rhizobium*, though DNA encoding most of the remaining *Klebsiella nif* genes did not hybridize. In January this year Ruvkun and Ausubel (*Proc. natn. Acad. Sci. U.S.A.* **77**, 191) and Mazur, Rice and Haselkorn (*Proc. natn. Acad. Sci. U.S.A.* **77**, 186) reported further evidence for the conservation of *nif* genes. Ruvkun and Ausubel looked at 19 strains of different nitrogen fixing prokaryotes, including Gram-positive and Gram-negative bacteria, cyanobacteria and the actinomycete *Frankia*. All showed DNA hybridization with the fragment of *K. pneumoniae nif* DNA carrying genes K D and H used by Nuti *et al.*, whereas no hybridization was observed with controls representing ten different non-nitrogen fixing species or with DNA carrying the other *nif* genes. Mazur, Rice and Haselkorn confirmed that hybridization could occur with three strains of cyanobacteria representing two different species. They further showed by heteroduplex studies of hybridized DNA that the genes were not contiguous cyanobacteria strains. It is unclear from the published data for *nif* gene hybridization whether or not all three structural *nif* genes (H D and K) hybridize in all these species. Hopefully this will be resolved in the near future.

Another problem which should be resolved soon is the determination of the extent of DNA sequence homology for these genes in different species. The DNA sequences for the *nif* H proteins of *Anabaena*, (Haselkorn pers. comm.) and *Klebsiella* (Ausubel pers. comm.) are now available. It will be interesting to see how highly conserved the sequences of the different genes are and whether or not the data support the idea that the enzyme has been conserved over a long evolutionary period, or that nitrogen fixation is a relatively new function which has been transferred between different bacterial genera.

These DNA hybridization studies have been of very great value for comparative studies of *nif* genes in different families. As described above, they can be used to determine whether *nif* genes are chromosomal or plasmid borne, whether they are linked to each other and as a method for isolating *nif* DNA for studies of its expression in different hosts or for further genetic studies. It is these last two uses of the *nif* hybridization work which are discussed by Ruvken and Ausubel in this issue of *Nature*. They show, as one would expect, that the *K. pneumonia nif* DNA can be used to isolate the corresponding *Rhizobium* genes and introduce them into *Escherichia coli*. Of much greater importance scientifically is the demonstration that this procedure can be used to induce mutations in the *Rhizobium nif* DNA within *E. coli* and then return the defective gene to its original host where recombination can be forced so that the defective gene is introduced into the chromosome replacing the existing functional gene. In this way mutants of *Rhizobium*, or potentially any other nitrogen fixing prokaryote, which are defective in known *nif* genes can be induced.

Once such a mutation has been induced it is possible to re-isolate DNA fragments extending from this region and induce mutations in them. By knowing the extent of the overlap with the original fragment a series of mutations can be induced at known distances from the original mutation by repeated rounds of mutagenesis and replacement of the corresponding host DNA. While the value of this technique for studies of genes linked to a particular *nif* gene is obvious it is also equally valuable for all species where cloned DNA fragments are available and there is a method for re-introducing the mutated DNA into the host. Thus we now have a technique which could be used to prepare maps of chromosomes or plasmids in a wide range of species of microorganisms.

Lineament and polygon patterns on Europa

David C. Pieri

Space Sciences Division, Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91103

A classification scheme for the lineaments and associated polygonal patterns seen on the surface of Europa is presented, and the polygon frequency distribution discussed.

THE surface of Europa is dominated by lineaments intersecting to form polygons and by complex systems of low ridges which often exhibit cycloid planimetric patterns[1,2]. Polygonal or nearly polygonal patterns are common in nature and are often associated with stress-relief fracturing. The interpretation that the albedo lineament patterns are associated with fracturing at different scales is used. Two major pattern groups are of interest: (1) roughly equant polygons formed by the surface expression of fractures formed in isotropic stress regions, both tensional and compressional (for example, shrinkage cracks in mud, cooling cracks in basalt, patterned ground, fracture patterns over salt domes); and (2) complex trapezoidal patterns formed by the intersection of faults or joints under directed stress.

The existence of either of these pattern types has implications for the state of stress under which each type formed. This article presents a classification scheme for the lineaments and associated polygonal patterns seen on Europa, and reports on the polygon frequency distributions. Possible fracture mechanisms and scenarios for the formation of lineament systems on Europa are examined in detail elsewhere[3–5].

Lineaments

Figure 1 is a low resolution sketch map of the global lineament patterns on Europa. The general orientation of lineaments along great circles is apparent and has been mentioned previously (ref. 1 and Plescia personal communication). Lineaments are seen less frequently in low albedo regions, although this may be due to loss of contrast across dark areas.

Figure 2 is a high resolution (4 kilometre per line pair (km/lp)) mercator projection mosaic. Figure 2 shows that at small scale the lineaments form extremely complex patterns. Some lineaments exhibit relief while others seem to be primarily albedo features. Most dark lineaments possess a white medial stripe and often, when dark lineaments lie across low albedo terrain, only the white interior stripe is visible across the low albedo patch. The first step to try to understand these enigmatic features was devising a preliminary classification system which is outlined in Table 1 and Fig. 3. Although this classification is rudimentary it allows different styles of lineaments to be discussed. The lineaments have been divided on the basis of albedo, morphology, orientation, and characteristic geometric style into eight groups. However, this analysis is based entirely on the limited set of Voyager 2 images taken from a distance of ~100,000 km and the best resolution of the images is ~4 km. Stereo coverage, while available, is marginal and of low resolution. Coverage at 4 km resolution is available only for ~25% of the planet, the remainder of the surface is covered at resolution at least an order of magnitude worse. Although this limits the analysis the classification scheme is, nevertheless, representative of the region for which coverage is available.

Figure 3 shows the various lineament geometries and Table 1 gives type descriptions and locations. These lineaments on Europa are clearly of several length scales and there are at least two basic types. Flexi (Type 6) and scarps (Type 8) seem to be topographic features with little or no albedo contrast to the surrounding terrain. The flexi are global features, and we do not know the extent of the low scarps. The linea appear to be primarily albedo features. Type 3 with white centre striations appear to have some positive relief although Soderblom (personal communication) reports that based on photometric measurements relief may be small to non-existent. Negative relief for one northern linea has been suggested[2]. Lineament Type 3 is clearly global. These are generally large great circles. Type 1, 4, and 7 seem to be regional in extent, whereas Types 2 and 5 may be the result of highly localized processes.

Polygonal areas

All the lineaments mentioned above define a system of polygons varying in size from small (limit of resolution 10 km^2) reticulate polygonal patterns to very large (10^6 km^2) individuals. The statistics of polygonal patterns in nature are well-known[6,7].

For macroscopic geological settings two pattern types are common in terrestrial experience: (1) equant five or six sided polygons; and (2) predominately four-sided polygons formed by faults or joints in complex settings.

The two types have distinct and characteristic frequency distributions for polygons of a given number of sides: the so-called Voronoi distribution (mode 6) is characteristic of polygonal patterns formed under uniform tension or compression; the Poisson distribution (mode 4) being characteristic of polygons formed by random intersections of lines on a plane or by the intersections of random great circles on a sphere[6,8,9] (Fig. 4*a*).

Literature data on several types of terrestrial polygonal patterns were compiled for polygon side-frequency distributions and these are presented in Fig. 4*b*. Slowly cooling basalt is reported to possess equant polygonal patterns[10–12]. Although the most famous columnar basalt occurrences exhibit a roughly Voronoi polygon distribution, they tend to have an excess frequency at the modal value[13]. Further, basalt, cooling in less than ideal conditions for the formation of polygons, tends to have a mode of five rather than the classic six. Rapidly cooling, basalt-glass crusts on lava lakes tend to have a different character[14]. Although they are grossly polygonal and have a large number of five- and six-sided polygons, they have a large number of three- and four-sided members as well. Concoidal fractures are common, and this characteristic undoubtedly plays a part in the observed side-frequency distribution. It is often difficult to define polygonal forms at all under these circumstances. Mud crack networks[6,12,15–19], and tensional fractures over salt domes[20] typically follow a Voronoi distribution as do contractional thrust ridges in playa salt crusts[21]. Ice wedges and patterned ground are also Voronoi distributed[7,22]. The common feature of these examples is their formation in isotropic or near isotropic stress conditions, which is not surprising as the ideal hexagonal pattern maximizes the reduction of strain energy per unit surface area by cracking and is therefore the most efficient pattern given an isotropic stress field (see ref. 7).

0028–0836/81/020017—05$01.00

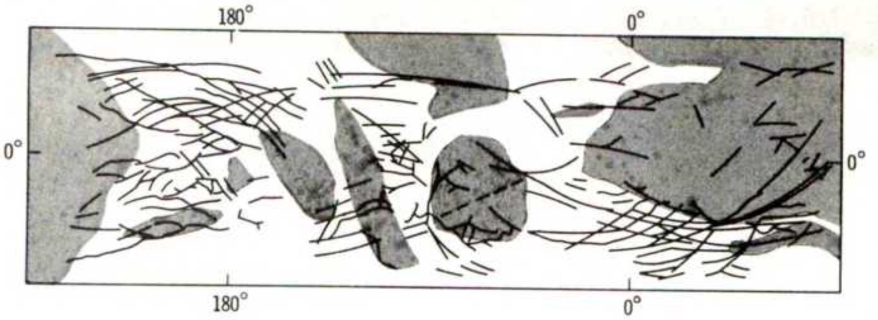

Fig. 1 Global map of lineament patterns on Europa between roughly ±30° latitude. Sub-jovian point on the planet is located at lat 0°, long 0° and the anti-jovian point at lat 0°, 180° long. This map is a cylindrical projection, was compiled from low resolution full-disk images from Voyager cameras. Shaded areas correspond to low albedo regions as seen in Voyager blue-filter images. The absence of many apparent lineaments in these areas may be due to either a lack of contrast or to a lack of lineament development in these areas.

The Poisson distribution characterizes randomly intersecting lines in a plane or on a sphere[6]. Statistics for various fracture and joint patterns are presented in Fig. 4*c* (refs 23, 24). All follow a left-skewed Poisson-type distribution. The most random fracture patterns, as expected, follow the Poisson distribution quite well; however, fracture patterns from strongly oriented stress fields tend towards having orthogonal intersections, thus resulting in left-skewed distribution but with great excess in frequency over the Poisson expectation value at the mode of 4.

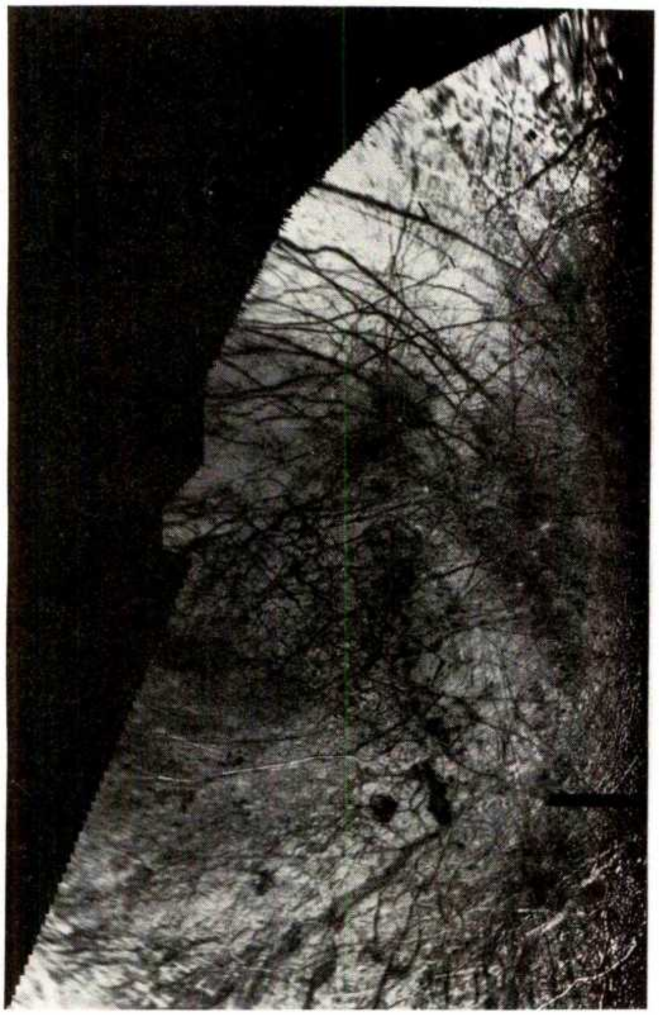

Fig. 2 A computer-enhanced and mercator projected mosaic of Voyager 2 images (resolution up to 4.5 km/lp) taken through the blue filter, in which about 25% of the European surface is shown in this mosaic. The anti-jovian point is near the dark, intensely lineated region at mid-left. Map coordinates of the upper right corner, lower right corner, and lower left corner are respectively: lat +65°, long 130°; lat −70°, long 130°; and lat −70°, long 240°.

If Europan lineaments were expressions of fracturing in the crust of Europa, then it would be logical to compare the statistics of polygons formed by lineament intersections with the statistics for various terrestrial fracture patterns as outlined above. The fundamental distinction between fracture patterns with a left-skewed (Poisson-type) side–frequency distribution and those with a mildly right-skewed (Voronoi-type) pattern is the presence of 'triple junction' fractures. In an isotropic stress environment (tensional or compressional) failure tends to create nonorthogonal intersecting fractures with intersection angles of about 120° (see ref. 21 for examples of compressional isotropic failure). These triple junctions tend to occur as part of five- and six-sided polygons. The more isotropic and uniform the stress, the more likely it will be that six-sided polygons form. For Europa it is important to determine whether structure exists in the pattern of myriad intersecting lineaments. Preferred orientations or coherent structure in the lineament patterns has implications for the organization of stresses in Europa's crust, if the fracture hypothesis is correct.

An apparently qualitative coherence to at least part of the lineament pattern has been reported[1,2,25,26]. Parmentier *et al.*[27] attempted to analyse the orientations of various lineament groupings and compare these trends with stress fields predicted by tidal stress models[28]. We have analysed the polygonal patterns[29] to find out whether there are statistical differences in the side–frequency distributions between polygons resulting from the intersections of the various lineament types, and if so, what those differences imply about the state of formational stress in the surface of Europa.

Preliminary analysis of three major polygon patterns are reported here:

(1) The polygons formed by the intersections of Type 3 lineaments.

(2) The polygons formed by the intersections of Type 1, Type 2, Type 4 and Type 5.

(3) The roughly equant polygons formed by the intersections of Type 1 and Type 2 lineaments.

The side–frequency distribution for polygons formed by Type 3 lineaments (Fig. 4*d*) are similar to those found in complex faulted terrain on the Earth, particularly in areas where stresses are well oriented. They have a mode of 4, are left-skewed and exhibit a Poisson-like frequency distribution. The maximum principal stress is apparently oriented roughly north–south as can be seen from lineament orientation[27]. Nothing can be inferred from the plan pattern alone about the sign of the stress in this case. Some models, however, suggest that it may be compressive[27,28].

Polygons formed by the intersections of Types 1, 2, 4, and 5 lineaments occur around the anti-jovian point on Europa. Their overall distribution is not grossly different than the polygons formed by Type 3 lineaments with one important exception: the number of five- and six-sided intersection polygons mapped for the Type 1, 2, 4 and 5 lineaments exceeds those seen in the Type 3 distribution by a factor of 2 and a factor of 12, respectively. That is, there is a significant shift in the distribution to the right (Fig. 4*d*).

The 'wedge-shaped lineaments' referred to elsewhere[2,25,26], and called Type 2 lineaments here, have been cited as evidence for a nascent type of plate tectonics on Europa[26]. The presence of numerous 'triple junctions' or three-cornered fractures associated with the intersections of Type 1 and Type 2 lineaments supports this line of speculation. Alternatively, they may be the result of local expansion/contraction phenomena. Regardless of their potential connection with possible plate movements, the Type 2 lineaments, when they are mapped separately from other lineaments, have a grossly equant polygonal pattern (Fig. 5). The side-frequency distribution associated with the polygons formed by Type 1 and 2 (Fig. 5) lineament intersections is shown in Fig. 4d. It appears to be much more right-skewed with a mode of 5, similar to the Voronoi-like distributions seen in tensional

Table 1 Descriptions and locations of lineament types

Lineament type	Location of best examples	Description
1	lat −55° to equator, long 160°	175–500 m long, regular spacing, trend ENE, soft appearance, disrupt and are disrupted by Type 2. Together, Types 1 and 2 form the generally equant equatorial polygonal features discussed in text.
2	lat −50° to equator, long between 160° and 210°	Short wedge-shaped markings; typically straight; form triple junctions; together with Type 1 lineaments they form equant polygonal features around anti-jovian point; darkest of the lineaments in Voyager blue filter; typically trend NW–SE.
3	lat +30°, long 180°	Smooth arcuate features; appear to lie on great circles; longest and most continuous of the linea; white medial stripe; remarkable continuity over large distances; intersect at shallow (≤30°) angles or are parallel; several tens of km wide; cross dark terrains of high and low albedo.
4	two main groups: lat +30°, long 165°; lat −30°, long 160°	Two main groups, but may be ubiquitous in light terrain; faint; reticulate patterns; linear; intersect at high angles; occur in remarkably parallel doublets which maintain constant separation (50 km) over distances of hundreds of km; narrowest of lineaments (5–10 km); subdivide polygons formed by the intersections of Types 1, 2, and 3; seem to cut Type 3 lineaments and are cut by Types 1 and 3; intersect Type 3 lineaments at high angles (80°).
5	lat 0° to −40°, long 165° to 210°	Very short (<10–20 km in length); subdivide equant polygons formed by Types 1 and 2 to the limit of resolution; ubiquitous around anti-jovian point.
6	lat −60°, long 150–210°	IAU *flexi*; complex series of cuspate ridges lying on a small circle crudely centred on the anti-jovian point and the complex of Types 1, 2, and 5 lineaments; appear as distinct ridges with a regular cycloid pattern[2]; one set convex towards the anti-jovian point, the other convex away; arranged in radial pattern around a possible impact crater (may be artefact of position with regard to sub-solar point).
7	lat −40°, long 180–220°	Rare; only two visible examples; may be a modification of Types 1 or 3; extremely high albedo; smooth, continuous and linear; very fresh appearance; not cut by other lineaments; one instance of darkening at intersection with another lineament.
8	lat −65°, long 120°; lat 55, long 120°	Possibly low sun facing scarps of indeterminate heights[2] although Soderblom (personal communication) claims they are albedo markings only; roughly parallel to trend of nearby flexi.

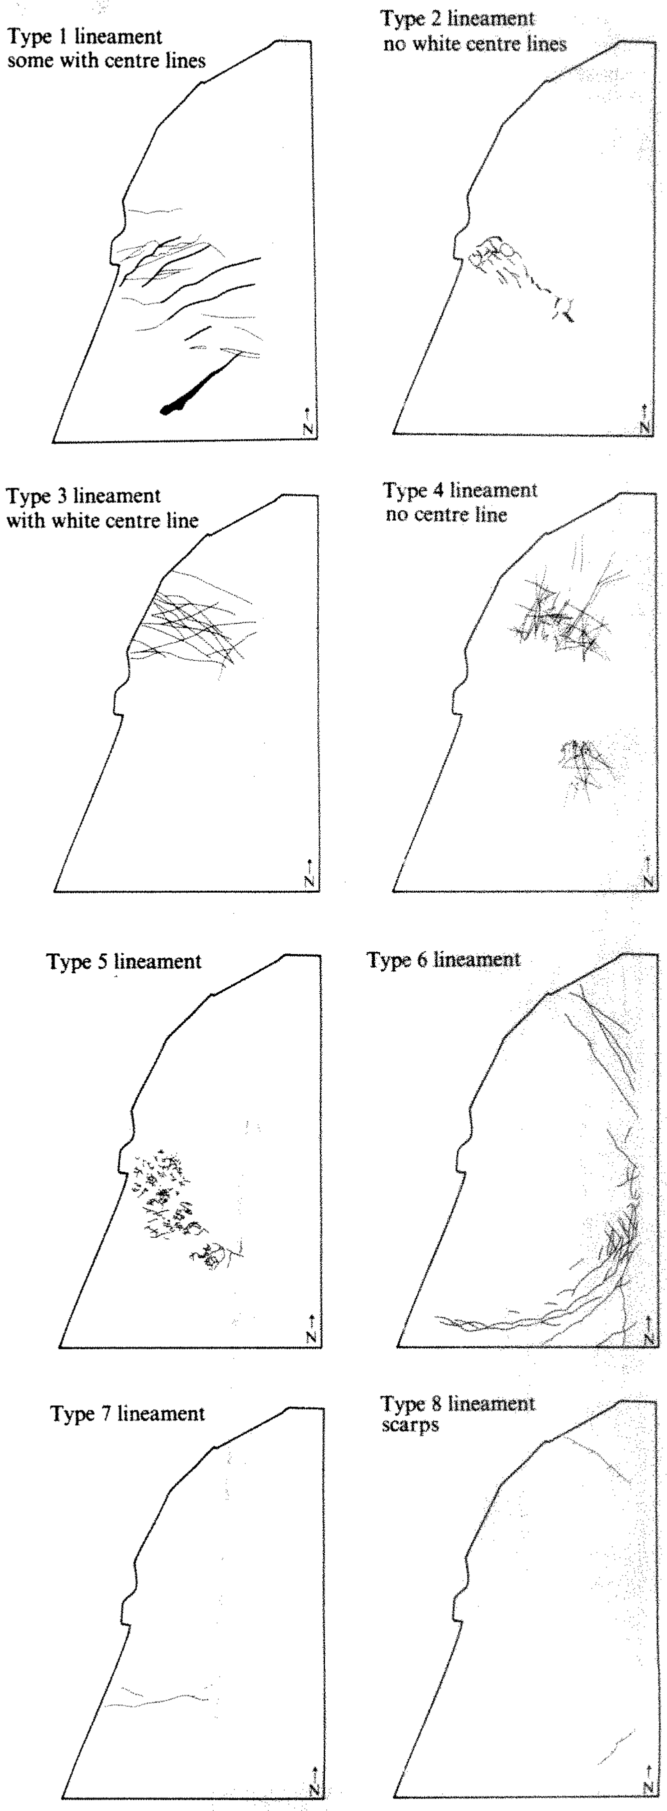

Fig. 3 Sketch maps showing the geographic positions and planimetric morphology of the various types of lineament features observed on Europa. The map outline is the limit of visibility shown in Fig. 2.

fracture patterns. Again, however, the pattern cannot provide information on the sign of the imposed stress; however, isotropic or near-isotropic tension is the predominate factor in terrestrial examples of this style of failure.

Conclusions and discussion

Qualitative and quantitative observations of lineament and polygon patterns on Europa enable several conclusions to be drawn.

First, definite classes of lineaments and their associated polygons have been found on Europa which are separable both by qualitative and quantitative analysis. Second, these classes form distinct groups-often localized, but also some of global character. Finally, these groups have separable geometrical and transectional characteristics, probably related to the stress fields in which they were formed.

These conclusions lead to several speculations. First, the several morphological classes and scales of lineaments may imply different processes acting at different scales, and may also be related to a temporal evolution of the lineament forming processes as suggested by Soderblom[25]. Further, geographically diverse areas on Europa may respond differently to lineament formation, which may be construed as evidence for heterogenity in the European crust. Classification schemes proposed so far[1,2,25,29] indicate a diversity of lineament type and thus, a complex geologic history.

Second, the observations of roughly equant five- and six-sided polygonal patterns near the anti-jovian point argue for a grossly uniform (probably tensional) stress field around the anti-jovian point on Europa. The uniform tension at the anti- and sub-jovian points may be consistent with tidal eccentricity stresses[5], however, preliminary calculations (B. Bannerdt, personal communication) point to very low (<10 bar) stresses from this mechanism. Other models invoking internally generated stresses (such as convection, and dehydration of interior) are being pursued[3,4] and suggest much higher stress levels in Europa's crust. Further, the areal density of the lineament patterns and associated polygons varies with position. Overall, the spacing of tensional polygons varies with material strength and/or rate of stress imposition[7]. Closely spaced reticulate patterns occur at the anti-jovian point and may be indicative of higher imposed stress, of a weaker (or possibly thinner) surface layer, or both.

A more detailed morphological/time-history lineament classification scheme, detailed morphological and geological

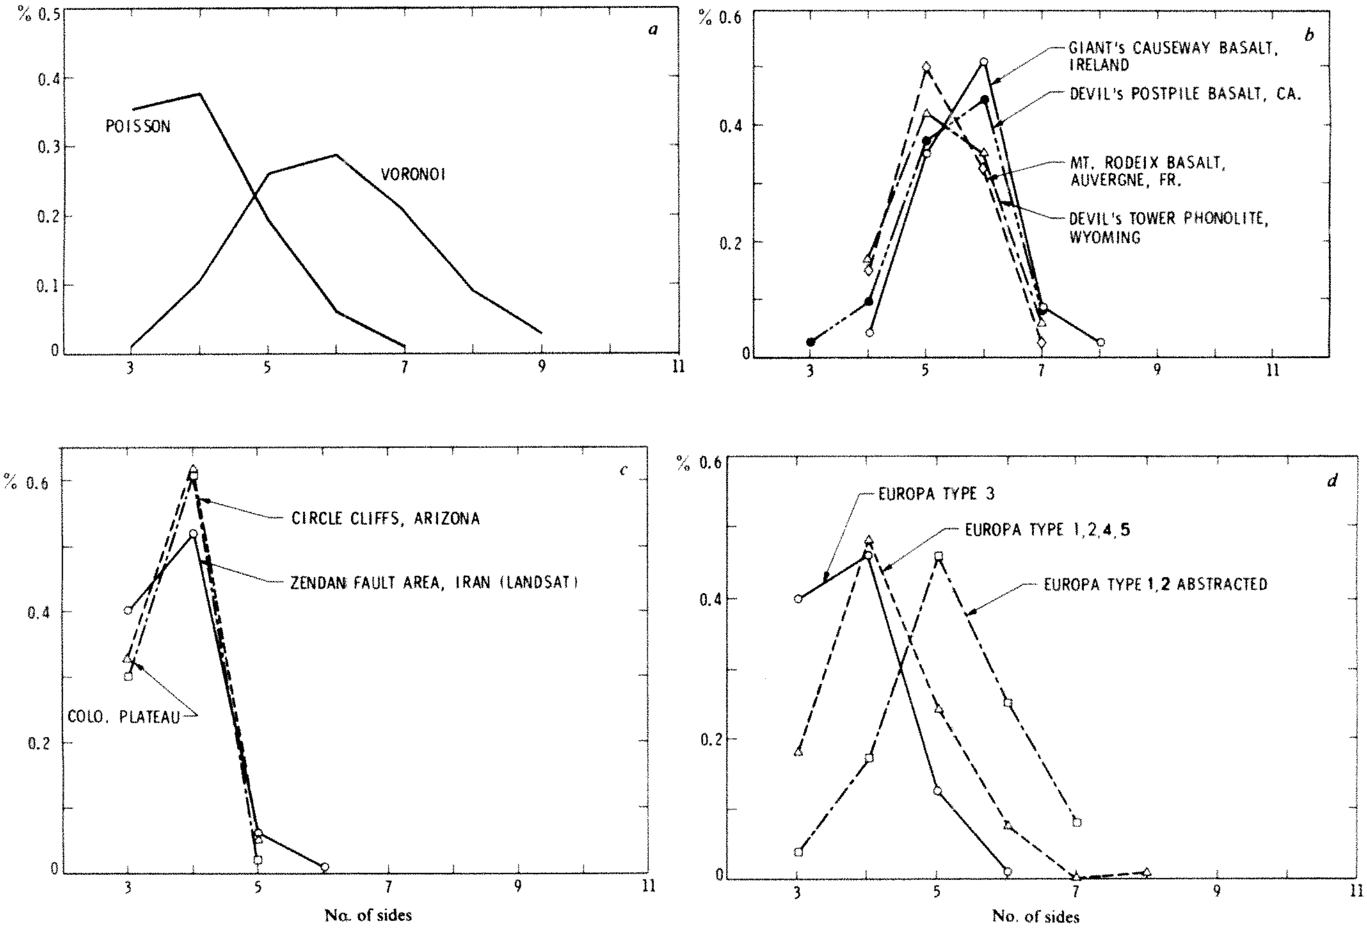

Fig. 4 *a*, Theoretical frequency distributions for polygons of a given number of sides formed by randomly intersecting lines (Poisson) and tesselation polygons formed, for instance by cracking mud (Voronoi) (adapted from Tables 2.1 and 2.2 of ref. 6). *b*, Measured side-frequency distributions for polygons formed by tensional cracking in columnar basalts at well-known localities, compiled from Beard[13]. Note that modes of both 5 and 6 sides are prevelant. The most pristine examples, having formed in presumably ideal conditions (slow cooling rates, few edge effects) have frequency modes of 6. *c*, Side-frequency distributions for intersecting faults in complexly faulted terrain in three areas on the Earth. All show an excess over the random Poisson distribution at the mode. The examples from Circle Cliffs, Arizona and from near the Grand Canyon are in areas where predominate fracture trends are nearly orthogonal, hence the extreme enhancement over the Poisson expectation mode. The Zendan fault area in Iran is part of the Zagros crush zone where faults are predominately parallel to the axis of the collision zone and tend to intersect at shallower angles than the other two examples. Nevertheless, there is enhancement at the mode over the Poisson expectation value, however, it is about 10% less than in the orthogonal systems.) *d*, Side-frequency distributions for polygons formed by various lineament types on Europa.

studies bearing on lineament formation mechanisms[3,26], and more comprehensive statistical analysis of patterns are needed both to confirm observed pattern structure, and to be used as an alternative and quantitative classification tool. Ultimately the existence of lineament patterns must be accommodated within, and may provide insights for, models of the structure and evolution of both the interior and surface of Europa.

I thank Ken Collerson, Tony Finnerty, Mike Malin, Dennis Matson, Mark Parmentier, Larry Soderblom, and Gary Ransford for useful discussions. Europa's petrological thermal history

G. A. Ransford*, A. A. Finnerty* & K. D. Collerson†

* Space Sciences Division, Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91103
† Research School of Earth Sciences, Australian National University, Canberra, ACT 2600, Australia

The thermal evolution of Europa is described by a new path of geophysical development. Petrological considerations suggest that heat may have been transported within Europa by sub-solidus convection, and that a large fraction of Europa's water content is retained as hydrated silicates.

We have reconsidered the thermal evolution of Jupiter's second galilean satellite, Europa, from its accumulation from circum-jovian debris until the formation of surface features imaged by Voyager. By including the petrological sequence that probably accompanied Europa's thermal evolution, a path of geophysical development which differs from previous studies[1–3] is indicated. This path gives a present geophysical state that seems to be more in concert with the Voyager observations than earlier models. The petrological considerations imply that heat transport within Europa by sub-solidus convection might have been important throughout much of that satellite's history. We also suggest that a large fraction of the water of Europa is retained in the interior in the form of hydrated silicates.

Thermal history

All previous studies of Europa's thermal history have assumed that the satellite was a mixture of ice and silicates after assembly from the primordial circum-jovian nebula. In these models, Europa is heated by the decay of long-lived radioactive isotopes, and heat is internally redistributed by conduction. High temperatures are reached rapidly, resulting in a differentiation episode. Silicates are segregated into a core of some 1,450 km radius, with a liquid water mantle of 75–100 km thickness, and a 40-km thick ice crust at the surface[3,4]. Cassen *et al.*[5] have studied further evolution from this state within the ice crust and water mantle due to tidal heating effects, and they have concluded that, if once formed, there are conditions in which the water mantle can remain liquid indefinitely. Schubert *et al.*[6] have argued, however, that solid state convection in an ice crust is likely to remove heat from a liquid water mantle sufficiently quickly to cause freezing of the mantle. Cassen *et al.*[7] have improved the earlier calculations, and confirm that persistence of a liquid water mantle is very unlikely.

The total amount of water required to dilute the density of a lunar or Io type body ($\rho = 3.5$) to Europa's value ($\rho \approx 3.0$) is ~5 or 6 wt%, compared with 35 or more wt% for Ganymede and Callisto. Such a small percentage of water need not have started in Europa as ice, because there are many hydrated minerals that

415

Table 1 Weight composition and cation proportions of minerals on Europa

	Weight proportions			Cation proportions (4-oxygen basis)		
	(1)	(2)	(3)	(4)	(5)	(6)
SiO_2	33.1	35.94	35.40	0.947	1.018	1.000
MgO	23.5	25.52	25.65	0.997	1.071	1.083
FeO	35.5	38.54	38.95	0.848	0.911	0.917
Al_2O_3	2.4			0.080		
CaO	2.3			0.070		
Na_2O	1.1			0.061		
NiO	1.9			0.043		
Total	100.0	100.0	100.0	3.043	3.000	3.000

(1) Average composition (wt%) of principal components of Type 1 carbonaceous chondrites on a C-, S- and H_2O- free basis, from ref. 33.

(2) Chondritic composition of column (1), normalized to $SiO_2 + MgO + FeO = 100.0$.

(3) Calculated composition (wt%) of an intermediate olivine with 46 mol% Fe-end member.

(4) Cation proportions for the chondritic composition in column (1).

(5) Cation proportions for (1), normalized to $Si + Mg + Fe = 3$.

(6) Cation proportions for intermediate olivine in column (3).

could be stable in a relatively cool planet of chondritic composition (for example, brucite ~30 wt% H_2O, serpentine ~14 wt% H_2O, chlorite ~12–15 wt% H_2O, talc ~5 wt% H_2O, micas ~2–4 wt% H_2O, amphiboles ~2 wt% H_2O). We consider the possibility here that water was present in Europa as water of hydration from the start.

Water of hydration hypothesis

There are two reasons which indicate that Europa might have started its thermal evolution with most, if not all, of its water in the form of water of hydration. The first is a consideration of the likely pressure–temperature conditions in the Europa zone of the circum-jovian nebula during the condensation of the material that eventually becomes the satellite. Fanale *et al.*[3] reconstructed the circum-jovian nebula in an attempt to understand the simultaneous presence of ice on Ganymede and the 3.0 density of Europa, taking into account the possible earlier luminosity of Jupiter. Whether Io condensed from the circum-jovian cloud without H_2O, or H_2O was subsequently lost from Io, all reconstructions that give high temperatures for the condensation conditions at Io's orbit result in conditions of high humidity and moderate temperatures at Europa's distance. In such conditions, hydrous silicates may condense stably (reviewed in ref. 8).

Accretional heating during the formation of Europa could have dehydrated these condensation products as they accumulated, but most accretion scenarios lead to the opposite conclusion. Harris[9] has shown that the matter accumulated into the galilean satellites had to be predominantly circum-jovian in origin for them to have survived their accretion. Ransford *et al.*[10] discussed how Jupiter completely dominates the dynamics of its circum-jovian swarm of planetesimals, making the problem of accretion in circum-jovian orbit different from accretion in circum-solar orbit. The growing planets exert sizeable perturbations or objects within the circum-solar swarm, which 'pump up' random velocities, and make for relatively high velocity collisions between the forming planets and circum-solar planetesimals. In the circum-jovian accretion case, the forming satellites do not randomize velocities, because of the overwhelming close presence of Jupiter, and relative velocities between circum-jovian planetesimals and the forming satellites are characteristic of the difference in velocity between two objects in nearby orbits. These velocities are much smaller than those in the circum-solar accretion cases, and the attendant heating is expected to be much less. In addition, the accumulation of the small bodies in circum-jovian orbit is thought to have been a moderate time scale process of 10^5–10^6 yr or longer[9,11], which would not raise temperatures inside Europa to above the dehydration temperature for moderate to low temperature accreting material. Thus, the hydrous minerals formed at the condensation stage were probably not dehydrated by the accumulation process.

The second reason for considering water of hydration contrasts with the first. If the circum-jovian nebula considerations cited above are not true, (if Europa does form as a mixture of ice and silicates), subsequent thermal evolution will melt the ice, which will then hydrate the surrounding silicates, forming minerals such as serpentine, brucite and chlorite. These reactions would occur in the low-to-moderate temperature environment that is presumed for Europa's interior early in its thermal evolution provided the appropriate bulk composition is present within the satellite.

If a volatile-free chondritic bulk composition (+5 wt% H_2O) is assumed for Europa, the anhydrous components are equivalent in composition to 92 wt% olivine with 45 wt% (64 mol%) Mg-end member (forsterite) (Table 1). With the presence of 5 wt% H_2O, therefore, reactions in which olivine is hydrated to give serpentine + brucite or chlorite + brucite are most appropriate to Europa. The phase equilibria for two such reactions from Kitahara *et al.*[12] are reproduced in Fig. 1. A curve representing the stability of clinochlore, a chlorite of composition $Mg_5Al_2Si_3O_{10}(OH)_8$ using data from refs 13, 14, is also plotted in Fig. 1. The presence of Fe, and of phases other than clinochlore, probably lowers the dehydration temperature of the chlorite by perhaps up to 200 °C. A curve for the maximum stability of brucite[15] is also shown. For comparison, pressure at the centre of Europa is calculated to be ~31 kbar.

The role of Fe in the stability of serpentine and chlorite is not well known for this bulk composition. Serpentine in terrestrial occurrences generally contain <1.5 wt% Fe_2O_3 or FeO (ref. 16). Chlorite in terrestrial occurrences generally contains some Al, while $Fe^{2+}/Fe^{2+} + Mg$ covers the complete range 0–1. In the temperature range below 600 or 700 °C it is likely that either immiscible Mg-rich and Fe-rich serpentines, Mg-rich serpentine + Fe-rich chlorite, or an intermediate chlorite with no serpentine, will coexist with brucite throughout the pressure range within Europa. Alternatively, the Fe component may crystallize to magnetite or metal, depending on oxygen fugacity. Such high density materials could separate to form a core.

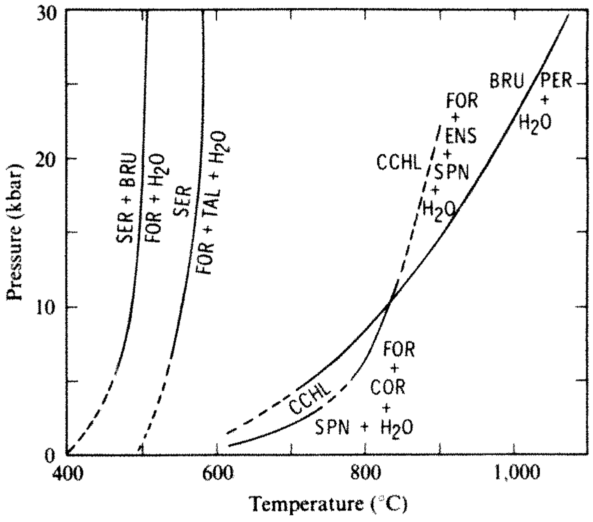

Fig. 1 Stability curves for hydrous minerals and assemblages. Data for forsterite (FOR), serpentine (SER) bulk compositions from ref. 17; clinochlore (CCHL) bulk composition at pressures above 3 kbar from ref. 13; CCHL below 3 kbar from ref. 14; brucite (BRU) composition from ref. 15. Curves are dashed where extrapolated. Other minerals talc (TAL), cordierite (COR), spinel (SPN), enstatite (ENS), periclase (PER).

The products of the hydration reactions represented in Fig. 1 contain 11.7–16.1 wt% H_2O, with 13.7 wt% for the 'chondritic' intermediate olivine composition of Table 1. Using the latter percentage as a likely value for chondritic composition, the entire 5 wt% H_2O in Europa would be consumed if reaction went 36.4% to completion. If water is evenly distributed within Europa, the interior would consist of about two-thirds olivine and one-third serpentine and/or (chlorite+brucite). Alternatively, all the water could be concentrated in an outer hydrated layer composed of serpentine and/or chlorite+brucite, having a thickness of ~270 km.

Discussion

While the water of Europa may once have been incorporated in the interior of the satellite as hydrous silicates, it is not obvious that the water currently exists in the interior after 4,500 Myr of thermal evolution. Using the Moon as an analogue, because its radius is nearly the same as that of Europa, current thermal models employing convective heat transport and materials properties thought to be appropriate for the Earth and the Moon[17–19] predict temperatures well above those at which hydrous minerals dehydrate over most of the interior (Fig. 2). The lithospheres in the models of Fig. 2 are ~300–400 km thick. In a convective Moon model with initial post-accretion temperature of 1,300 °C, Schubert *et al.*[20] calculate a lithospheric thickness of 550 km after 4,500 Myr. While Europa probably started at a much lower initial post-accretion temperature, a planetary object's thermal state after 4,500 Myr has been shown[17,20] to be more dependent on the rheology of the planetary interior than on initial temperature. The upper 200–300 km of the thermal boundary layers or lithospheres in the models cited above are at temperatures below the 500–700 °C dehydration temperatures. Therefore, the hypothesis that most of the water of Europa is incorporated in a relatively cool lithosphere composed of hydrous minerals, which is situated above a hot convecting interior of anhydrous silicates, is consistent with our current knowledge of planetary thermal evolution.

An alternative model may be considered. Tozer[21,22] has suggested that water of hydration affects silicate material properties by decreasing the resistance to creep, that is, by decreasing the effective viscosity. In his convection models for the Moon, the term for temperature dependence of assumed newtonian viscosity was scaled to the solidus temperature of hypothetical rocks Because water lowers the solidus temperature of basalt, the viscosity of the hydrous model Moon is lowered by a factor of ~20, and consequently convection can take place at temperatures below 500 °C. A thermal profile for a Moon composed of "water saturated basalt" from Tozer's work is incorporated in Fig 2. If such a model is applied to Europa, it is clear that hydrated silicates can remain stable throughout the interior, because the low-temperature convection transports heat at a rate sufficient to maintain the interior below the dehydration temperatures.

While "it is generally accepted that subsolidus creep is negligible at temperatures below about 800°C"[20], and therefore that hydrous minerals are unstable in regions that are convecting, this prediction is based on values of materials properties for anhydrous silicates. Hydrolytic weakening of silicate minerals has been convincingly demonstrated only for quartz[23], despite the work of Blacic[24] on olivine. The presence of water weakens the rocks under uniaxial compression, including the serpentinite[25] and chloritite[26] of special interest for our model. However, this weakening is probably a pore-pressure effect[27] and is likely to be ineffective at high pressures (>10 kbar) where pore volume is expected to be negligibly small Additional information on the rheology of 'wet' serpentinite and chloritite will be needed before the possibility of convection within hydrated mineral assemblages can be properly evaluated.

It is expected that some free water gains access to the surface during this evolution, but not in vast quantities. Most of the water present in Europa can be retained in the hydrated minerals in the interior. We predict, therefore, that the ice layer on the surface of Europa is much thinner than the 150 km that had been estimated before the Voyager mission. A thin ice crust on Europa has important implications for tidal coupling and surface morphology (such as cracking—see refs 28, 29 for more details).

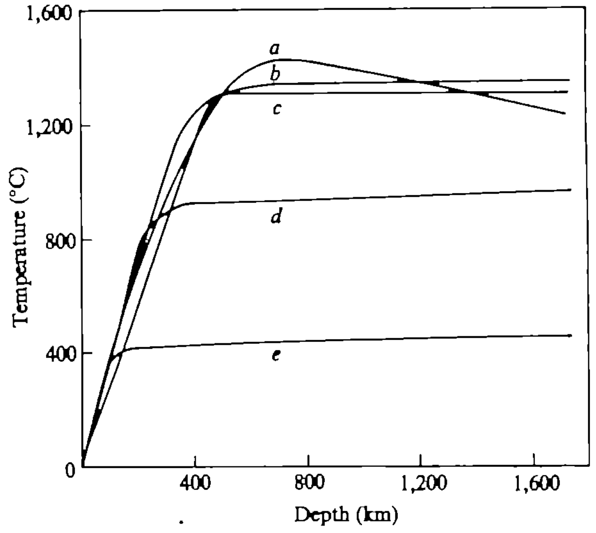

Fig. 2 Spherically averaged temperature–depth curves for the Moon Data for *a*, ref. 34, *b*, ref. 19; *c*, ref 18, *d*, ref 22 (anhydrous dunite model); *e*, ref. 22 (water-saturated basalt model).

The geophysical state that results from a convective evolution agrees with the basic observations about Europa. The synchronous rotation of the satellite would result soon after the subsolidus convection began because of the triaxiality that such patterns could induce in its body[31]. Tidal energy dissipation could involve the entire satellite, as opposed to the crust and core arrangement of the earlier estimates of the thermal history[5]. The completely solid Europa described here would remove a heuristic concern about the earlier Europa—what are the dynamics of a crust with almost no coupling to the core during a tidal interaction? Do they interact with Jupiter independently and librate with respect to each other?

The cracking patterns on Europa's surface suggest some sort of global deformation mechanism[28,32] and internal convective activity would certainly provide such deformation. This aspect will be discussed in more detail by Finnerty *et al.*[29]. The distortions of the silicate surface that are created by the areas of upwelling and subduction in the convective model can fracture the overlying thin layer of ice, generating crack patterns which can be tested against the observed patterns for various orders of convective activity.

Conclusions

We have argued that most of Europa's complement of water can be locked up in the form of hydrated silicates in a thick convective boundary layer or possibly even throughout most of the body of Europa. The water of hydration is in the minerals chlorite and/or serpentine, and brucite, and solid state convection probably keeps a sufficient volume of the planet at temperatures below the dehydration temperatures for these minerals to incorporate all the water needed to explain the density of Europa. With most of the water tied up in hydrated silicates, the ice layer at Europa's surface is probably quite thin, perhaps only a few kilometres.

Is Europa surface cracking due to thermal evolution?

We propose that some of the surface features of Europa may have originated by processes within a model planet in which hydrated silicates are stable.

THE images of Europa obtained from Voyager display remarkable curvilinear albedo features that range in scale from the limits of resolution to truly global. It has been proposed that most of these features (the lineae) are fractures, and that some (the flexi) are ridges[1–6]. We point out that some surface features of Europa may have originated by processes within a model planet in which hydrated silicates are stable, as proposed by Ransford *et al.*[7]. Because we deal with only a few types of the features that have been observed, additional processes, or perhaps entirely different processes than proposed here, may be operating. Because of the paucity of data bearing on remote planetary objects, however, our understanding of these processes can be advanced only by constructing successively more realistic models that can be tested against the limited observations.

In the Ransford *et al.*[7] model for Europa, a region of convecting anhydrous silicates is overlain by a lithosphere, the upper 200–300 km of which is composed of hydrous minerals. The ice crust need not be thick (not nearly the 75–150 km of ice and possibly water in pre-Voyager models) because all the H_2O needed to explain the lower density of Europa compared to Io can be contained within the hydrated silicates. To relate surface features of Europa to this model, we first examine the mechanical properties of hydrated silicates and ice.

Mechanical properties

The compressive strengths and ductilities of serpentinite, of partially serpentinized peridotite, and of chloritite have been measured at confining pressures up to 6.6 kbar at various temperatures [8,9]. Complex but consistent behaviour was observed. At temperatures below the dehydration temperatures (500–700 °C) serpentinites and chloritites are about as strong as granite, and brittle, becoming more ductile as confining pressure and temperature increase. As temperatures approach the dehydration temperatures, the hydrous rocks weaken slightly, but at the dehydration temperatures, strengths decline drastically to <500–1,000 bar and the specimens become much more brittle. This is apparently due to release of free water, because at temperatures below the dehydration temperatures, the introduction of free water causes similar weakening and embrittlement. This behaviour has been related to some types of faulting on Earth[8–10]. If free water is present in the lithosphere of Europa, therefore, fracturing should occur at quite low stress levels.

The mechanical behaviour of water ice is very similar to that of anhydrous silicates. At a small fraction of its melting temperature it deforms in a brittle fashion[11], while at a high fraction of melting temperature it deforms plastically by a creep mechanism (reviewed in ref. 12). The mechanical behaviours of thin and thick ice crusts on Europa should consequently differ. (We do not consider a liquid water mantle for Europa because new calculations[13] suggest that the previously proposed liquid zone[14] is very unlikely.)

Thickness of the ice crust

Using a near-surface (below diurnal influences) temperature for Europa of 93 K (ref. 15), and a thermal gradient of $3\ \mathrm{K\ km^{-1}}$ (from the conductive region of the thermal models discussed in ref. 7), a temperature of 60% of the melting temperature of ice will be reached at ~24 km depth. If such a relative temperature is taken as marking the brittle-to-ductile transition, then any ice existing below 24 km depth will deform by plastic rather than brittle mechanisms. While such deep ice will be capable of transmitting isotropic stresses and allow shallower brittle ice to fracture, any nonisotropic stress from below will be compensated by lateral flow within warm ice. The presence of a reticulate or polygonal fracture pattern in the anti-jovian region of Europa[6] on a scale larger than the 150 km maximum depth of an ice layer, but on a smaller than planetary scale, suggests that nonisotropic stresses have propagated through the ice crust and that the crust is consequently thinner than about 24 km, at least in the anti-jovian region. Smith *et al.*[1] have also suggested that the ice layer may be thin (<50 km) based on the implications of two terrain types and very low surface relief. Therefore, we will consider the ice crust to be thin and brittle, acting as a recorder of stresses imposed on the underlying hydrated silicate mantle.

0028-0836/81/020024—07$01.00

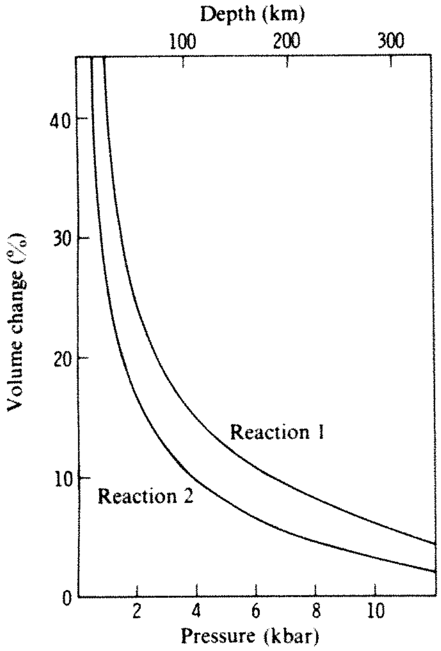

Fig. 1 Relative volume changes as a function of depth for dehydration reactions involving serpentine.

Models for two sets of surface features on Europa have been developed: (1) the long, relatively dark lineaments that lie on great and small circles, and frequently possess bright medial stripes (principally the Types 1 and 3 lineaments of ref. 6); (2) the complex reticulate network of fractures in the anti-jovian region, surrounded by the series of cuspate ridges defining a small circle about 60° outside the anti-jovian point (Types 5 and 6 lineaments of ref. 6).

Global scale lineaments

The great lengths (>1,000 km in many cases) and distribution (for example, Asterius Linea defines a nearly complete great circle) require a global scale mechanism for formation of Types 1 and 3 lineaments. A possible mechanism is planetary expansion. Volume changes due to thermal expansivity can be positive or negative depending on the thermal history (see ref. 16). Dehydration of hydrated silicates at relatively low pressures, however, results in large positive volume changes, and may be responsible for formation of Types 1 and 3 lineaments.

Dehydration may be represented by reactions such as:

$$\underset{\text{serpentine}}{Mg_3Si_2O_5(OH)_4} + \underset{\text{brucite}}{Mg(OH)_2} \rightleftharpoons \underset{\text{forsterite}}{2Mg_2SiO_4} + \underset{\text{fluid}}{3H_2O} \qquad (1)$$

and

$$\underset{\text{serpentine}}{5Mg_3Si_2O_5(OH)_4} \rightleftharpoons \underset{\text{forsterite}}{6Mg_2SiO_4} + \underset{\text{talc}}{Mg_3Si_4O_{10}(OH)_2} + \underset{\text{fluid}}{9H_2O} \qquad (2)$$

Other reactions involving iron-bearing components and/or chlorite lead to similar conclusions. Considering a closed system in which the total H_2O cannot vary, the change in volume for reactions (1) and (2) may be calculated from the data summarized in Table 1. The molar volumes of the minerals do not change dramatically with temperature and pressure, and in any case these changes approximately cancel in calculating the change in volume, so their room temperature, one atmosphere volumes are used. For H_2O, however, the molar volume does change drastically with temperature and pressure. The dehydration temperature of serpentine is ~500 °C, and is nearly independent of pressure. Therefore, volume changes for reactions (1) and (2) are calculated as a function of pressure at 500 °C and plotted in Fig. 1. A depth scale for Europa is also illustrated. Molar volume data for H_2O at pressures >10 kbar are not available, but the volume probably does not decrease below 14.4 $cm^3\,mol^{-1}$ at 30 kbar and 500 °C. This corresponds to volume changes at the centre of Europa that are close to zero.

If Europa accreted at low temperatures[7], hydrated minerals would initially be distributed throughout the satellite. The temperature at a given depth would increase with time due to decay of radioactive isotopes. Assuming an adiabatic or superadiabatic temperature gradient, the hottest location is at the centre of the planet, regardless of whether solid state convection commences. At some time the temperature at the centre of the planet would rise above 500–700 °C, and dehydration would commence. A dehydration front would coincide with the upward evolution of the 500–700 °C isotherm. If H_2O did not escape upwards, the assemblage of anhydrous minerals + vapour would expand relative to the original hydrated assemblage.

If H_2O can percolate upwards, it will react with anhydrous minerals in the layer above the 500–700 °C isotherm to increase the hydrous mineral content from about 40% to as high as 100%. Any excess H_2O will migrate still higher and hydrate additional layers. In this case, the dehydrated region decreases in volume while the layer of increased hydration expands. Because ΔV is greater with shallower depth, however, the net volume change is positive.

This expansion creates stress in the overlying hydrated silicates, and at the same time the dehydration process provides the free water that completes the hydration of these rocks. Eventually, the water is concentrated in a completely hydrated layer extending from the surface to ~270 km depth[7]. Additional water percolating from below can no longer be bound in hydrated minerals, and thus weakens and embrittles these rocks even though they are below their dehydration temperatures. The hydrated silicate shell may be modelled as a spherical pressure vessel, in which tangential and radial stresses due to dehydration are at maximum at the inner surface and minimum at the outer surface. For a fracture to propagate to the surface, the crack probably needs to be filled with water, provided by the dehydration, as it grows. As Anderson and Grew[17] noted, water is particularly effective at promoting crack growth in silicates by stress corrosion.

The presence of bright medial stripes within lower albedo lineaments hundreds of kilometres long and tens of kilometres wide must be explained by any hypothesis of the origin of these features. Malin[2] noted that the bright 'cores' are in places hundreds of metres above the surrounding terrain. Also, we note that whereas the white medial stripe is usually very uniform in width within a particular lineament, the darker portion is

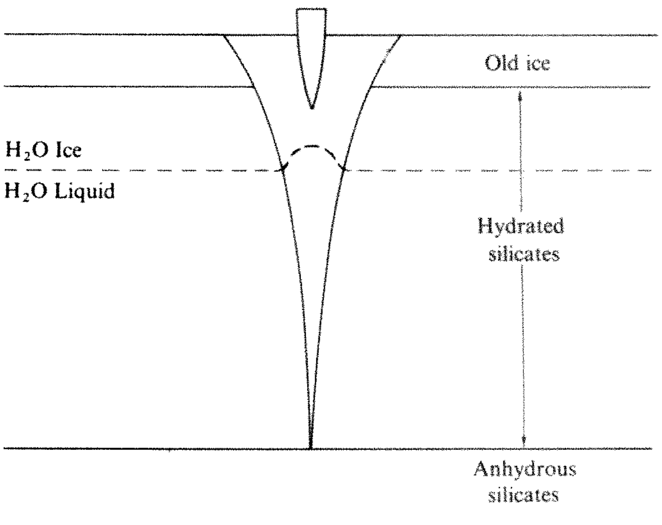

Fig. 2 A representation in cross-section of the formation of planetary scale dark lineaments with bright medial stripes. The shaded region is xenolith-rich H_2O 'magma'. The dashed line represents the freezing temperature of ice. The wedge at the top is new ice extruded upwards as the freezing isotherm migrates downward during thermal re-equilibrium of the magmatic column.

Table 1 Molar volumes of components ($cm^3\ mol^{-1}$)*

Serpentine	$Mg_3Si_2O_5(OH)_4$	108.5
Brucite	$Mg(OH)_2$	24.63
Forsterite	Mg_2SiO_4	43.786
Talc	$Mg_3Si_4O_{10}(OH)_2$	136.25
Vapour	H_2O	18.169†

* Mineral data from Robie *et al.*[26].

† Data from Burnham *et al.*[27] for H_2O vapour at 500 °C, 10 kbar.

quite variable and, where it widens on one side of the medial stripe, there is frequently a corresponding widening on the opposite side.

We suggest the following explanation (Fig. 2), analogous perhaps to CO_2-driven kimberlite eruptions on Earth. When a crack is initiated at the base of the lithosphere, its propagation upwards is aided by stress corrosion as water from the dehydrating region fills the crack. Because this aqueous fluid is highly corrosive to Si–O–Si bonds and of low viscosity, the crack tip can propagate rapidly[17]. Relatively high fluid velocities may be attained, in which case xenoliths can be broken from the sides of the crack and incorporated into the ascending fluid. As the surface is approached, velocity of the fluid will diminish due to loading in the 'magmatic' column and loss of heat to the walls of the conduit. A breccia of frozen water and xenolithic silicates and ice, of lower albedo than the surrounding icy crust, will fill the upper reaches of the conduit, while in the lower portion H_2O will remain liquid and xenoliths can settle out. As the crack propagates laterally, presumably following a great circle, eruptions of this brecciated material with varying vigour will cause variations in the surface width of the low albedo material. At the conclusion of this process, the isotherm coincident with the water-ice transformation will be bowed upwards within the 'breccia pipe'. As this isotherm evolves downwards within the fracture towards thermal equilibrium, additional water will freeze, causing expansion and a new stress. Because the depth of ice breccia in the crack will be least at the centre of the crack, a second stage fracture will form within the ice breccia and in the middle of the initial crack. New ice will extrude along the new fracture, rising above the surrounding terrain due to the liquid-ice volume change. Inasmuch as the new ice is essentially xenolith-free, it will have higher albedo than the ice breccia on either side.

Features about the anti-jovian region

A concentration of fractures interpreted as tensile features, in polygonal or reticulate patterns has been noted[4,6,18] over a region near the anti-jovian point on Europa. This interpretation, based on an analysis of the frequency distribution of polygon sides, has been justified by Pieri[6]. The polygonal pattern is formed by the intersections of Types 1 and 2 lineaments and is subdivided to the limits of resolution by the Type 5 lineaments of Pieri. For this modelling exercise, we also assume that these are fractures formed in a tensional environment.

Because of their geometrical relationship to the tensional fractures in the anti-jovian region, we consider the flexi, or Type 6 lineaments of Pieri in any model of processes occurring in this locality. These cuspate ridges appear to surround the tensile fractures in a ring about 60° out from the anti-jovian point, and have up to several hundred metres of relief. Their maximum extent is not known because of incomplete high-resolution coverage and unfavourable lighting angles. There is no recognized evidence of erosional or magmatic processes on Europa to form these ridges. If they are of tectonic origin, they probably formed within a region of compressional stress. Strom *et al.*[19] described lobate scarps and ridges up to 500 km long and 3 km high on Mercury, uniformly distributed over the hemisphere imaged by Mariner 10, and attributed their formation to crustal compression during thermal contraction of Mercury. While the distribution of Europan cuspate ridges differs from that on Mercury, and we do not yet know the profiles of the ridges, we feel that the interpretation as compressional tectonic features is most likely. In the absence of data to the contrary, we assume that the compressional features formed contemporaneously with the tensional features discussed above.

We are faced, then, with a broad region of extension centred near the anti-jovian point, surrounded by a region of compression. Based on the radial distribution of tensional features, doming, and concentration of volcanism in the Tharsis area of Mars, Carr[20] suggested that a region of upwelling within a convecting mantle was centred under Tharsis. Solomon and Chaiken[16] rejected this interpretation because no regions of compression corresponding to zones of return flow are apparent on Mars. Although this model may not work for Mars, for Europa, we suggest that a region of upwelling in the convecting anhydrous silicate interior, surrounded by a region of return flow, may have been located beneath the hydrated silicate mantle at roughly the anti-jovian point during the formation of the tensile and compressional features. The lineaments formed above the convection cell by brittle deformation within the hydrated silicate lithosphere.

We still need to explain the location of the convective upwelling at the anti-jovian region. This is probably not accidental, because the redistribution of hot, low density and cold, high density material by convective processes alters the moments of inertia of the satellite, and can thus influence the orientation of the satellite when it achieves orbital period–spin rate lockup with the primary.

In combination with the mass distribution associated with equatorial bulging due to rotation, a second-order convection pattern would cause the triaxiality needed for the tidal locking of the rotation period of Europa. This process has been discussed extensively in connection with heat transfer and nonhydrostatic shape of the Earth's Moon (see refs 21–23), and results in diametrically opposed zones of upwelling becoming aligned with the radial to the primary. In the case of the Moon, the maximum shear stress imposed by the nonhydrostatic figure is probably insufficient to fracture the lithosphere[24], and a dynamic process such as convection is not required. For Europa, the 'wet' hydrated silicate lithosphere should be far weaker than the probably anhydrous lithosphere of the Moon, and consequently a dynamic process such as convection should be revealed by failure of the lithosphere.

A second-order convection pattern requires a small core, as might have been provided in Europa by separation of iron or magnetite on deserpentinization[7]. Such a pattern is shown in Fig. 3. The distribution of extensional and compressional fea-

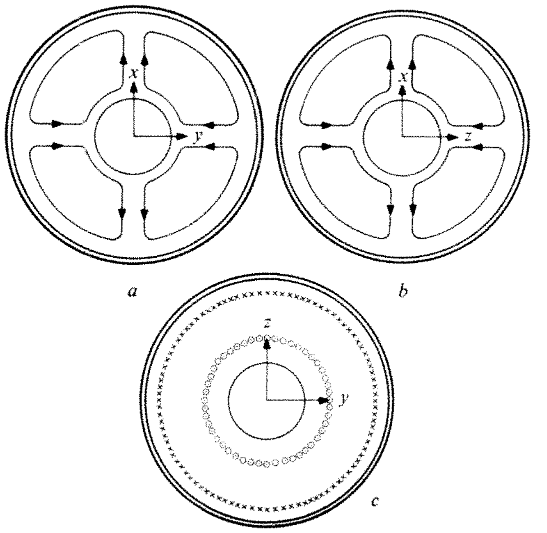

Fig. 3 Idealized second-order convection patterns in three mutually orthogonal projections. Axis of rotation is the z-axis, direction towards Jupiter is along the x-axis, and the y-axis points in the instantaneous direction of motion of Europa in its orbit around Jupiter. ○, Upwelling; ×, downflow.

tures in the anti-jovian region of Europa is remarkably similar to the locations of zones of upwelling and return flow in Fig. 3*c*. However, the effects of other processes may be superimposed on the surface of Europa, and convection within a planetary interior is probably more complicated than second order. Nonetheless, a major second-order component may be present.

Discussion

A spherical pressure vessel model for Europa predicts no preferred orientation for the planetary-scale fractures. Helfenstein and Parmentier[18] have noted, however, a tendency for these lineaments to intersect with an angle of 60–70°. They use the elastic shell theory developed by Melosh[25] to show that the patterns of these lineaments and the location of a region of tension in the anti-jovian region are consistent with relaxation of a triaxial figure composed of two biaxial distortions: an equatorial bulge and a bulge along the radial to Jupiter. They propose a mechanism in which the equatorial bulge relaxes as Europa despins due to tidal interactions, and the anti-jovian bulge relaxes as the orbit of Europa recedes from Jupiter. We are not convinced that such a preferred orientation of global scale fractures exists on Europa because of limited photographic coverage, uncertainty about which fractures were studied by Helfenstein and Parmentier, and the probability that fractures formed by several different processes may have been included in their analysis. There are also two difficulties with their model: the magnitude of stresses imposed by relaxation of the figure of Europa (tens of bars) probably does not exceed the strength of the lithosphere (Banerdt, personal communication); and the tidal bulge cannot have been located in the anti-jovian region until after Europa had despun into a tidally-locked configuration. If preferred orientations of global scale fractures are documented, we suggest that global expansion due to dehydration of the interior provided stresses great enough to fracture the lithosphere, and that superimposed stresses due to tidal despinning may have influenced the orientation of these fractures. The triaxial contribution to the fracture patterns may have been provided by dynamic loading of the lithosphere by convection in the interior.

We re-emphasize the hypothetical nature of our arguments. We hope that these speculations will stimulate new observations and will lead to new models that will improve or supersede the model proposed here.

Sex ratio evolution in a variable environment

We develop a natural selection model for sex ratio control in a spatially variable environment. Predictions of sex ratio alteration as a function of environmental change are tested in laboratory experiments with two parasitic wasps. Field data from a variety of other organisms also support the model. Finally, we discuss possibilities and difficulties for testing this type of evolutionary model.

SEX allocation theory deals with the impact of natural selection on the allocation of resources to male compared with female reproductive function[1]. For dioecious species the problem of interest is the evolution of the sex ratio; for a simultaneously hermaphroditic species, it is the allocation to sperm versus eggs in each breeding season[2–5]; for a sequential or sex-reversing hermaphrodite, the questions are the sex order (male or female first?) and the proportion of an individual's lifetime devoted to each sex[6–12]. The theory also gives the conditions for a sexual state to be evolutionarily stable. For example, it specifies when some form of hermaphroditism is favoured over dioecy[1–16].

It was previously[1] shown that many sex allocation problems have the property that the equilibrium or ESS[17] condition satisfies a particular optimality principle. The allocation to male versus female function, which is favoured by natural selection, can often be shown to maximize the fitness gains through male function multiplied by the gains through female function[1]. From this product formalism, one can derive the classic results of sex ratio theory. Examples are the 'equal resource into each sex' theorem of Fisher[18], the 'local mate competition' results of Hamilton[19] and several results from the Trivers–Hare theory for eusocial Hymenoptera[20,21]. Here, we shall apply the formalism to sex ratio evolution in a variable environment and will provide a set of laboratory tests for the resulting predictions. As the organisms which stimulated our modelling efforts were parasitic wasps, we shall develop the model with reference to their life histories.

Parasitic wasps in a variable environment

Imagine an outcrossing parasitic wasp which has discrete generations and where the females attack hosts over a wide range of sizes[22–34]. A single egg is laid on each host. The host is paralysed or killed by a sting from the female wasp, so that the total food for her offspring's development is contained in the host at the moment of attack. If the host is small, the wasp larva will have relatively little food and will emerge as a small adult. If

0028-0836/81/020027—07$01.00

the host is large, the resulting wasp will be large. Suppose further that the reproductive consequences of being a large compared with a small adult wasp differ, depending on whether the individual is a male or a female. For example, over her lifetime, a large female may lay 10 times as many eggs as a small female; however, a large male may be only three times as effective as a small male at inseminating females. As the female wasps lay eggs in a variety of host sizes, the environment is thus variable with respect to opportunities for production of sons versus daughters. The mother is assumed to control her sex ratio (proportion male eggs) as a function of host size. Haplodiploid sex determination provides her with a physiological mechanism for this control. Our interest is in predicting what sex ratio she will produce in a given host size. To do this, we first specify the host size distribution and the expected reproductive success for an adult wasp of a given sex and size.

Let $f(x)$ be the probability density function for hosts of size x which are attacked by the female. For simplicity, assume x to be continuous. Let $W_1(x)$ be the relative fitness of a son derived from a host of size x. A male's fitness is measured relative to other males[1], so that $W_1(x)$ scales the ability of a male of size x to inseminate females over his lifetime. Let $W_2(x)$ be the lifetime egg production of a female derived from a host of size x. Both these fitness measures include survivorship to adulthood, which may vary with host size[22]. Finally, let $r(x)$ be the proportion of unfertilized or male eggs laid in host size x. $r(x)$ is controlled by the mother wasp. Using techniques from population genetics, one can show that the equilibrium or ESS[17] $r(x)$ satisfies the following product relationship[1]. It is the function, $r(x)$, which maximizes the product of the fitness gained through the decisions to produce sons and that gained through the decisions to produce daughters, or:
Maximize

$$\left[\int_x f(x)W_1(x)r(x)\,\mathrm{d}x\right]\times\left[\int_x f(x)W_2(x)(1-r(x))\,\mathrm{d}x\right]0\leq r(x)\leq 1 \qquad (1)$$

If we impose the condition that a large daughter gains more in relative fitness than a large son [$W_2(x)/W_1(x)$ increases with x], the solution to equation (1) reduces to a very simple form[1,35]. Only sons should be produced in small hosts and only daughters in large ones. There is a certain host size (τ) where the switch from sons to daughters occurs (Fig. 1*a*). Equation (1) now takes the form:
Maximize

$$\left[\int_0^{\tau} f(x)W_1(x)\,\mathrm{d}x\right]\times\left[\int_{\tau}^{\infty} f(x)W_2(x)\,\mathrm{d}x\right] \qquad (2)$$

Although the model predicts a threshold (τ) for the sex ratio change, it is unlikely that biological data would show such an abrupt transition. A more likely pattern would be that of all sons in small hosts and daughters in large, with a gradual sex ratio transition in between (illustrated in Fig. 1*a*)[1,35]. We expect a gradual transition for two reasons. First, the model assumes time constant fitness and host distribution values. If these vary through time, then so does τ. The quality of a host may also depend somewhat on factors which cannot be known to the mother when she deposits an egg. Selection would then favour a more gradual shift in sex ratio. However, a second reason is that even if the mother wasp made perfect decisions, the experimenter may not be able to classify the hosts perfectly with respect to criteria used by the wasps. For example, differentiation of equation (2) with respect to τ shows that the hosts are theoretically to be classified by the ratio $W_2(x)/W_1(x)$. Those with low ratios are son hosts, those with large are daughter hosts. Let k be the threshold ratio. Now, suppose that the wasp makes perfect decisions, with all hosts above k being given to daughters. If the experimenter, however, uses a measure of host size ($\hat{x}$) which is imperfectly correlated with the $W_2(x)/W_1(x)$ ratio, we will not see the threshold. The experiment would show a gradual shift in sex ratio as a function of $\hat{x}$, our measure of host quality.

In addition to the sex ratio shift with host size, the model makes one other general type of prediction. The concepts of large and small host as discussed above have no absolute meaning. That is, a host is only large or small relative to the other hosts being attacked. To calculate theoretically whether a host is to be a son or daughter host, we must first know the host size distribution which is being attacked. We expect to find an increasing fraction of daughters in larger hosts; however, what constitutes larger may vary from place to place, or time to time. Consider the host marked z on Fig. 1*b*. If the distribution of host sizes is i, z is a large host. If the distribution is ii, z is a relatively small host. Host z should contain a greater proportion of daughters when large (case i) than when small (case ii).

Two other factors implicit in the model deserve further comment. First, the sex ratio under discussion is the ratio at the egg stage. Data often show that survivorship declines in small hosts[22]. If this decline is different for the two sexes, the differential mortality as a function of host size would itself generate a sex ratio shift among emerging wasps, independently of a true sex ratio shift at the egg stage. However, such differential mortality would also contribute to natural selection favouring a shift by the mother wasp. Some evidence indicates that daughters may sometimes be unable to reach pupation size in very small hosts (a pupal parasite of Lepidoptera[34]), but even here a strong sex ratio shift at the egg stage with host size could be demonstrated. The relativity prediction discussed previously is a good control for

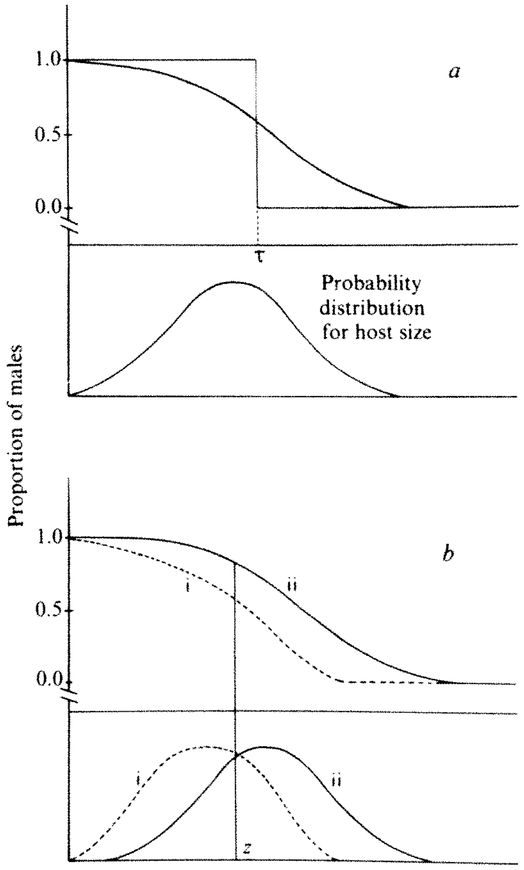

Fig. 1 Sex ratio as a function of host size. *a*, Provided females gain more fitness by being larger than do males (that is, $W_2(x)/W_1(x)$ increases with x), the sex ratio is predicted (equation (2)) to be female biased in large hosts, male biased in small. There is a threshold host size (τ) where a change-over occurs. For reasons discussed in the text, the expected pattern is not a threshold, but more gradual sex ratio shift. *b*, Whether a given host is to be a son host or a daughter host depends on the entire host size distribution. Host z is a relatively large host if the host distribution is i; it is a small host if the distribution is ii. It should contain more males when it is small. Host size distributions are simply illustrative.

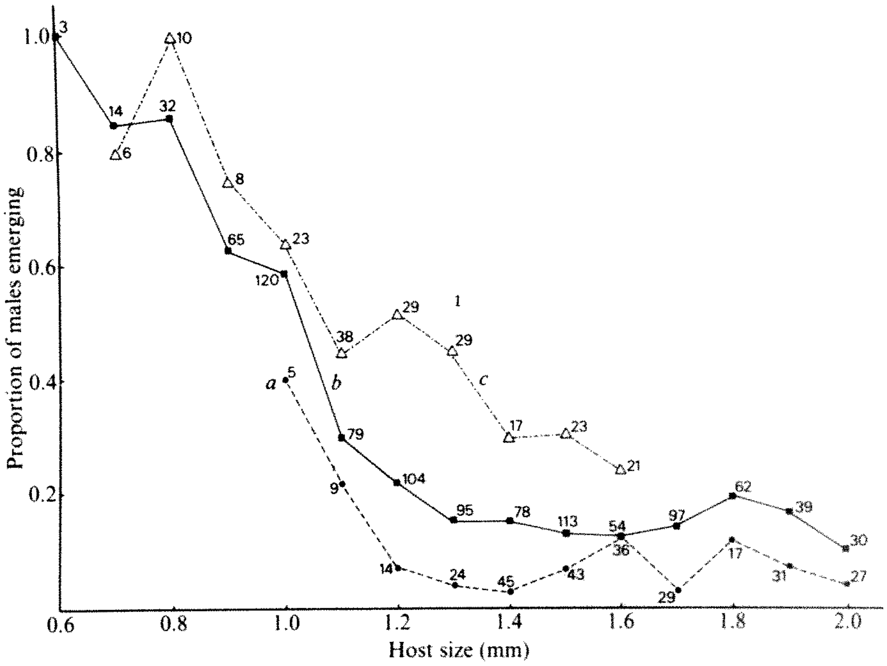

Fig. 2 Sex ratio in *Lariophagus*. The proportion of males emerging is plotted against the size of the hosts (weevil larvae) (tunnel width) which were offered in a 'carousel experiment'. Curve *b* results when female wasps are presented sequentially with 20 hosts of a single size. Curves *a* and *c* result when wasps are presented with an alternating sequence of two host sizes, where the hosts are 0.4 mm different is size. Curve *c* is where the host of interest was the smaller of the two. For example, hosts of 1.4 mm were offered alone and gave a sex ratio of 15% males (curve *b*). When they were offered alternately with 1.8-mm hosts, they gave a sex ratio of 30% males (curve *c*). When offered with 1.0-mm hosts, their sex ratio dropped to 2% males (curve *a*). The number of emerging wasps is given for each data point. The experimental technique is as follows: the weevil *Sitophilus* is cultured on wheat grains at 25 °C. Twice a week freshly emerged weevils are placed on fresh (unfrozen) grain for oviposition and removed again 7 days later. Grains with the necessary age range of larvae can then be irradiated with X rays to measure the exact size of the larvae by measuring tunnel diameter[37]. The grains are then stored at 10 °C for up to 14 days. At 10 °C the larvae do not grow and only a small percentage die. Grains with larvae of a desired size are picked out and used in carousel experiments. The oviposition carousel (described in ref. 30) makes it possible to offer individual female wasps grains with known contents for a specified period of time in a specified order. Inseminated females are isolated from cultures on the day of their emergence and stored for 24 h at 18–20 °C. They are used in a carousel experiment, with a series of 20 grains. Each grain is offered to a female for 2.5 h, then labelled and stored at 25 °C until a weevil or a wasp emerges. If there is no emergence, the grain is opened to see what happened to the weevil larvae. The head width was measured for all wasps.

this effect, as the shift is predicted within a single host size. The model also predicts that the overall sex ratio should be biased towards males. However, this is again sex ratio at the egg stage. If survivorship declines with host size, then at emergence the overall sex ratio may be female biased (because males are put in small hosts).

The second factor is the assumption that the species is outbred. Hamilton[19,36] has developed a theory for certain forms of inbreeding, or nonrandom competition among males for mates, which predicts a generally female-biased sex ratio. In the most extreme cases, all females in a brood are inseminated by their brothers. Here, theory predicts (and data strongly support) that a mother wasp should produce mostly daughters. This 'local mate competition' (LMC) is thus a factor which may alter the overall sex ratio in the direction of females. Although we cannot eliminate it as a factor in our wasp systems, it seems unlikely as a general explanation for a host shift in sex ratio. Long-term (~20 yr or 200 generations) laboratory cultures of one species studied here[22] consist of hundreds of wasps mixed together. There is much mixing of the offspring of individual females. Such conditions are quite the opposite of those postulated by Hamilton and would select against LMC effects. In this same species (*Lariophagus*), other experiments presented the wasps with groups of hosts and sometimes put two or more female wasps together with a batch of hosts. The present experiments presented a single female with one host at a time and they gave essentially the same results as the former. With a strong LMC model, the wasps would be predicted to behave differently in the two conditions. For these reasons, we have derived the predictions from a model with outbreeding (Fig. 1).

On testing the model

A general test of the model would consist of showing that sex ratio varied as a function of host size, and that the daughter/son fitness comparison also changed with host size. Both would have to change in the predicted directions. We would also have to show that differential mortality or LMC could not account for the results. The predicted relative nature of the sex ratio shift itself provides a powerful, qualitative test of the hypothesis. There are at least three ways in which we might test this prediction.

(1) Geographical variation. If in different places the wasp species is associated with different host size distributions, this natural variation can be turned into a test. For instance, if the same host is present in both locations, but is a small host in one place and is large in the other, a sex ratio shift is expected in that host.

(2) Laboratory selection experiments. It should be possible to mimic the effects of geographical variation in the laboratory. If the parasitoids can be reared on only small hosts, or only large hosts, sex ratio shifts through time (over several generations) are expected, if the sex ratio is a heritable character. The small hosts should shift from producing mostly males towards a more equal sex ratio. The large hosts should shift from mostly females towards a more equal ratio.

(3) Temporal variation. If the wasps naturally confront host size distributions which change from generation to generation, they might have the ability to alter their sex ratio on a short time scale, in response to the prevailing distribution. The most reasonable source for a shift in host size utilization would be a shift in host abundance. Because small hosts are poorer for offspring, a mother might be expected to ignore them when confronted with an abundance of larger hosts. This behavioural shift would require the wasps to pick up, store and use information about the distribution. However, if the natural host size distribution was either constant through time, or continued to change within a wasp generation, we might expect the wasps not to respond to short-term shifts in the distribution. We would then require geographical variation or a laboratory selection experiment to test the relativity idea.

We report here the results of a series of experiments on this host size model. Our experiments relate to the abilities of two parasitoid species to alter their sex ratio decisions on a short time scale. We tested the basic model by looking at sex ratio as a function of host size. We then confronted wasps with altered

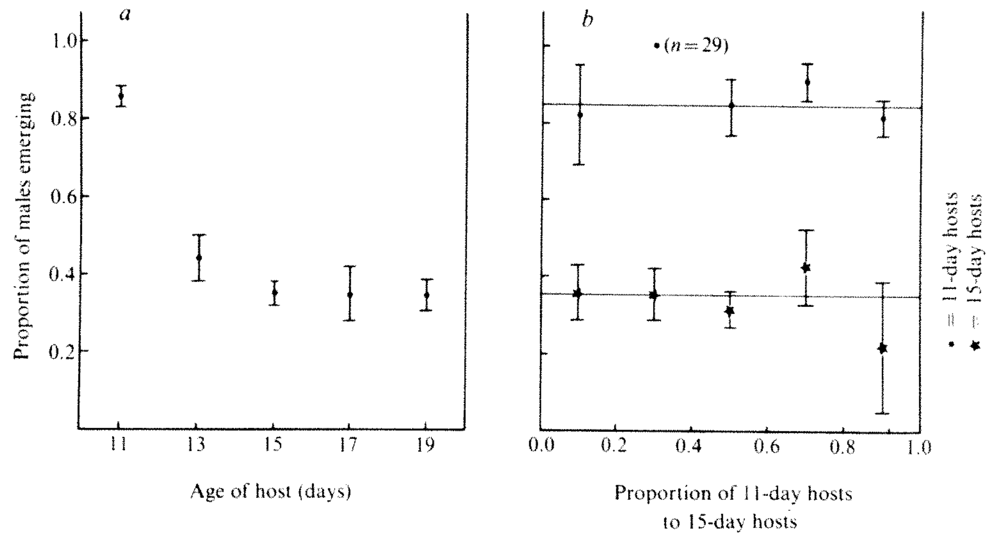

Fig. 3 Sex ratio as a function of host age for *Heterospilis* attacking *Callosobruchus*. *a*, Wasps presented with a single-aged host for a period of 24 h (30°C and 70% relative humidity, host density at ~20 hosts per female wasp). Data given are means ±2 s.e. *b*, Wasps were in an environment consisting of 11- and 15-day hosts presented simultaneously. In the five experiments, the proportion of 11-day hosts varied from 0.1 to 0.9. Data are the mean sex ratios within each host age (±2 s.e.). The lines in *b* refer to the proportion of males found in *a*.

host size distributions and measured the sex ratio shift. Our data indicate that large wasps come from large hosts and that both males and females gain increased reproductive success by being large.

Sex ratio in *Lariophagus* and *Heterospilis*

Lariophagus distinguendus is a small (1–3 mm) parasitic wasp (family Pteromalidae) which attacks larvae of the common granary weevil, *Sitophilus granarius*[22,29,30]. The weevils oviposit in grains of wheat, and a single larva develops inside the grain. The parasite stings the larva and deposits a single egg. An adult wasp emerges about 18 days later (at 25 °C). The wasp will parasitize a variety of host sizes[22]. The larva hollows out the grain as it develops. Size of weevil larvae is correlated with age, but the relationship is imprecise. For the present experiments we measured host size directly. The size of the weevil larva is strongly correlated with the diameter of its tunnel[37]. Tunnel diameter was measured on X-ray photographs[22,37].

Heterospilis prosopoidis is a small (1–3 mm) parasitic wasp in the family Braconidae. It has a similar life history to that of *Lariophagus* in that it lays a single egg on the larvae of weevils, attacking a variety of host sizes. It was studied here attacking the azuki bean weevil, *Callosobruchus chinensis*. At 30 °C, weevil development (egg to adult) takes about 21 days. Weevil larvae 11–19 days old are accepted by the wasp. Experiments with this system used weevil age as a measure of host size.

Van den Assem[22] had previously shown, using weevil age as a measure of size, that *Lariophagus* adjusts its sex ratio as a function of weevil size. Mostly males were produced in young weevils, mostly females in older weevils. His experiments were carried out by presenting wasps with weevils of only one age class. The experiments were also controlled to show that the observed sex ratio shift could not be due to differential, sex-specific mortality (even though young weevils produced a much higher death rate). The data also suggested that the wasp used a relative measure of host size.

We have repeated these earlier[22] experiments, using the more exact measure for host size. Figure 2*b* shows the results. As expected, sons are produced in small hosts, daughters in large. A second experiment consisted of presenting wasps with two host sizes, offered in equal abundance. The hosts were always 0.4 mm different in size and the wasp was presented with an alternating sequence (large, small, . . .). The data from these two experiments thus consist of a given host size in three situations: alone, smaller of two sizes and larger of two sizes. For example, we have 1.4-mm hosts alone, and paired with 1.0- or with 1.8-mm hosts. If we consider some host size *z*, it is clear that the three experiments (*z* small, *z* alone, *z* large) represent successively more left-shifted host size distribution curves. This corresponds to a shift from distribution ii to distribution i in Fig. 1*b*. If the wasp is adapted to alter its sex ratio on a short time scale, it should put relatively more daughters into host *z* as we move across the three treatments.

Curve *a* in Fig. 2 represents the sex ratio as a function of host size, when the host represented was the larger of the two hosts (for example, 1.0 was paired with 0.6). Note that every point lies below (is more female biased) the curve for the hosts when they were by themselves. Curve *c* (Fig. 2) shows the corresponding relationship for hosts where they were the smaller of the two hosts (for example, 1.0 was paired with 1.4). With a single exception, 0.7 mm, this curve lies above (more male biased) the other two curves. We have not provided statistical tests for the individual host sizes because the hypothesis relates to the general order of the curves. It is indeed remarkable that, even given small (10–30) to moderate (50–100) sample sizes, the curves preserve their theoretically predicted order, over the entire range of host sizes. This is the strongest evidence for the shift predicted by sex ratio theory.

Using host age as a measure of size, one of us (W.J.T.) carried out a similar set of experiments with *Heterospilis*. Presenting wasps with a single host size produced the relationship in Fig. 3*a*. Small hosts (11 days) were very male biased, whereas larger hosts were more female biased. A series of control experiments showed that this result could not be due to differential, sex-specific mortality. To see if these wasps could also adjust the sex ratio to a shifting host environment, we carried out a second set of experiments with just two host ages (11 and 15 days, or 15 and 19 days), presented in equal numbers. In comparison with the experiments in which the wasp received only one host size, the 11- and 15-day hosts now showed no altered sex ratio. Indeed, the 15-day hosts showed the same sex ratio when alone, or when combined with either 11- or 19-day hosts. Moderate to large sample size (88–1,024 emerging wasps per host size) makes these results quite reliable. Only one predicted sex ratio shift was seen. When 19-day hosts were presented alone, they gave a proportion of males of 0.36 ($n = 786$). However, when they were presented with equal numbers of 15-day hosts, the sex ratio dropped to 0.25 ($n = 88$). Such a shift is statistically significant (one-sided, Fisher exact test; $P = 0.03$) in the predicted direction.

We carried out a further set of experiments with *Heterospilis*. These involved 11- and 15-day hosts, presented to the wasp in various proportions (proportions of 11-day hosts 0.1, 0.3, 0.5, 0.7, 0.9). As can be seen in Fig. 3*b*, the wasp failed in 8 out of 10 cases to show any deviation (significant at the 0.05 level) from the sex ratio predicted from the experiments with only one host size. Clearly, there is no pattern of sex ratio shift with changing host proportions (at least for 11- and 15-day hosts). Although

Heterospilis does not immediately adjust its sex ratio to host size distributions, it is still possible that its offspring sex ratios are attuned to host distributions in a way predicted by the model. It may be that the host size distributions naturally encountered by *Heterospilis* do not vary greatly between wasp generations or that they vary within generations, and thus these wasps would not be expected to respond to short-term shifts in the distribution. At least for this species, a selection experiment or geographic comparison seems to be necessary to test the model further.

At least two other parasitic wasps which show a sex ratio shift with host size also show short-term adjustment of the sex ratio[23,24]. Both species overproduce daughters in large hosts, sons in small. Chewyreuv[23] studied parasitoid wasps of the genus *Pimpla* (family Ichneumonidae) which attack lepidopteran pupae. When he offered a female wasp a mixture of host pupae consisting of *Sphinx* (large) and *Piéris* (small), the wasp produced mostly females in the large, males in the small. However, when the *Piéris* pupae were alternated with those of *Vanessa* (still smaller), the same wasp produced female offspring in the former and males in the latter. Sandlan[24] also studied a pupal parasite of Lepidoptera, the wasp *Coccygomimus turionella*. Here, individual wasps confronted with a single host size gradually altered the sex ratio through time. If the single size was large, the sex ratio declined from being female biased to being more male biased. A small size showed the opposite change—male biased towards more female biased. All these sex ratio shifts are in the theoretical direction.

Fitness as a function of host size

As the sex ratio shift is towards daughters in larger hosts, a further test of the theory consists of determining whether a female gains more fitness by being large than does a male. Measuring individual fitness is very difficult, especially for males, where the value must reflect the relative ability to gain access to females. Using *Lariophagus*, a set of experiments was designed to investigate whether wasp size was correlated with the size of its host, and also whether increased wasp size became translated into increased individual fitness. Figure 4 shows the result of rearing almost 2,000 individuals. Clearly, larger weevils give rise to large wasps. Two facts about Fig. 4 are of particular interest. First, the relationship is different for males and females. From the same-sized host, males are on average smaller than the corresponding female. This presumably reflects the fact that males show a shorter developmental time to adulthood on any given host size[22]. Second, both curves show a steep linear increase over the weevil size range 0.7–1.3 mm. At 1.3 mm both show an abrupt transition. Average male size no longer increases with weevil size, whereas average female size goes up at a much reduced rate (slope of curve here is about 12% the previous slope).

Figure 5 shows that increased size translates into both increased male and increased female fitness. For females the measure is the lifetime production of eggs, for males it is length of life. This is not a complete measure of male fitness, because it gives no indication of male mating ability. Small males have no difficulty in getting females to accept them as mates[22]. Because females typically mate once for life, small males would seem to give adequate numbers of sperm, but we do not know how such small males fare in mate competition with larger males.

A similar set of experiments with female *Heterospilis* showed that lifetime fecundity increased about 20 times, comparing 11-day with 15-day hosts [1.3 offspring (s.d. = 2.87, $n = 61$) compared with 27.9 (s.d. = 8.38, $n = 46$)]. Interestingly, males from the same-aged hosts showed a much smaller fitness size effect, the measure here being females inseminated over a 3-h period (with 20 females available). Eleven-day males inseminated an average of 2.8 females (s.d. = 2.91, $n = 38$), compared with 8.3 (s.d. = 2.36, $n = 31$) for 15-day males. Although these data suggest that daughters gain more by being large than do sons, they are not conclusive. It would be very useful to know how individual size affects other fitness components such as female search ability or female ability to attack large hosts.

There is another type of data which bear on this fitness gain issue, at least for *Lariophagus*. If fitness within each sex is related to the size of the wasp, host sizes over the range 1.3–2.0 mm show very little change in relative female/male size (Fig. 4), whereas relative female/male size is increasing over the host size range 0.6–1.3 mm. We might then expect that host sizes above 1.3 would be treated quite similarly with respect to sex ratio. As shown in Fig. 2*b* (host size alone experiments), the proportion of sons drops rapidly with increasing host size until a host size of 1.3 mm. The sex ratio is about 0.17 males at this host size, but it does not become more female biased as we move to even larger hosts. The experiments presented in Fig. 2 show that the wasp can alter its sex ratio when a two-host environment consists of both hosts above 1.3 mm. However, these shifts are small relative to the alteration in sex ratio observed over a host size range of 0.6–1.3 mm. The sex ratio versus host age relationship measured earlier by van den Assem[22] shows a similar abrupt transition in sex ratio at the host age of 23–24 days. X-ray calibration shows that this age corresponds to a mean host size close to 1.3 mm.

Other hymenopteran systems

There are other parasitoid systems where a range of host sizes is attacked, and where sex ratio alters with host size[22–34]. The shift is always in the direction of more females from larger hosts. There are other hymenopteran systems which show similar trends. 'Trap nesting' (ref. 38) refers to free-living bees and wasps where the mother places food plus an egg in a cell constructed inside a crevice (for example, a hollowed-out twig). The size of the crevice places constraints on the cell size, the amount of food packed in and consequently the size of the resulting adult wasp[38,39]. Trap nesters have been much studied because they will commonly nest in soda-straws, holes drilled in wood blocks, or other man-made crevices[38,39]. Because of the importance of some trap-nesting bee species for agricultural pollination[39], many data now exist. Figure 6 shows the sex ratio (proportion of emerging males) as a function of hole diameter in artificial nesting material for 11 species of bees and wasps. With one exception, these data are from the book by Karl Krombein[38]. This documents no trap nester with a reverse sex ratio shift, although several species show evidence of no sex ratio shift for the hole sizes presented (several wasps of the genera *Stenodynerus* and *Ancistrocerus*). A reverse shift might be expected in species where the males show aggression and territoriality with respect to mating[35,40]. Here, increased size could

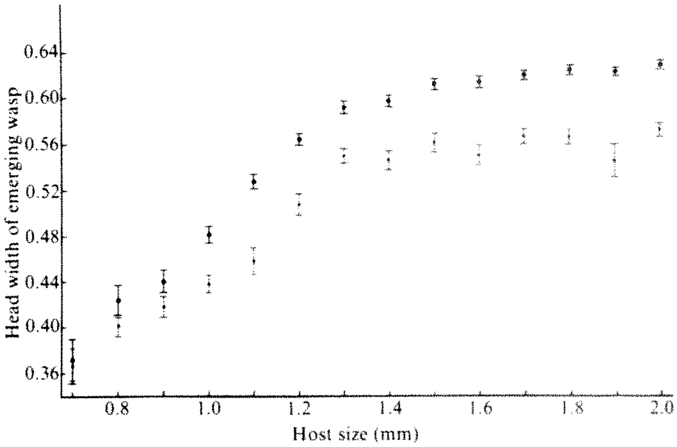

Fig. 4 Size of *Lariophagus* related to its host size (tunnel width). Means (±1 s.e.) of head width of males (lower curve) and females (upper curve) are plotted against host weevil size. Experimental details are given in Fig. 2 legend. Least squares regressions calculated on the means: (1) ♂, host sizes 0.7–1.3 mm, $y = 0.16 + 0.28x$, $r = 0.98$, $P < 0.001$. (2) ♂, host sizes 1.4–2.0 mm, correlation not significant at 0.05 level. (3) ♀, host sizes 0.7–1.3 mm, $y = 0.11 + 0.37x$, $r = 0.99$, $P < 0.001$. (4) ♀, host sizes 1.4–2.0 mm, $y = 0.54 + 0.044x$, $r = 0.92$, $P < 0.01$.

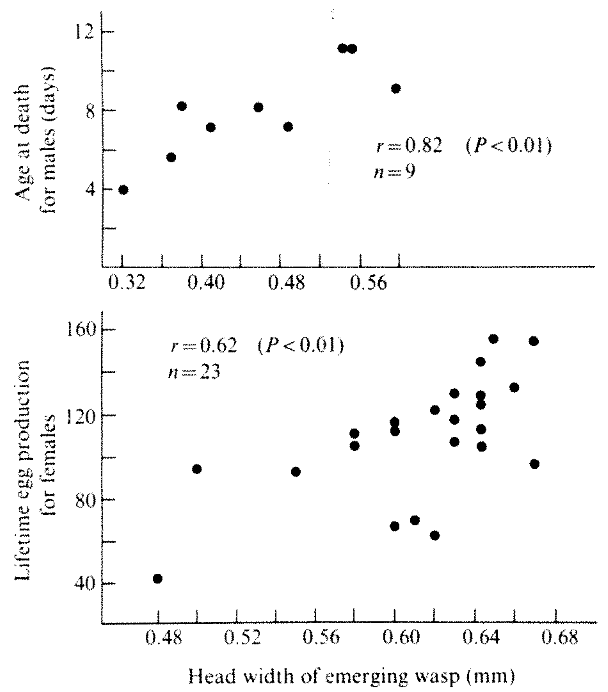

Fig. 5 Fitness as a function of individual size in *Lariophagus*. Both males and females gain by being large. Females were presented with an abundance of hosts. Experiments were run at 18 °C.

be translated into relatively greater male reproductive success[35]. It would be very interesting to know if any trap-nesting species shows geographical variation in the hole-size distribution. Such variaton should correlate with sex ratio shifts within a specified hole size, similar to those predicted (Fig. 1*b*, host size *z*) for parasitoids. However, the situation for trap nesters is somewhat more complicated than the simple model developed here. At least two other sex ratio effects occur with the hole-size shifts. There are often several cells placed in the same crevice—that is, a straw will contain a sequence of offspring. Because males typically emerge before females, it is common for the mother to put more daughters in the deep cells, more sons near the opening[38]. In this way, the sons can get out first without having to destroy the wasp in front. Except where different mothers may supersede eath other at a particular hole, the offspring in a given hole will be siblings. Some degree of cooperation may be expected[41], but the parents should benefit by using deep crevices for a mixture of sons and daughters. The other factor affecting sex ratio is that a son costs (in the sense of Fisher[18,21]) less than a daughter to produce. They require smaller cells (regardless of the diameter of the hole) and less food[38]. The equilibrium sex ratio should reflect this lowered cost through production of more males[20,21]. Even though these two factors complicate the situation, the hole-size effect, as illustrated in Fig. 6, still seems to be a dominating factor.

Discussion

Various biological systems in addition to Hymenoptera show sex ratio shifts of the type discussed here. These include pandalid shrimp[12,42], various orchids[43], entomogenous nematodes[44,45] and molluscs of the genus *Crepidula*[11]. In these cases, larger individuals typically become females, smaller ones male. Some of these species are sex reversers (sequential hermaphrodites), beginning life as a male and later changing into a female. Of course, many sex reversers go in the other direction; particularly among coral reef fish, species are known where individuals begin life as females, and become males when they are large enough to compete for a breeding territory[6-10,46].

As developed here and elsewhere[6-12,35,42,47,48], an understanding of the direction of the shift seems to depend on knowledge of which sex gains relatively more by being large. Whether the problem is the sex ratio to be produced by a wasp constrained to rear a small offspring or the 'choice' to develop into a small adult male or female imposed on a nematode in a crowded host[44,45], the principles underlying the force of natural selection remain the same.

Probably the largest gap in our knowledge is a clear demonstration of which sex gains relatively more by being large (except perhaps for some protogynous fish[6,7,46], where it seems fairly clear that males gain more). Because of the difficulty in measuring fitness with sufficient precision to test whether females gain more by being large, we propose here an alternative experiment. The data suggest that males also gain by being larger. If a laboratory culture can arrange for females not to gain fitness by being larger, the selection pressures will be to reverse the sex ratio shift. The culture conditions will then favour males in larger hosts, females in smaller.

Isolation of a gene from *Drosophila* by complementation in yeast

Steven Henikoff[*], Kelly Tatchell[†], Benjamin D. Hall[†] & Kim A. Nasmyth[†]

[*] Department of Zoology and [†] Department of Genetics, University of Washington, Seattle, Washington 98195

Transformation of mutant yeast cells by cloned genomic DNA from a higher eukaryote has made it possible to isolate a Drosophila *DNA sequence that complements a yeast adenine-8 mutation. A 0.8-kilobase poly(A)-containing RNA is transcribed from the cloned* Drosophila *segment in transformed yeast cells and can account for functional expression of the gene.*

PHYSICAL analysis of a large number of genes from animals has yielded an overall picture of the eukaryotic gene as a complex entity, sandwiched between long untranslated regions and interrupted several times by sequences which are not present in the mature mRNA. The procedures for isolating animal genes generally depend on specific nucleic acid sequence probes obtained by virtue of an enriched content of a particular mRNA in some specialized tissue or developmental stage. Consequently, the animal genes that have been most studied are seldom expressed in more than a few cell types. It is possible that some of the structural features attributed to higher eukaryotic genes are only typical of genes for differentiated functions. It is not known whether genes for cellular metabolism and cell division show these same features because of the absence of methods for isolating them from animal cells.

We now describe a gene substitution method for the isolation and molecular genetic analysis of metabolic genes from higher eukaryotes. The method is based on functional complementation of mutant yeast cells by recombinant plasmids from a random genomic library of *Drosophila* DNA fragments inserted into a yeast vector. By this procedure we have cloned a *Drosophila* gene that complements a mutation at the yeast adenine-8 locus.

Yeast transformation with pYF DNA

The cloning of yeast genes by complementation of yeast mutations has been successfully applied for genes affecting both cell metabolism[1-3] and the cell cycle[4]. In our experiments adenine auxotrophs were chosen because all organisms are thought to synthesize purines by a universal *de novo* pathway. We constructed recombinant plasmids by inserting *Drosophila* genomic fragments into a vector that could be replicated and selected for in both *Escherichia coli* and yeast. *Drosophila melanogaster* embryonic DNA was partially digested with *Sau*3A, a restriction endonuclease that recognizes GATC, cutting 5′ to the G to leave single-stranded GATC ends[4]. A mixture of such *Sau*3A fragments with a mean size of ~5 kilobases was then ligated into the single *Bam*HI restriction site (G↓GATCC) of the plasmid YEp13 (ref. 2), and the ligation mix was used to transform *E. coli* to give a quasi-random pool of cloned *Drosophila* fragments. Figure 1 shows the structure of a pYF plasmid. The bacterial ampicillin resistance gene of pBR322 allows selection in *E. coli* and the yeast *LEU*2 gene allows selection in *Saccharomyces cerevisiae*. The presence of yeast 2-μm circle DNA permits plasmid replication in yeast without integration.

A plasmid DNA pool containing many YEp13-*Drosophila* recombinants was purified from *E. coli* and used to transform mutant yeast strains[4,7]. To determine the adequacy of selective conditions, DNA from an identically constructed yeast DNA pYe pool was used to transform aliquots of mutant cells. Cells mutant for both *leu*2 and the test marker were plated in the absence of both leucine and adenine, so that only cells carrying a plasmid with both *LEU*2 and the Ade$^+$ gene being tested should have grown. We tested six purine auxotrophic strains, *ade*1–*ade*4, *ade*5,7 and *ade*8. Ade$^+$ prototrophs were found in every case for cells transformed with the pYe pool, except for *ade*2. (The pYe pool was constructed with DNA from an *ade*2 mutant strain.) For cells transformed with the pYF pool, Ade$^+$ prototrophs were found in one case out of six—*ade*8.

For *ade*8, six independent prototrophs were found from the pYF pool—these were picked up at a frequency of about 1 per 10^4 Leu$^+$ transformants whereas prototrophs from the pYe pool were picked up about an order of magnitude more frequently. Because the genome size of *Drosophila* is about 10 times that of yeast, one would expect the fly *ADE8* gene to be present ~1/10th as often in the pYF pool as its counterpart in the pYe

0028–0836/81/020033—05$01.00

pool. These pYF and pYe prototrophs were shown to be genuine *ADE*8 transformants rather than revertants or contaminants by the behaviour of these cells when grown without selection. YEp13 plasmids are lost at a frequency of ~1% per cell generation from yeast so that after several generations of growth on complete medium, a large fraction of cells will be leucine-requiring. Such cells should also be *ade*8 if *ADE*8 is carried on the recombinant plasmid. By this test, all *ADE*8 transformants, whether derived from the pYe or from the pYF pool, were found to be carried on a *LEU*2 plasmid—that is, loss of Leu$^+$ was always accompanied by adenine auxotrophy.

Restriction analysis of *ADE*8 plasmids

DNA was isolated from the six pYF and from six pYe *ADE*8 transformants grown up with adenine selection. DNA samples were used to transform *E. coli*, from which single ampicillin-resistant clones were grown and plasmid DNA extracted. Restriction endonuclease analysis of these plasmids is summarized in Fig. 2. The six pYF plasmids showed three different but partially overlapping restriction patterns, and the six pYe plasmids showed two. Apparently the smallest pYF insert is contained entirely within the other two: it has the same orientation as the second longest. This was confirmed by hybridization analysis using one of the plasmids as a probe (data not shown). No cross homology was detected, however, between the pYF and the pYe *ADE*8 plasmid inserts.

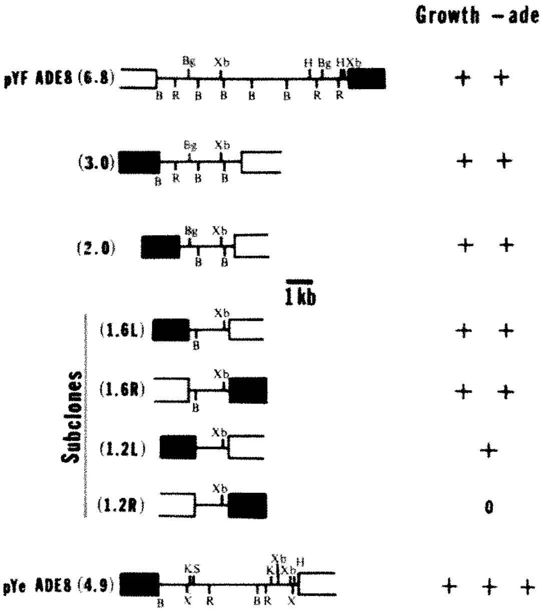

Fig. 2 Restriction endonuclease analysis of *ADE*8 plasmid inserts and relative growth with adenine selection of *ade*8 cells carrying *ADE*8 plasmids. Orientation of the inserts within the YEp13 vector is indicated by the solid panel, which corresponds to the region on the left hand side of the *Drosophila* segment in Fig. 1. Subclones were constructed by ligating the gel-purified 1.6-kilobase *Bgl*II–*Bam*HI and the 1.2-kilobase *Bam*HI–*Bam*HI fragments, derived from pYF *ADE*8(3.0) and pYF *ADE*8(2.0) respectively, into the *Bam*HI site of YEp13 (ref. 2). All pYF *ADE*8 inserts appeared to overlap with one another but showed no similarity to the pYe *ADE*8 inserts, one example of which is shown. The following enzymes were used: *Bam*HI (B), *Bgl*II (Bg), *Hin*dIII (H), *Kpn*I (K), *Eco*RI (R), *Sal*I (S), *Xba*I (Xb), and *Xho*I (X). Growth rates were determined by colony size estimation for initial isolates and subclones tested in the same yeast strain used for the initial selection (5028-1Dα ade8-18 leu2-1 met2 his4-4 lysX gal cup^s). Transformants were tested on plates minus leucine and on plates minus adenine. No differences in colony size were noted for any transformant using leucine selection. Growth using adenine selection was estimated from colony size after 3 days at 29 °C. kb, Kilobase.

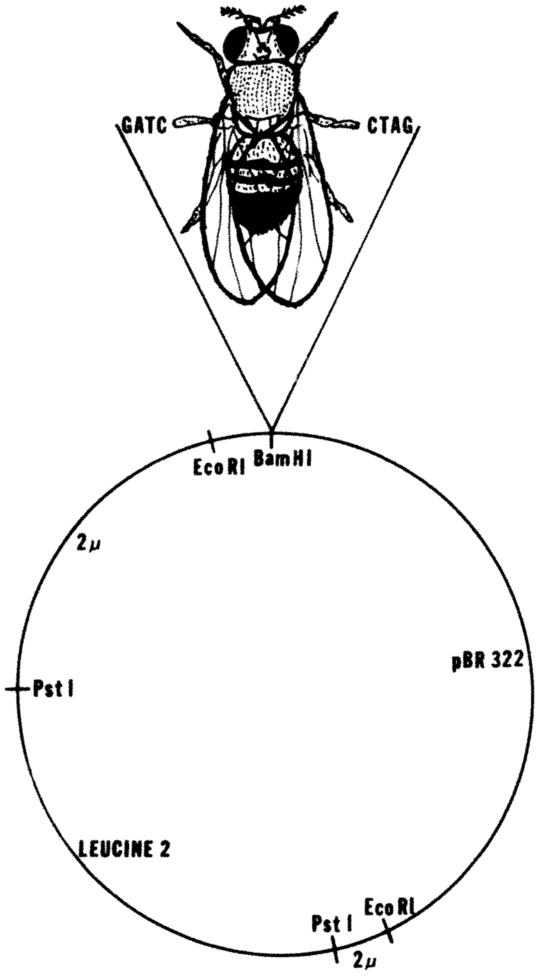

Fig. 1 Schematic map of pYF plasmid DNA derived from the bacterial plasmid pBR322, yeast 2-μm circle DNA, the yeast *LEU*2 gene and *Drosophila* embryonic DNA. Fresh *D. melanogaster* (wild-type 'Sevelin') embryos were thoroughly washed and dechorionated 8–15 h after egg deposition, and 2,000*g* nuclei were prepared[5]. Microbial contamination was checked by plating out and was found to be insignificant. Nuclei were lysed in 10 mM Tris *p*H 7.9, 4 mM EDTA, 1% Sarkosyl, and DNA was banded in CsCl and dialysed. Partial digestion of this DNA with *Sau*3A, ligation into YEp13 (ref. 2) and transformation was performed as described elsewhere[4]. A pool of *E. coli* transformants (3×10^5) with mean *Drosophila* insert size of 4–5 kilobases was obtained and was enriched by selection for ampicillin resistance and tetracycline sensitivity[6]. A log-phase culture inhibited with chloramphenicol was used for plasmid DNA isolation and purification[4].

To demonstrate directly the presence of an *ADE*8 gene, *ade*8 *leu*2 yeast cells were transformed with each one of the plasmids being analysed. In every case, both *ade*8 and *leu*2 were simultaneously complemented, proving that an *ADE*8 gene is present within each plasmid insert (data not shown). Using leucine selection, all such transformants grow about as well as wild-type cells regardless of which plasmid is used. However, when adenine is absent, an interesting difference appears. Whereas yeast cells carrying pYe-derived plasmids grow about as rapidly as do wild type, those with any of the pYF plasmids grow at about two-thirds the normal rate. This reduced rate of growth attributable to the pYF *ADE*8 gene suggests that the *Drosophila* *ADE*8 gene functions less effectively in yeast than its yeast functional counterpart.

Hybridization of pYF *ADE*8 to *Drosophila* DNA

An unlikely artefact that could account for complementation of a yeast auxotroph by pYF plasmids is microbial contamination of the *Drosophila* DNA, although precautions were taken to prepare very clean dechorionated embryos. Southern transfer experiments can rule out this possibility by demonstrating that the pYF plasmid inserts are derived from *Drosophila*[8]. Figure 3 shows an agarose gel on which *Drosophila* genomic DNA was electrophoresed after cutting with *Bam*HI restriction enzyme. In another lane, an amount of pYF *ADE*8(2.0) representing a genome equivalent was also digested with *Bam*HI and electrophoresed. This gel was blotted and probed with the 1,200-base pair fragment produced by *Bam*HI digestion of pYF *ADE*8(2.0) and labelled with ^{32}P by nick-translation. Figure 3*c*, *d* shows that a 1,200-base pair band is present in both lanes which indicates that the pYF *ADE*8 inserts are derived from *Drosophila*. Also, the extent of hybridization is the same in both lanes which suggests that the sequence is single-copy.

This result has been confirmed using *Drosophila* genomic DNA from embryos of different strains and from polytene fat body cut with *Eco*RI, *Xba*I and *Bgl*II. In each case, a single band of the expected size was hybridized to the extent expected for a sequence present once per haploid genome (data not shown). Thus we conclude that the pYF sequence complementing *ade*8 is derived from *Drosophila* and is single-copy.

A *Drosophila* sequence present once per haploid genome in polytene tissue can be localized unambiguously on salivary chromosomes. Figure 4 shows the result of an *in situ* hybridization experiment using ^{3}H cRNA to pYF *ADE*8(6.8) as a probe. A single site, 27C on chromosome arm 2L, is labelled. Even exposures 10 times longer than for the example in Fig. 4 do not show labelling of any other site. The region around the labelled site is not one of extensive genetic characterization[13]. However, in screening for adenosine auxotrophs on chromosome 2, Naguib and Nash (personal communication) have isolated two non-allelic *Drosophila* mutations, and both map to this region. It is tempting to speculate that one of these auxotrophic mutations blocks the reaction catalysed by the *Drosophila* enzyme that is coded for by pYF *ADE*8. In yeast, adenine-8 is presumed to be the gene for the enzyme glycinamide ribotide (GAR) transformylase[14]. It will be interesting to determine whether the same enzyme activity is specified by this sequence in *Drosophila*.

Transcription of pYF *ADE*8

Because the *Drosophila* segments that complement *ade*8 were carried on plasmids that also included bacterial and yeast DNA, we wondered whether or not *ADE*8 gene expression depends entirely on *Drosophila* DNA. For example, transcription and translation could conceivably initiate or terminate within flanking vector DNA so that the *Drosophila* sequence would supply only structural information. We found that this was not likely.

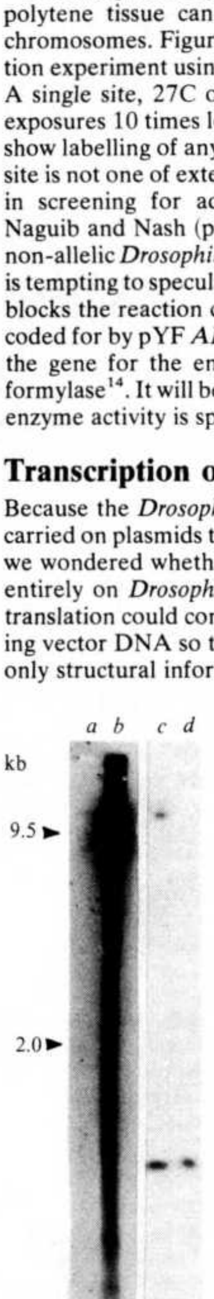

Fig. 3 Hybridization of *Drosophila* genomic DNA with pYF *ADE*8 probe. *a*, An aliquot (3 ng) of pYF *ADE*8(2.0) DNA was digested with *Bam*HI and electrophoresed on a 0.9% agarose gel[9] adjacent to *b*: 10 μg *Bam*HI-digested *Drosophila* embryonic DNA. After staining with ethidium bromide and photographing, the DNA was transferred to nitrocellulose and hybridized[10] with the 1,200-base pair *Bam*HI fragment partially purified (95%) from pYF *ADE*8(2.0) and labelled with ^{32}P by nick-translation. The nick-translation reaction mixture (50 μl) contained 10 μCi [α-^{32}P]dCTP (NEN); 4 μM dATP, dGTP and dTTP; 50 mM Tris-HCl *p*H 8; 5 mM $MgCl_2$; 50 μg per ml bovine serum albumin; ~1 μg DNA; 3 units DNA polymerase I (Boehringer) and 75 pg DNase I (Worthington). *c*, *d*, Autoradiograms of tracks *a* and *b*, respectively.

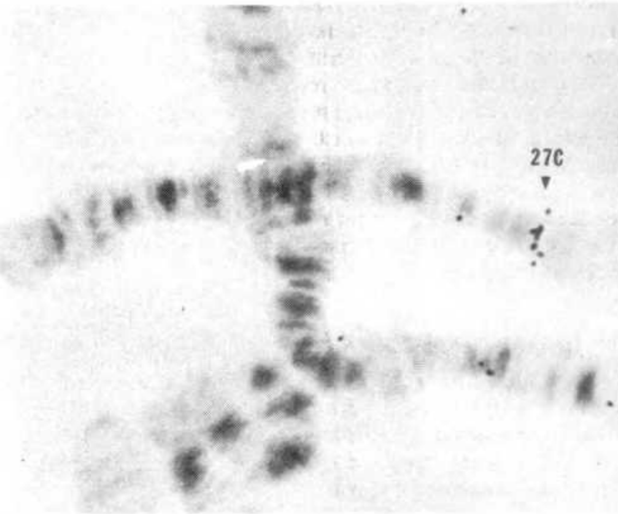

Fig. 4 Hybridization of pYF *ADE*8(6.8) to polytene chromosomes *in situ*. ^{3}H-labelled copy RNA[11] was hybridized as described elsewhere[12] to *gt* w^a/gt^{X11} prepupae. Exposure was for 3 days.

The gene functioned at the same reduced rate for all three different plasmid types, even though their inserts had different orientations. More direct evidence that *ADE*8 gene expression depended on *Drosophila* DNA and not flanking vector sequences came from an investigation of transcription on a pYF *ADE*8 plasmid.

If pYF *ADE*8 complements the yeast *ade*8 mutation by making a protein, then one would expect to find poly(A)-containing RNA hybridizable to *Drosophila ADE*8 DNA in cells transformed with pYF *ADE*8 plasmids. Adenine-8 mutant cells that carry pYF *ADE*8(2.0) were grown with adenine selection and poly(A)$^+$ RNA was isolated. An aliquot of this RNA was denatured in dimethyl sulphoxide (DMSO) and glyoxylated, then electrophoresed on agarose and transferred to nitrocellulose as described elsewhere[15]. This 'Northern' transfer was probed with the 1.5-kilobase fragment derived from the pYF *ADE*8(2.0) insert by digestion with *Bgl*II and *Xba*I and labelled with ^{32}P by nick-translation. Figure 5 shows the resulting autoradiogram. Two prominent bands are seen, one at 0.8 kilobases and another at 2.2 kilobases, with a few minor bands and some heterogeneous labelling also visible. The 2.2-kilobase transcript is very likely to have been read from vector sequences in part, as it seems to be longer than the entire 2-kilobase *Drosophila* insert in the plasmid that was carried by the cells from which the RNA was derived. Experiments described below demonstrate that the 0.8-kilobase transcript is derived entirely from *Drosophila* DNA, and that it is responsible for *ADE*8 function.

One way to determine which transcript provides *ADE*8 function is physically to map the transcript on the plasmid, then compare this map with a functional map determined by testing partially deleted subclones for *in vivo* function. We used S_1 nuclease protection of transcripts by various fragments to map the transcribed region[18]. Poly(A)$^+$ RNA used in the above Northern blot experiment was hybridized to the 1,500-base pair *Bgl*II–*Xba*I fragment in conditions that allow RNA–DNA but not DNA–DNA duplex formation. In parallel reaction mixtures, the DNA fragment was also first digested with either *Bam*HI or *Ava*II to give fragments that were 350 or 375 base pairs shorter, as shown in Fig. 6*a*. These mixtures were then digested with S_1 nuclease, electrophoresed on an agarose gel and transferred to nitrocellulose. This blot was probed with pYF *ADE*8(2.0) labelled with ^{32}P by nick-translation and autoradiographed—the result is shown in Fig. 6*a*. All three fragments are protected by transcript to give a major band at ~0.8 kilobases and a minor band at ~0.7 kilobases. Both these bands are the same size when either the *Bgl*II–*Xba*I fragment or

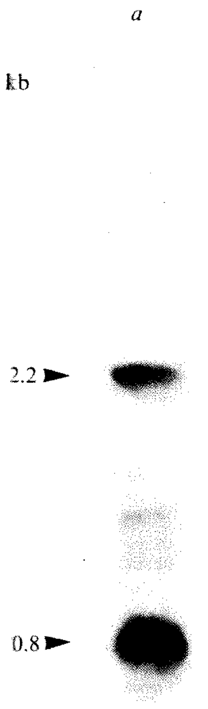

Fig. 5 Hybridization of pYF *ADE*8 DNA to a Northern blot of poly(A)-containing RNA. Log-phase *ade*8 *leu*2 yeast cells carrying *a*, pYF *ADE*8(2.0) and *b*, pYE *ADE*8(4.9) were grown with adenine selection. RNA was extracted[16] and the poly(A)$^+$ fraction isolated[17]. Samples (10 μg) were glyoxylated in 80% DMSO at 65 °C, electrophoresed, transferred to nitrocellulose and hybridized using the procedure of Thomas[15]. The probe used was the purified *Bgl*II–*Xba*I fragment derived from the insert of pYF *ADE*8(3.0) purified on a 1.1% agarose gel[9], electroeluted and labelled with ^{32}P by nick-translation.

the *Bam*HI–*Xba*I fragment is used for hybridization but are reduced in size by about 25 nucleotides when the *Ava*II–*Xba*I fragment is used. This result allows assignment of both transcripts to a region stretching from the *Bam*HI site to a point 0.8 kilobases to the right for the major transcript and 0.7 kilobases for the minor. This minor transcript is probably produced as a result of the S_1 digestion procedure because in milder conditions it is absent (data not shown). An S_1 nuclease-protected region of 0.8 kilobases corresponds well to the 0.8-kilobase transcript detected on the Northern blot. Failure to detect the 2.2-kilobase transcript here suggests that it is complementary to only a small part at one end of the *Bgl*II–*Xba*I fragment, and due to its small size, escapes detection. This experiment also suggests that there are no intervening sequences because the protected fragments are all of the same size in this neutral gel, as they were in an alkaline denaturing gel run in parallel (not shown).

The orientation of the 0.8-kilobase transcript was determined in a similar S_1 nuclease protection experiment using fragments labelled at one end only. Two different fragments were used (Fig. 6*b*). Starting with the 1.2-kilobase fragment liberated by *Bam*HI digestion, one labelled fragment (A) was made by cutting with *Ava*II, labelling the 3′ ends and then cutting with *Xba*I. The other labelled fragment (B) was made similarly but without the *Ava*II digestion. Ignoring the small fragments produced, fragment A is labelled at the *Ava*II site on its 3′ end and fragment B is labelled at the leftmost *Bam*HI site on its 3′ end. Only if the transcript is oriented with its 5′ end on the left and covers the labelled 3′ end restriction site will that site be protected from S_1 nuclease digestion. This is the case for the *Ava*II site as seen in the autoradiogram of a polyacrylamide gel (Fig. 6*b*). For fragment B, S_1 nuclease protection is also found, although not as much as for fragment A. Partial protection of the *Bam*HI site shows that the 5′ end of the 0.8-kilobase transcript is within a few nucleotides of this site.

Behaviour of subcloned pYF *ADE*8 fragments *in vivo*

Our evidence that the 0.8-kilobase transcript made in yeast starts and stops within the *Drosophila* sequences of pYF *ADE*8(2.0) does not unequivocally demonstrate that this

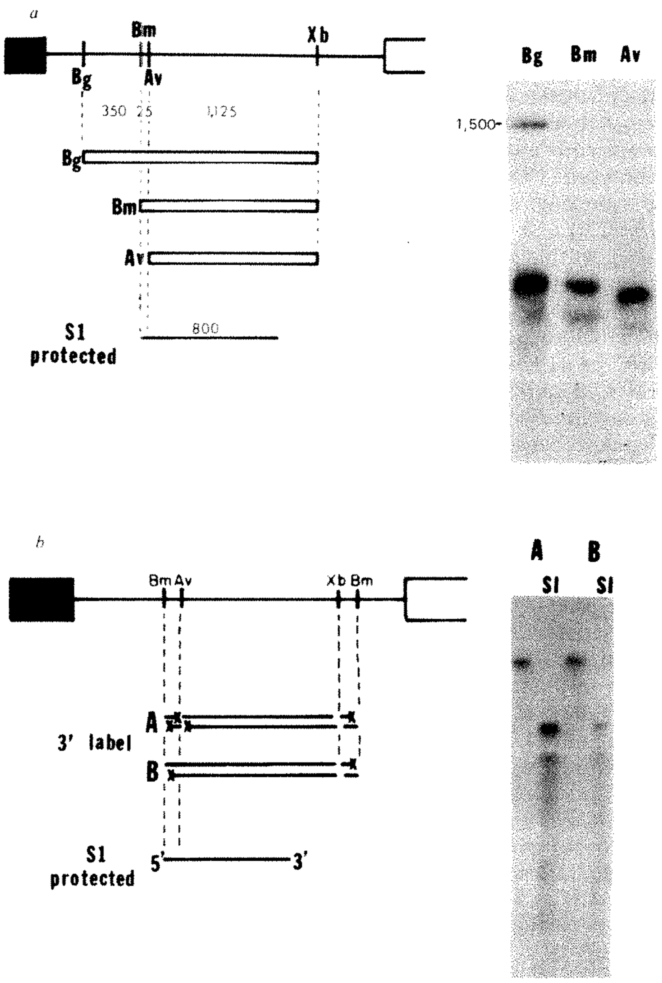

Fig. 6 Mapping of transcription by S_1 nuclease protection of restriction fragments derived from pYF *ADE*8(2.0). Purified restriction fragments were hybridized to poly(A)-containing RNA from cells carrying pYF *ADE*8(2.0) and S_1 nuclease-digested according to Holmgren *et al.*[19]. Each hybridization mixture (20 μl) contained 80% formamide, 0.3 M NaCl, 1 mM EDTA, 10 mM PIPES *p*H 6.8, 10–40 μg RNA and 80–160 ng DNA. Samples were kept at 70 °C for 10 min then transferred to 53 °C for overnight incubation. These were mixed with 20-μl aliquots of 0.3 M NaCl, 6 mM $ZnCl_2$, 100 mM Na-acetate, *p*H 4.0, and 50,000 units per ml S_1 nuclease, incubated for 5 min at 37 °C, extracted with phenol and ethanol-precipitated. *a*, Protection of unlabelled fragments. Hybrids were electrophoresed on a neutral 1.5% agarose gel, blotted onto nitrocellulose, hybridized with pYF *ADE*8(2.0) which was labelled with ^{32}P by nick-translation, and autoradiographed. The band at 1,500 base pairs is apparently due to DNA–DNA reassociation of the *Bgl*II–*Xba*I fragment. *b*, Protection of 3′ end-labelled DNA fragments. Before hybridization, the 1.2-kilobase *Bam*HI–*Bam*HI fragment purified from pYF *ADE*8(2.0) was either digested with *Ava*II (A) or used uncut (B) to fill the 3′ ends (indicated by x) with ^{32}P-labelled deoxynucleotide triphosphates. Both samples were digested with *Xba*I and aliquots used for hybridization and S_1 nuclease digestion. Hybrids were then redissolved in 0.1 M NaOH and electrophoresed on 4% acrylamide gels containing 7 M urea[20]. The resulting autoradiogram is shown at the lower right. For each labelled fragment A and B, an aliquot of the fragment itself was run to the left of the S_1 nuclease-digested sample (S1). Because the specific activities of the A and B large fragments differed, their concentrations were adjusted for the gel to give the same amount of radioactivity in both untreated large fragments. For the S_1 nuclease-treated samples, the same relative adjustment in concentration was made so that these gel tracks could be quantitatively compared for A and B. The 0.7-kilobase minor band seen after S_1 nuclease digestion is probably a digestion artefact (see text). Restriction sites are *Bgl*II (Bg), *Bam*HI (Bm), *Ava*II (Av) and *Xba*I (Xb). The orientation of the poly(A)$^+$ transcript is shown.

sequence is responsible for *ade*8 complementation. For example, it is possible that a less abundant transcript accounts for *ADE*8 function. However, the following *in vivo* tests of subcloned fragments strongly suggest that the 0.8-kilobase transcript mapped above is the functional message. As shown in Fig. 2, we tested fragments subcloned into the *Bam*HI site of YEp13 in both orientations. The 1.6-kilobase fragment made by *Bgl*II digestion and *Bam*HI partial digestion of pYF *ADE*8(2.0) showed *ADE*8 complementation activity equivalent to that of the original plasmids when subcloned in either orientation. The 1.2-kilobase fragment made by complete *Bam*HI digestion of pYF *ADE*8(2.0) showed reduced *ADE*8 activity in one orientation and no activity at all when subcloned in the other orientation. Because the 350 base pairs between the *Bgl*II site and the leftmost *Bam*HI site are the only difference between the subclones in either orientation, the structural gene apparently lies between the two *Bam*HI sites with a control region just to the left. This mapping of *Drosophila* adenine-8 based on function agrees well with the transcriptional mapping, because the entire transcript, except for possibly a few nucleotides at the 5′ end, is read from a region that can function in a subclone. It seems likely that substitution of sequences just upstream of the structural gene, perhaps even replacing the initiation site, has reduced or eliminated gene expression. Therefore, we conclude that the 0.8-kilobase poly(A)$^+$ transcript is the message in yeast and that the *Drosophila* segment from which it is transcribed is entirely responsible for complementation of *ade*8.

That this transcript functions as message is also apparent from a preliminary analysis of its nucleotide sequence. An open reading frame has been found to cover most of the transcribed region (C. E. Furlong and S.H., unpublished results). Presumably, this sequence codes for the enzyme GAR transformylase from *D. melanogaster.*

Concluding remarks

We have shown that yeast transformation can be used to isolate a gene from a higher eukaryote and to determine that transcription of the gene corresponds to its functional expression. Of the six adenine pathway genes investigated, only *Drosophila* adenine-8$^+$ was isolated in yeast by our procedure. Several explanations can be offered for the failure to find complementation for mutations in the other five yeast genes, including cases in which multi-enzyme genes in yeast may not be linked in *Drosophila* (for example, *ade*3 and *ade*5,7), transcripts may not be correctly processed or efficiently translated in yeast, or enzyme products may not be sufficiently functional or stable. Our characterization of *Drosophila* adenine-8$^+$ shows that it is transcribed in yeast to make a product that can substitute for the yeast *ADE*8 gene product. This suggests that the requirements for functional expression of this gene are very much the same in insects and fungi. As this is one of the first higher eukaryotic genes of a general metabolic nature to be analysed, it is possible that such genes will generally be similar to those in yeast. The gene substitution method used may prove useful for further inter-kingdom comparisons.

We thank Charles Laird for support and encouragement, Carol Sandstrom for help with embryo collection, Jim Sloan for testing yeast strains, Pat Thomas for providing the RNA blotting protocol and Seymour Fogel for the *ade*8 strain. This work was supported by grants from NIH to B. D. H. and to C. Laird, by a Damon Runyon-Walter Wichell Cancer Fund postdoctoral fellowship to K. T. and by a Jane Coffin Childs Memorial Fund for Medical Research postdoctoral fellowship to K. A. N.

Intervening sequences in a plant gene—comparison of the partial sequence of cDNA and genomic DNA of French bean phaseolin

S. M. Sun[†], **J. L. Slightom**[*†] **& T. C. Hall**[‖]

Departments of Horticulture and Genetics*, University of Wisconsin, Madison, Wisconsin 53706

A plant gene coding for the major storage protein (phaseolin, G1-globulin) of the French bean was isolated from a genomic library constructed in the phage vector Charon 24A. Comparison of the nucleotide sequence of part of the gene with that of the cloned messenger RNA (cDNA) revealed the presence of three intervening sequences, all beginning with GT and ending with AG. The 5′ and 3′ boundaries of intervening sequences IVS-A (88 base pairs) and IVS-B (124 base pairs) are similar to those described for animal and viral genes, but the 3′ boundary of IVS-C (129 base pairs) shows some differences. A sequence of 185 amino acids deduced from the cloned DNAs represents about 40% of a phaseolin polypeptide.

PHASEOLIN, the first globulin (Gl) fraction to precipitate on dilution of an acidic saline extract[1], is the major storage protein in the seeds of French bean (*Phaseolus vulgaris* L.). One-dimensional SDS-polyacrylamide gel electrophoresis of phaseolin from cotyledons of the cultivar 'Tendergreen' resolves three polypeptides, α, β, and γ, with apparent molecular weights of 53,000, 47,000 and 43,000, respectively[2]. Analytical ultracentrifugation reveals the free polypeptide (3S) conformation in highly alkaline (>pH 11) solutions (or in solution containing SDS), but as the pH values are lowered (in the

absence of dissociating agents), reversible association to 7.1S protomeric (at neutral *p*H values) and 18.2S tetrameric (at *p*H 3.5) forms occurs[3-5]. Mapping according to the method of Cleveland *et al.*[6] established that the α, β and γ polypeptides share a general sequence homology for some 60% of their length[7]. However, two-dimensional electrophoresis[8] shows the presence of charge microheterogeneity[9]. It is likely, therefore, that phaseolin is encoded by a multigene family, of an as yet undetermined size. Similar, or even more complex, situations are indicated for other seed crop proteins such as zein[10-12] from corn and the soybean storage proteins[13,14].

Phaseolin accumulates rapidly in the developing seed cotyledon over a 2- to 3-week period following anthesis[15,16]. Indeed, we estimated that, at certain stages of development, phaseolin polypeptides represent some 90% of the total protein synthetic activity of this tissue. At maturity it comprises about 50% of the total protein stored in the seed[17]. Phaseolin does not occur anywhere in the bean other than in the cotyledon[15]; hence, its synthesis is under strict tissue and temporal regulation.

We describe here the isolation and characterization of a phaseolin gene. This is a major step towards investigating the expression of this economically important protein at the molecular level, and subsequently, in the use of molecular biological techniques to improve the bean as a crop plant[18].

Preparation of bean DNA and construction of a genomic library

The preparation of a genomic library[19-21] of bean DNA was particularly attractive because it makes possible the isolation of phaseolin and other genes of specific interest so that their structure, organization and regulation can be studied. It also facilitates determination of the number of genes coding for phaseolin polypeptides, their variability and cellular location. Only limited information concerning these questions can be obtained by classical genetic techniques. An initial step in preparing such a library was the isolation of DNA of adequate length, free from contaminating polysacharides or RNA, yet without nicks. We could prepare DNA of over 60 kilobase pairs in length from embryonic axes dissected from dry bean seeds (see Fig. 1 legend and ref. 22). After partial digestion of the DNA with *Eco*RI endonuclease, DNA fragments of 8–20 kilobase pairs were selected[23] and inserted into the phage λ cloning vector, Charon 24A. Approximately 2×10^6 recombinant phages were screened for phaseolin sequences using a ^{32}P-cDNA probe made from highly purified phaseolin mRNA[23,24]. From 12 candidate clones, two, Ch24A-176.2 and Ch24A-177.4, were selected for further characterization.

Characterization of cloned DNA

Restriction analysis of 'mini-lysates'[19] of clones Ch24A-176.2 and Ch24A-177.4 showed that they both contained a 7.2.-kilobase *Eco*RI fragment (Fig. 1, lanes *b*, *c*) that hybridized strongly the cDNA probe (Fig. 1, lanes *d*, *e*). DNA from clone Ch24A-177.4 was purified[25] for further analysis. This revealed (Fig. 1, lanes *f*, *g*) that, in addition to a strongly hybridizing 7.2-kilobase fragment, weak hybridization to a 1.7-kilobase fragment could also be discerned. An additional 2.2-kilobase fragment was detected that showed no hybrization to the probe. To facilitate the preparation of large quantities of cloned DNA, the 7.2- and 1.7-kilobase DNA fragments were subcloned into pBR322 (refs 20, 26).

Although the material used as a template for the synthesis of the ^{32}P-cDNA probe was known to be highly enriched in phaseolin mRNA[23,27], it was necessary to confirm that the cloned DNA did contain a phaseolin gene sequence. The first confirmation was obtained by electrophoretic separation of bean 18S and 28S rRNAs, poly(A)$^-$RNA, total poly(A)$^+$RNA, and the 16S fraction of poly(A)$^+$RNA (phaseolin mRNA) in an agarose gel (Fig. 2*A*). After electrophoresis, the RNAs were transferred to diazobenyloxymethyl (DBM)-paper[28,29] and then hybridized to the 7.2-kilobase cloned DNA fragment which was ^{32}P-labelled by nick-translation[30]. No hybridization to rRNA

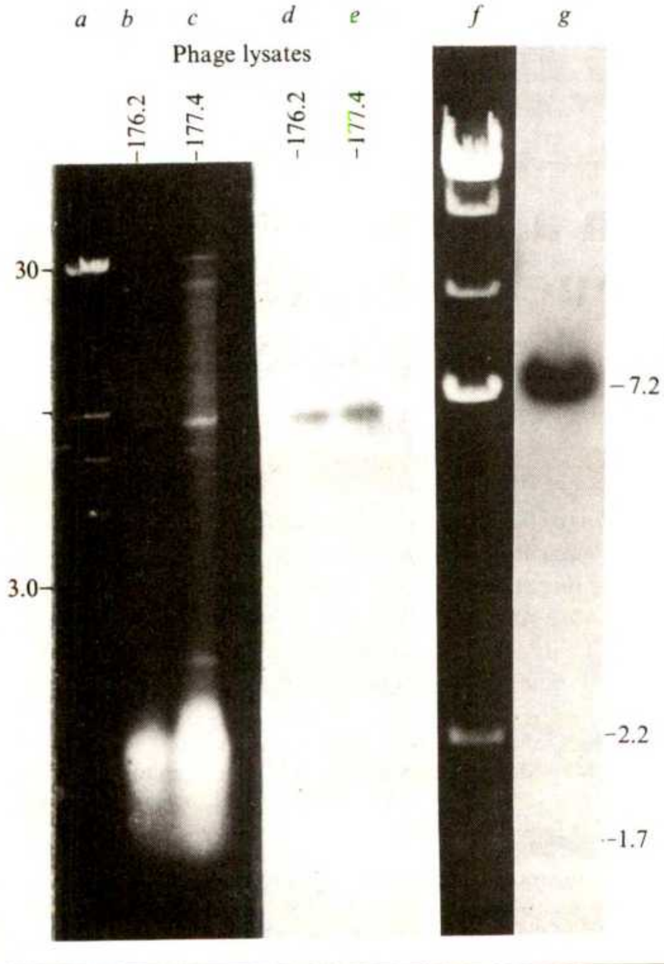

Fig. 1 Identification and selection of clones containing phaseolin sequences from a bean DNA library. French bean genomic DNA was isolated from embryo axes of dry seeds by the method of Blin and Stafford[22] with the following modifications. After extraction with phenol and dialysis, the DNA solution was adjusted to 0.95 g ml^{-1} CsCl and 0.5 mg ml^{-1} ethidium bromide, then centrifuged twice for 60 h (45,000 r.p.m., Beckman Ti-60) at 20 °C to band the DNA, which was recovered from the gradient after each cycle. Ethidium bromide was removed by several extractions with CsCl-saturated isopropyl alcohol and the DNA dialysed against 10 mM Tris-Cl, *p*H 8.0, 5 mM NaCl and 1 mM EDTA before use. The DNA obtained had a length of about 60 kilobase pairs. An additional extraction with phenol was necessary after the dialysis step to obtain normal *Eco*RI digestion kinetics and higher cloning efficiencies. The construction of a 'shotgun' collection of 1.5×10^6 Charon 24A bacteriophage recombinants containing partial *Eco*RI fragments from 10 µg of genomic DNA was as described by Blattner *et al.*[19] and Slightom *et al.*[20]. This original library was amplified to 2×10^9 recombinant phages and approximately 2×10^6 of these were screened[19] using a ^{32}P-labelled phaseolin cDNA probe prepared according to Kacian and Myers[24]. DNA was extracted from mini-lysates[19] of two clones that showed especially strong plaque hybridization to the probe. *Eco*RI digests of these clones were electrophoresed in a 0.7% agarose gel (lane *b*, clone 176.2; lane *c*, clone 177.4; lane *a* contained marker DNAs[19] whose sizes are shown at the left in kilobases). The DNA was then transferred to nitrocellulose paper by the method of Southern[40] and hybridized to the phaseolin ^{32}P-cDNA probe. The 7.2-kilobase *Eco*RI fragment from each clone hybridized strongly to the probe (lanes *d*, *e*). After purification of DNA from clone Ch24A-177.4 and digestion with *Eco*RI, two additional bands (2.2 and 1.7 kilobases, see lane *f*) were revealed. The ^{32}P-cDNA probe hybridized weakly to the 1.7-kilobase fragment but showed no recognition of the 2.2-kilobase fragment (lane *g*).

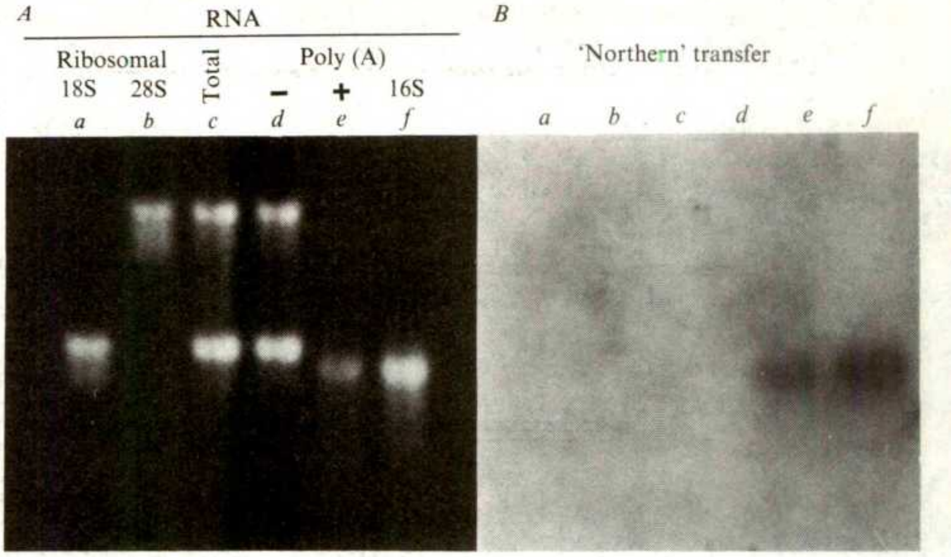

Fig. 2 Hybridization of cloned DNA to bean RNAs. Total RNA was isolated from maturing French bean cotyledons (grown in the Madison campus Biotron) using a hot (~70 °C) Na borate-NaOH (0.2 M, *p*H 9.0) extraction buffer containing 1% SDS, 30 mM EGTA and 5 mM dithiothreitol, followed by deproteinization at 37 °C with proteinase K (Beckman) as described by Buchbinder[41] and Hall *et al.*[23,27]. The total RNA was separated into poly(A)$^+$ and poly(A)$^-$ fractions by oligo(dT)-cellulose chromatography. The poly(A)$^+$RNA was fractionated by centrifugation in a linear–log[42] sucrose gradient (0–32.5% sucrose in 0.1 M NaOAc, 0.1 M NaCl and 1 mM EDTA, *p*H 5.0), and the 16S fraction collected. These RNA fractions, together with 18S and 28S bean rRNAs, were electrophoretically separated on a 1.5% agarose gel containing 6% formaldehyde and stained with ethidium bromide (*A*: lane *a*, 18S rRNA; lane *b*, 28S rRNA; lane *c*, total RNA; lane *d*, poly (A)$^-$ RNA; lane *e*, poly(A)$^+$RNA; lane *f*, 16S RNA), and subsequently transferred to DBM-paper (Schleicher and Schuell) according to the procedures of Alwine *et al.*[28] and Rave *et al.*[29]. The RNAs bound to the paper were then hybridized to the cloned 7.2.-kilobase bean DNA fragment labelled with ^{32}P by nick translation[30]. As seen in *B*, the radioactive cloned DNA hybridized to only the poly(A)$^+$ (lane *e*) and 16S (lane *f*) RNAs.

was seen, only the total poly(A)$^+$ and the phaseolin mRNAs showed positive reactions (Fig. 2*B*). This established that the clone does not contain any rRNA sequences and shows that it reacts with the expected poly(A)$^+$RNA fractions.

A second confirmation came from hybrid-arrested translation[31], in which only those mRNAs complementary to the supplied DNA sequence are prevented from functioning as messengers during cell-free protein synthesis. Figure 3*A* shows that increasing amounts of cloned DNA competed out products identified as phaseolin polypeptides, although synthesis of the other products coded by the bean cotyledon poly(A)$^+$RNA was unaffected. Further confirmation that a phaseolin gene had been isolated was obtained by binding the recombinant DNA to a nitrocellulose filter and hybrid-selecting[32] phaseolin mRNA

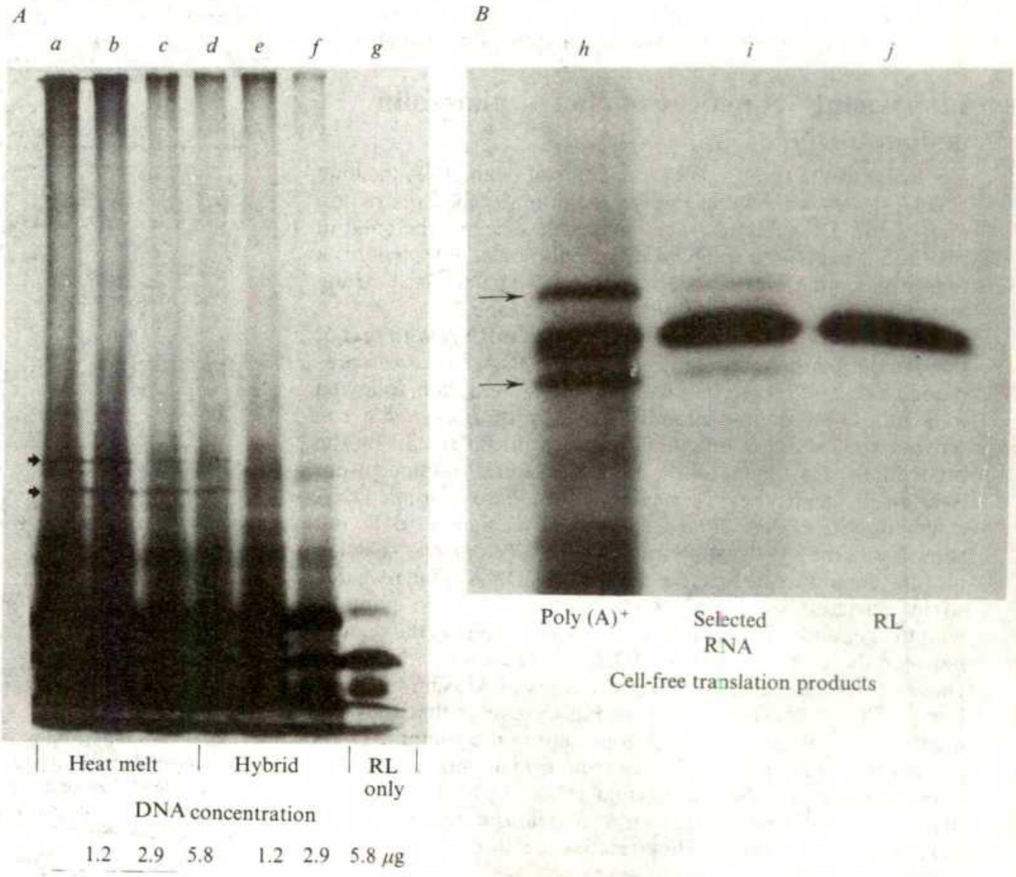

Fig. 3 Hybrid-arrested and hybrid-selected translation of phaseolin mRNA. *A*, Hybrid-arrested translation[31] in the rabbit reticulocyte system was performed using various amounts (2.4 μg, 5.8 μg or 11.6 μg) of *Eco*RI-digested Ch24A-177.4 DNA hybridized to 0.4 μg bean poly(A)$^+$RNA for 2 h at 48 °C in the presence of 80% deionized formamide. The samples (250 μl) were each divided into two equal portions, one of which was heat melted at 100 °C for 60 s before translation (lanes *a*, *b*, *c*; heat melt) and the other allowed to remain in hybrid form during translation (lanes *d*, *e*, *f*; hybrid). A reaction containing no added mRNA is shown for comparison in lane *g* (RL only). The ^{35}S-Met-labelled products were separated on a 13% SDS-polyacrylamide slab gel[43] and subjected to fluorography[44]. The arrows indicate the position of phaseolin polypeptides. *B*, Phaseolin mRNA was selected from total poly(A)$^+$mRNA by hybridization with pBR322-7.2 kilobase pair DNA (plasmid containing the 7.2-kilo base pair genomic fragment), immobilized on a nitrocellulose filter according to the procedures of McKnight *et al.*[32]. DNA (32.5 μg) was digested with *Eco*RI, the protein extracted with phenol and then precipitated with ethanol before immobilization. Hybridization was carried out in PIPES buffer (950 mM, *p*H 7.5) containing 50 μg ml^{-1} bean RNA, 2 mM EDTA, 0.4% SDS, 0.5 M NaCl and 30% formamide at 47 °C for 2 h with gentle shaking. After being thoroughly washed, the hybridized RNA was eluted from the filter and translated. The products of cell-free translation were analysed as described for *A*. Lane *h*, products coded by bean poly(A)$^+$ RNA; lane *i*, products coded by RNA selected by cloned phaseolin DNA; lane *j*, products made in the absence of added RNA, showing the prominent band (apparent 44,000) observed when ^{35}S-Met is used as substrate in the reticulocyte system.

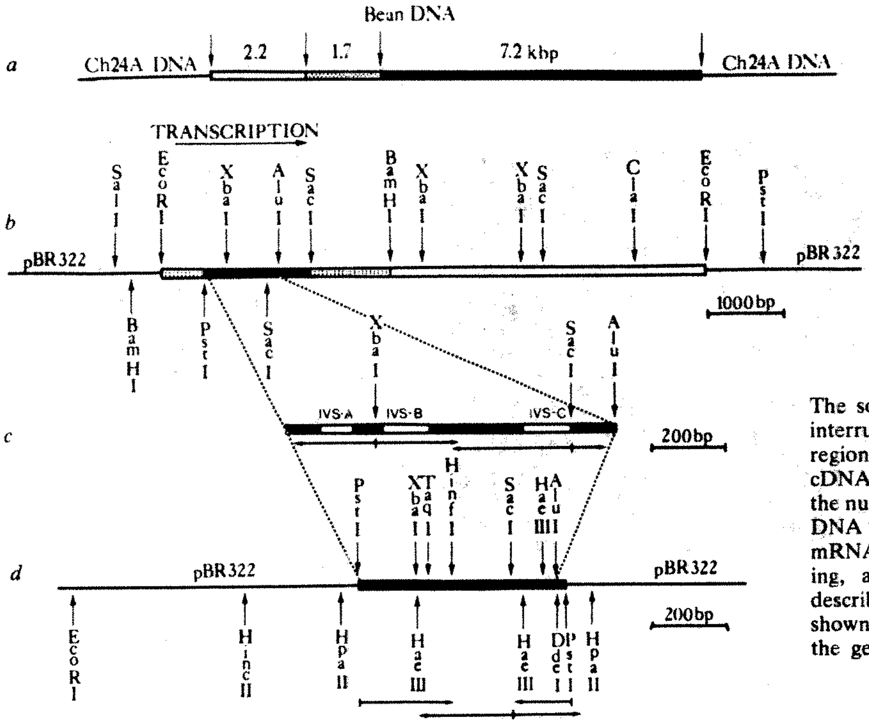

Fig. 4 Restriction maps of bean genomic DNA and phaseolin cDNA clones. *a*, Arrangement of bean DNA in clone Ch24A-177.4. Vertical arrows indicate *Eco*RI sites. The solid black line shows the region of the bean DNA that hybridizes strongly to phaseolin cDNA, the stippled area denotes weak hybridization and the white area indicates no hybridization. *b*, Detailed map of the 7.2-kilobase *Eco*RI fragment of bean DNA after subcloning in pBR322. The direction of transcription shown above frame *b* was oriented by the GT-AG rule of intervening sequences[36] and by the method described by Fryberg *et al.*[45]. *c*, Sequenced portion of the 7.2-kilobase DNA (see Fig. 5). The solid black areas indicate coding regions that are interrupted by three intervening sequences (white regions), IVS-A, IVS-B and IVS-C. *d*, Map of phaseolin cDNA in clone pBR322.74. The solid black area contains the nucleotide sequence shown in Fig. 5. Complementary DNA was prepared by reverse transcription of 16S bean mRNA[24]; synthesis of double-stranded cDNA, G-C tailing, and cloning into pBR322 were performed as described by Weinand *et al.*[33]. The horizontal arrows shown in *c* and *d* indicate the direction of sequencing for the genomic and cDNA clones, respectively. bp, Base pairs.

from a total poly(A)$^+$RNA preparation (Fig. 3*B*). Cell-free translation of the hybridized mRNA showed that only mRNA coding for phaseolin proteins had been removed by the genomic clone (Fig. 3*b*, lane *i*); no additional protein bands were observed. In agreement with the extensive sequence homology revealed by peptide mapping[7], the messenger-arrest and messenger-selection procedures affected translation of both phaseolin polypeptides *in vitro* (processing events, including glycosylation, give rise to the three polypeptides resolved for the native protein[23]).

Intervening sequences in cloned phaseolin genomic DNA

The order of the three *Eco*RI fragments of bean DNA in clone Ch24A-177.4 is shown in Fig. 4*a*. A more detailed restriction map of the 7.2-kilobase fragment that has been subcloned in pBR322 is presented in Fig. 4*b*. The solid black line denotes a region of about 1,300 base pairs that showed particularly strong hybridization to the phaseolin ^{32}P-cDNA probe.

To compare the squence of the phaseolin mRNA with that of the cloned phaseolin genomic DNA, a cDNA clone was prepared by reverse transcription of the mRNA template, followed by synthesis of double-stranded DNA with *Escherichia coli* polymerase I, G-C tailing, and insertion into pBR322 by the procedures of Weinand *et al.*[33]. cDNA clones obtained were hybridized against the ^{32}P-labelled 7.2-kilobase genomic DNA fragment; 30 cDNA clones gave positive signals (data not shown) and the strongest hybridizing cDNA clone was selected for further study. A restriction map of this cDNA clone revealed some restriction sites (*Pst*I, *Xba*I, *Sac*I and *Alu*I) in common with the genomic clone (compare Fig. 4*b*, *d*). Hence, the regions between these sites in both the cDNA and genomic clones were chosen for sequencing by the procedures of Maxam and Gilbert[34]. The comparison shown in Fig. 5 reveals that they are identical except for three regions present in the genomic DNA but absent from the cDNA. These sequences are presumed to be intervening sequences (introns) that are deleted during processing of the initial nuclear transcript to yield the mature mRNA found in the cytoplasm[35]. Their relative locations are mapped in Fig. 4*c*.

All three intervening sequences (introns) of this plant gene begin with the nucleotides GT and end with AG, as do those of animal and virus genes[36]. Recently, Lerner *et al.*[37] have compared the regions bounding introns of some 43 eukaryotic DNAs. Their study revealed a general pattern for these regions,

Fig. 5 Comparison of phaseolin genomic and cDNA sequences and the deduced polypeptide sequence. The upper line (*g*) gives the sequence of the portion of genomic DNA denoted in Fig. 4*c*. Dots indicate that the genomic sequence is identical to that of the phaseolin cDNA clone shown in the middle line (*c*). Asterisks denote intervening sequences (*IVS-A*, 88 base pairs; *IVS-B*, 124 base pairs; *IVS-C*, 129 base pairs) that are present in the genomic clone but absent from the cDNA clone. The sequence of 185 amino acids corresponding to the cDNA sequence is shown in the bottom line (*a*) by the single-letter code[46]. ^{32}P-end labelling and DNA sequencing were according to the procedure of Maxam and Gilbert[34], as modified by Slightom *et al.*[20].

Fig. 6 Comparison of phaseolin intervening sequences with that of a consensus sequence. The consensus sequence shown is from Lerner *et al.*[37]; single underlines indicate a frequency of occurrence of 45% or greater (in 43 sequences) and double underlines a frequency of 95% or more. Dots under nucleotides (nt) denote differences from the consensus sequence where a purine, X (A or G) replaces a pyrimidine, Y (U or C).

suggesting an involvement in recognition by enzymes responsible for intron excision and exon splicing[38]. A 'consensus' sequence was derived, and this is compared with the intron–exon boundaries of the phaseolin gene in Fig. 6. For phaseolin introns IVS-A and IVS-B, the boundaries agree closely with the consensus sequence, but 6 of the 11 nucleotides at the 3′-end of IVS-C differ from the generalized sequence. Of these six positions, two purine residues replace pyrimidine locations found in 95% of the sequences analysed by Lerner *et al.*[37].

Amino acid sequence from the cloned nucleotide sequences

The DNA sequences were subjected to computer analysis to determine the derived amino acid sequence. Only one open reading frame was found in the DNA sequence of the cDNA clone, and the corresponding amino acid sequence (representing a fragment of about 40% of the length of a phaseolin polypeptide) is shown in Fig. 5. The amino acid composition of this fragment seems to be representative of the overall protein as a good agreement (coefficient of correlation 0.95) was obtained between the derived sequence and that found by amino acid analysis of the native protein[39].

Peptide mapping of phaseolin positioned two methionine residues some 12 kilodaltons apart, with one residue located about 6 kilodaltons from one end of the polypeptide[7]. Only two methionine residues were present in the derived sequence shown in Fig. 5 and these are 110 amino acid residues (about 12 kilodaltons) apart. It seems likely, therefore, that the derived sequence starts some 6 kilodaltons from the N-terminus of the phaseolin polypeptide. The peptide mapping data[7] also showed that the phaseolin polypeptides have an essentially identical amino acid sequence for some 60% of their length; the heterologous region lying to the C-terminal (direction deduced from the present data) end of the molecules is presumed to be primarily responsible for the multiple phaseolin polypeptides resolved in high-resolution two-dimensional electrophoresis[9]. The cloned DNA fragments are located within the homologous region of phaseolin. Therefore, the correspondence of the genomic and cDNA sequences, and also the cross-hybridization to multiple phaseolin mRNAs (as evidenced by the hybrid-selection and hybrid-arrest data), are not surprising.

Interestingly the derived sequence reveals that 13 of the 19 aspartate residues are asparagine and of the 36 glutamate residues, 10 are glutamine; that is, there are 23 amide residues in the defined sequence of 185 amino acids. The high amide content of phaseolin reflects its role as a N-storage protein for the seed, but a high proportion of acidic residues is also expected from the general properties of this protein.

The sequence CG is rarely found in either the first or second (absent, but expected four times by random chance) or second and third (occurs once; random expectation is seven times) codon positions. Thus, of the six arginine codons available, only two are used to an appreciable extent in the sequence analysed thus far.

Conclusions

From the data available, most of the region coding for phaseolin probably lies within the area denoted by the heavy black line in Fig. 4*a*, *b*. The remainder is presumed to be within the stippled regions at each side of this area because they show weaker hybridization to the phaseolin probe and because no hybridization occurs outside these regions. Thus, it seems that clone Ch24A-177.4 contains an entire phaseolin gene, together with extensive sequences flanking its 3′ and 5′ ends.

Our results show that the structure of this plant gene is similar to that of animal DNAs in containing intervening sequences. This isolation of one of the genes encoding the major storage globulin in bean seeds should provide a basis for exploring regulatory constraints for the expression of this nutritionally significant protein.

We thank Dr O. Smithies (NIH grant GM-20069) and his associates, especially Tom Szeto, Ann Blechl and Natalie Borenstein, for guidance in cloning operations and for the use of his P2 facility in which all recombinant operations were carried out according to current NIH guidelines. We also thank Dr W. M. Fitch for the computer derivation of the amino acid code from the nucleotide sequence and Dr J. Ross for advice and a gift of S_1 nuclease. Reverse transcriptase was obtained from Dr J. W. Beard of Life Sciences through the Viral Cancer Program of the NCI and the Charon 24A was a gift from F. R. Blattner. This study was supported by grants from USDA/SEA (5901-0410-9-0357-0), NSF (PCM 78-11804), the Herman Frash Foundation and by the Research Division of the College of Agricultural and Life Sciences (Hatch 1482) of the UW-Madison.

Spectral evolution of the 5 March 1979 γ burst

E. E. Fenimore, W. D. Evans, R. W. Klebesadel, J. G. Laros & J. Terrell

University of California, Los Alamos Scientific Laboratory,
Los Alamos, New Mexico 87545

The γ burst[1] of 5 March 1979 was observed by nine experiments[2-6] widely spaced on an interplanetary scale allowing an accurate position for a γ-burst source to be determined[2,6] for the first time. Spectral observations in the range 50–1,000 keV had sufficient time resolution to resolve spectral changes within the main burst. Early in the main burst, the typical photon energies declined from a spectrum similar to a 30 keV black body to that of a ~26 keV black body. Thereafter, at the shoulder on the main burst the spectrum became harder ($KT \sim 31$ keV). The γ burst apparently triggered an X-ray pulsar with a period of ~8.0 s (refs 3–5, 7) and with a softer spectrum ($KT \simeq 12$ keV). We show here that, although the source is probably a neutron star with an obliquely rotating magnetic field, simple cooling of residual hot spots does not completely explain the pulsations.

Figure 1 presents the time history and spectral development of the 5 March 1979 γ-burst as observed by the Pioneer Venus Orbitor (PVO) detector (see ref. 8 for instrumental details). The PVO instrument varies its sampling rate depending on the count rate, which was near saturation during the burst. As a result, the intensity and spectra were recorded at the highest sampling rate of any of the satellites observing the event (either every 0.25 ms or 0.5 ms for the intensity and every ~6 ms for the spectra). Figure 1*a*, *b* presents the intensity and a hardness ratio for the burst phase of the event, Fig. 1*c*, *d* shows the intensity and hardness ratio plotted on a scale intended to display the 8-s periodicity[3-5,7]. The intensities and the hardness ratios in Fig. 1 have been binned to improve the statistics.

The hardness ratio is defined to be the ratio of the sum of (background-corrected) counts in three channels spanning 100–1,000 keV to the counts in the 50–100 keV channel. Each ratio is represented by a box whose width is the range of time of the sample and whose height is determined by $\pm 1.0\sigma$ error limits. By folding a range of black-body spectra with the instrumental response, this ratio has been mapped into an effective black-body temperature at the right-hand side of Fig. 1*d*. A black-body form was used to parameterize the data in a manner which allows an estimate of the size of the emitting region by Stefan's law.

A key feature of this burst is its very fast rise time. A reanalysis[7] of the PVO data reveals that rise times of ≤ 1 ms are consistent with the data. (This value is larger than our original[2] value of 0.25 ms.) After the sharp rise, the intensity continues to rise for ~25 ms. During this rise and until $t = 75$ ms the hardness ratio has a downward trend. Black bodies with KT from 30 to 26 keV can reproduce the observed hardness ratio during this phase. However, the observed distribution of counts has too many counts in the two higher energy bins (250–500 and 500–1,000 keV) to be entirely consistent with black-body radiation. Thus, during this phase, the hardness ratio and the effective kT should be used only as an indicator of typical energies involved. Starting at ~80 ms after the initial rise, there is a shoulder on the light curve of the main burst which lasted for ~0.1 s. This shoulder has a tendency to have a somewhat harder spectrum (~31 keV).

The significance of these variations was checked by χ^2 tests. Two ranges were tested, from $t = 0.0$ to 75 ms and from $t = 0.0$ to 120 ms. Random fluctuations could account for the observed distribution of hardness ratios only 3% and 2% of the time, respectively. We conclude that there is a statistically significant trend for the spectrum to soften initially (until t ~75 ms) and then harden during the shoulder on the γ-burst light curve. In contrast to the first 80 ms, the spectrum during the shoulder can be fit by a black-body spectrum (among other spectral forms) to within the accuracy of the statistics. As the intensity within the shoulder decays to near background (~150 c.p.s. (counts per s) at t~2.0 s), the spectrum softens dramatically.

Following the γ-burst, the source exhibited many of the characteristics of a hard X-ray pulsar[3]. The period was observed to be 8.0 ± 0.1 (refs 3–5, 7). Figure 1*c* shows the time history for the first few cycles of the pulsations. (For longer time histories where the periodicity is more evident see refs 3–5, 7). Note that, particularly for the first pulse, the hardness ratio varies in phase with the intensity from near zero between the pulses to a KT_{eff} of ~12 keV at the peak of the pulse (see Fig. 1*d*). This statistically significant variation in phase with the intensity is probably due to a varying look angle to the source as the object rotates. Due to deteriorating statistics and a greater contribution of the interpulse, it is not possible to determine whether similar spectral changes occur in the subsequent pulses.

The short rise time, the pulse period, the regularity of the pulses, the existence of an interpulse, and the observation of a line at a location consistent with the 511-keV line[3] redshifted by a 1 solar-mass neutron star, all argue that the pulsations are due to hot spots at the magnetic poles of a rotating neutron star. If so, a possible explanation for the difference between the γ-burst temperature and the X-ray pulsar temperature is that the X-ray pulsar is due to residual hot spots at the poles which are cooling.

If the observed lower temperature ($KT \sim 12$ keV) in the pulses represents a cooling from the initial hotter γ-burst, one would expect the side of the star giving the γ-burst to show a continually decreasing temperature and count rate. Figure 2

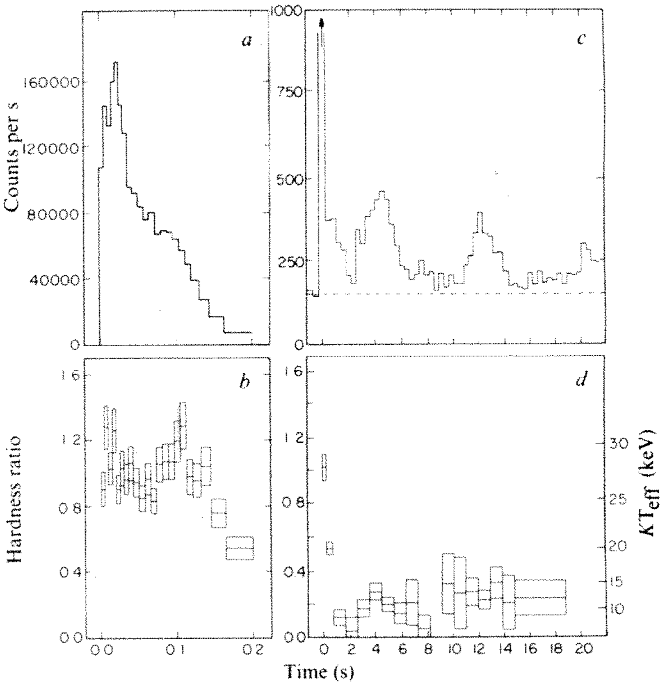

Fig. 1 The Pioneer Venus Orbiter time history and hardness ratio for the 5 March 1979 γ-burst. Initial time t_0 is at 57118.019 s UT. The dotted line in *c* is the background level. *a*, *b*, Burst; *c*, *d*, 8-s pulsation.

0028-0836/81/020042—02$01.00

contrasts the behaviour of the two sides of the star and is based on the Venera 11 and 12 observations[3] because they had the highest sensitivity and were made from three-axis stabilized satellites. Each point on the histogram represents the average intensity (scaled to the PVO sensitivity) near the peak of a pulse, determined by summing the Venera 11 and 12 observations[3] for 2 s. The cross-hatched regions represent the pole on the side of the star from which the γ-burst was observed. The diagonally striped regions are due to the opposite pole.

The flux from the side away from the burst is consistent with cooling (that is, it is decreasing). However, the pole associated with the burst shows an increasing average count rate, being 95 ± 1.57 c.p.s. for the pulse at ~8 s and 113 ± 1.7 for the pulse at $t \sim 16$ s. Applying a standard statistical test, one finds that the difference in count rate represents an $\sim 10\sigma$ deviation. We conclude that, unless the Venera data contains nonstatistical uncertainties, the 2-s averaged count rate from the pole associated with the burst increased between $t \sim 8$ and ~16 s.

Figure 1*d* shows how the spectrum changed between these two intervals. From $t \sim 7.0$ to 8.25 s, the hardness ratio was ~0.05. During the period $t \sim 8.25$–9.25 s, the high energy channels (100–1,000 keV) were below anticipated background, implying a hardness ratio of zero. In contrast to these values, the interval from $t \sim 15.0$ to 18.75 s had a hardness ratio of 0.23. The increase in the observed count rate in the higher energy channels between the two pulses is statistically significant at the 98% confidence level. Also, according to the PVO data the overall observed count rate significantly decreased (5.8σ), implying that the temperature was indeed increasing while either the source size was decreasing or the column density was increasing. However, the decrease in the PVO overall count rate is not in accord with the increase observed from the three-axis stabilized observations of the Veneras. The PVO observations were possibly affected by spin modulation of the satellite. Although the spin axis was pointed to within 3 degrees of the location of the burst[2,6], there could have been sufficient material moving in and out of the field of view to cause the small discrepancy between PVO and the Veneras. In either case (if the intensity increased as observed by the Veneras or if the hardness ratio increased as observed by PVO), the cooling explanation is unlikely. Because the PVO had a possible (although unlikely) source of systematic error, we are inclined to accept the Venera result that the intensity increased. If so, the increase in hardness ratio observed by PVO is less certain.

One possibility consistent with the observations is that the γ-burst altered the magnetosphere, triggering a short-lived (few minutes), accretion-driven, hard X-ray pulsar. The difference in hardness ratio between the γ-burst and the pulsation then is a result of their being produced by separate but related energy sources. One constraint on such a model would be whether the magnetosphere can hold sufficient material without violating the observed upper limit on the steady state X-ray flux[9]. In addition the source would have to be close enough to avoid violating the Eddington limit[10], ruling out N49 as the counterpart. A similar explanation is that the neutron star suffered a collision with a nearly intact comet (as recently proposed in ref. 11 for the 5 March γ-burst) with the pulsations then being due to left over debris accreting down the field lines.

An accreting model for the pulses is not the only possible explanation. For example, if the initial γ rays were collimated into a beam that was not colinear with our line of sight to the pulsar, and if the beam subsequently broadened between $t \sim 8$ s and ~16 s, then the average count rate could increase even if the source were cooling. Indeed, ref. 3 shows that the pulse at $t \sim 8$ s was probably narrower than subsequent pulses, contributing to its lower average count rate. There must be other possible beam geometries that could have a similar effect.

The nature of the γ-burst remains uncertain. We will not consider magnetospheric accretion because current models[12,13] predict rise times that are 100–1,000 times larger than observed for the γ-burst. Because both thermonuclear flashes[14,15] and internal restructuring[16,17] probably originate beneath the outer surface of the neutron star but propagate to the surface in a similar manner, they might be expected to have similar characteristics. However, other features of the source might be used to distinguish between them. In particular, a successful model must be able to function in the presence of a magnetic field, be able to turn on a hard X-ray pulsar, and give recurring bursts with a dynamic range of 100 (refs 3, 18).

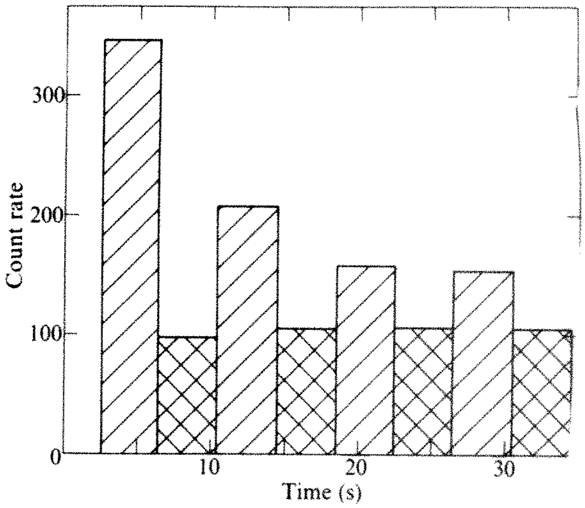

Fig. 2 Average count rate for the X-ray pulses obtained by summing the Venera 11 and 12 observation over 2-s periods (see ref. 3), normalized to the PVO count rate. The cross-hatched regions represent the side of the star associated with the γ-burst and the diagonally-striped regions represent the opposite side.

In the context of internal restructuring, a spin axis different from the magnetic axis (as implied by the pulsations) can apply external torques to the crust of the neutron star which builds up strain even for a slowly rotating neutron star (see review in ref. 19). The resulting starquake would alter the magnetosphere, perhaps providing the short-lived instability driving the X-ray pulsar by accretion. Current models of thermonuclear flashes have reached the quantitative stage for unmagnetized stars but not for magnetized stars. It has been suggested[15,20] that a magnetic field inhibits the flashes and that is why X-ray bursters show no sign of rotational modulation[15]. Because neither internal restructuring models nor magnetized neutron star models have yet reached a stage where quantitative comparisons can be made, the mechanism of the 5 March 1979 γ-burst remains uncertain.

Is the light cylinder the site of emission in pulsars?

Houshang Ardavan

Institute of Astronomy, University of Cambridge, Madingley Road, Cambridge CB3 0HA, UK

There is no agreement in reports on the oblique-rotator model of pulsars[1-9] as to the site of emission within the pulsar magnetosphere. It is generally assumed, however, that the plasma-electromagnetic fields constituting the magnetosphere obey the quasistatic constraint $\partial f/\partial t = -\omega_0 \partial f/\partial \varphi$, where ω_0 is the angular frequency of rotation of the central neutron star, t the time, and the cylindrical coordinates (r, φ, z) refer to an inertial frame whose z-axis is coincident with the axis of rotation of the star. Accordingly, the pulsar emission is attributed to a source whose distribution has a rigidly rotating pattern; though, of course, none of the charged particles which constitute the source and provide the medium for the propagation of the pattern associated with the source, are themselves constrained to be co-rotating. Here, the spectral distribution of the power emitted by such a rotating pattern is calculated and it is shown that electromagnetic radiation of frequency $\omega \gg \omega_0$, the observed radiation from pulsars, is produced predominantly by the electric currents at the light cylinder $r = c/\omega_0$ of the magnetosphere. This is a model-independent result; it is valid irrespective of the type of emission mechanism and applies to all previously proposed models of the magnetosphere which are quasistatic and in which the radial length scale of the plasma distribution is of the order of c/ω_0.

From the retarded solution of the inhomogeneous Maxwell's equations it follows[10] that the energy radiated per unit frequency and per unit solid angle by any localized distribution of electric current is

$$\frac{\mathrm{d}I(\omega)}{\mathrm{d}\Omega} = \frac{\omega^2}{4\pi^2 c^3}\left|\int \mathrm{d}t \int \mathrm{d}^3x\, \hat{\mathbf{n}} \times [\hat{\mathbf{n}} \times \mathbf{j}(\mathbf{x}, t)] \exp[\mathrm{i}\omega(t - \hat{\mathbf{n}}\cdot\mathbf{x}/c)]\right|^2 \tag{1}$$

where $\mathbf{j}$ is the current density, $\hat{\mathbf{n}}$ is the unit vector directed from the position of the source to the observation point, and the domain of integration extends over all values of the space-time coordinates $\mathbf{x}$ and t. In the inertial coordinate system whose origin is coincident with the position of the neutron star and whose z-axis lies along the rotation axis $\hat{\mathbf{k}}$, an arbitrarily fixed direction of $\hat{\mathbf{n}}$ may be designated by the spherical angles (θ_0, φ_0) where $\theta_0 = \cos^{-1}(\hat{\mathbf{n}}\cdot\hat{\mathbf{k}})$. If in addition the vector $\mathbf{j}$ is decomposed into its cylindrical components (j_r, j_φ, j_z) and $\mathbf{x}$ is expressed in terms of (r, φ, z), then equation (1) assumes the form

$$\frac{\mathrm{d}I(\omega)}{\mathrm{d}\Omega_0} = \frac{\omega^2}{4\pi^2 c^3}|A_\|(\omega, \theta_0, \varphi_0)\hat{\mathbf{e}}_\| + A_\perp(\omega, \theta_0, \varphi_0)\hat{\mathbf{e}}_\perp|^2 \tag{2}$$

$$= \int \mathrm{d}t \int r\,\mathrm{d}r\,\mathrm{d}z\,\mathrm{d}\varphi\, j_{\|,\perp}(r, \varphi, z, t) \times \exp\left\{\mathrm{i}\omega\left[t - \frac{r}{c}\sin\theta_0\cos(\varphi - \varphi_0) - \frac{z}{c}\cos\theta_0\right]\right\} \tag{3}$$

$$j_\| = j_r \sin(\varphi - \varphi_0) + j_\varphi \cos(\varphi - \varphi_0) \tag{4}$$

and the $\theta_0[j_\varphi \sin(\varphi - \varphi_0) - j_r \cos(\varphi - \varphi_0)] + j_z \sin\theta_0$ (5)

$\hat{\mathbf{e}}_\perp = \hat{\mathbf{n}} \times \hat{\mathbf{e}}$ns $\|$ and $\perp$ are defined by $\hat{\mathbf{e}}_\| = (\hat{\mathbf{k}} \times \hat{\mathbf{n}})/|\hat{\mathbf{k}} \times \hat{\mathbf{n}}|$ and

The qua. the cylindric constraint can now be introduced by requiring of φ and t in nponents of the current density to be functions that is by writi ombination $\varphi - \omega_0 t \equiv \hat{\varphi}$ only (see refs 1, 11),

$$j_{r,\varphi,z}(r, \varphi, z, t) = j_{r,}(r, z, \hat{\varphi}) = \int_{-\infty}^{+\infty} j_{r,\varphi,z}(r, z, \hat{\varphi}')\delta(\hat{\varphi}' - \hat{\varphi})\,\mathrm{d}\hat{\varphi}' \tag{6}$$

The second part of equation (6) is no more than a mathematical identity in view of the definition of the Dirac delta function. It provides a useful representation of the quasistatic functions (j_r, j_φ, j_z), however, because by making the integrals over φ and t in equation (3) independent of $\mathbf{j}$, this representation enables us to derive general expressions for $A_\|$ and $A_\perp$ in which the two variables φ and t are everywhere replaced by the single variable $\hat{\varphi}' = \varphi' - \omega_0 t'$. In the case of $A_\|$, for instance, once equation (6) is inserted in equation (3) the integration over t may be immediately performed to obtain

$$\begin{aligned} A_\| = {} & \frac{1}{\omega_0}\exp\left(\mathrm{i}\frac{\omega}{\omega_0}\varphi_0\right)\int r\,\mathrm{d}r\,\mathrm{d}z\,\mathrm{d}\hat{\varphi}' \\ & \times \exp\left[-\mathrm{i}\frac{\omega}{\omega_0}\left(\hat{\varphi}' + \frac{z\omega_0}{c}\cos\theta_0\right)\right]\left\{j_r(r, z, \hat{\varphi}')\int_0^{2\pi}\mathrm{d}\sigma \sin\sigma\right. \\ & \times \exp\left[\mathrm{i}\frac{\omega}{\omega_0}\left(\sigma - \frac{r\omega_0}{c}\sin\theta_0\cos\sigma\right)\right] \\ & + j_\varphi(r, z, \hat{\varphi}')\int_0^{2\pi}\mathrm{d}\sigma\cos\sigma \\ & \left.\times \exp\left[\mathrm{i}\frac{\omega}{\omega_0}\left(\sigma - \frac{r\omega_0}{c}\sin\theta_0\cos\sigma\right)\right]\right\} \end{aligned} \tag{7}$$

where $\sigma \equiv \varphi - \varphi_0$. The integrals over σ can also be carried out explicitly. They are non-zero only when the ratio ω/ω_0 is an integer (ref. 10, p. 96), and are expressible in terms of Bessel functions of integer order m when $\omega = m\omega_0$ (ref. 12, p. 209). Because $\mathbf{j}(r, z, \hat{\varphi})$ is left unchanged whether φ is increased by 2π or equivalently t is decreased by $2\pi/\omega_0$, it is not unexpected that the spectral distribution of the radiation should in the present case be discrete.

The quasistatic versions of $A_\|$ and $A_\perp$ thus obtained, when inserted in equation (2), yield the following expression for the angular distribution of power radiated into the mth harmonic:

$$\frac{\mathrm{d}P_m}{\mathrm{d}\Omega} = \frac{m^2\omega_0^2}{2\pi c^3}|C_\|(m, \theta)\hat{\mathbf{e}}_\| - C_\perp(m, \theta)\hat{\mathbf{e}}_\perp|^2 \tag{8}$$

where

$$C_\| = \int r\,\mathrm{d}r\,\mathrm{d}z\,\mathrm{d}\hat{\varphi}\exp\left[-\mathrm{i}m\left(\hat{\varphi} + \frac{z\omega_0}{c}\cos\theta\right)\right] \times \left[j_\varphi\frac{dJ_m(m\xi)}{d(m\xi)} + \frac{\mathrm{i}}{\xi}j_r J_m(m\xi)\right] \tag{9}$$

$$C_\perp = \int r\,\mathrm{d}r\,\mathrm{d}z\,\mathrm{d}\hat{\varphi}\exp\left[-\mathrm{i}m\left(\hat{\varphi} + \frac{z\omega_0}{c}\cos\theta\right)\right] \times \left[j_r\cos\theta\frac{dJ_m(m\xi)}{d(m\xi)} - \mathrm{i}\left(\frac{\cos\theta}{\xi}j_\varphi - \sin\theta j_z\right)J_m(m\xi)\right] \tag{10}$$

and

$$\xi \equiv \frac{r\omega_0}{c}\sin\theta$$

Here, $\hat{\varphi}'$ and θ_0 have been written $\hat{\varphi}$ and θ for brevity, and $\mathrm{d}I/\mathrm{d}\Omega$ has been replaced by $(2\pi/\omega_0^2)(\mathrm{d}P_m/\mathrm{d}\Omega)$ to convert energy per unit frequency to power per harmonic. Note that j_r, j_φ and j_z are functions of $(r, z, \hat{\varphi})$, and that the integrals extend over all values of r, z and $\hat{\varphi}$ for which the current density is non-zero. It is easy to see that when specialized to the case of a point source for which $j_r = j_z = 0$, equation (8) is the same as the corresponding expression for synchrotron radiation[12].

In the range of frequencies $m \gg 1$, asymptotic values of the Bessel function appearing in equation (8) are given by[13]

$$J_m(m\,\mathrm{sech}\,\alpha) \sim (2\pi m\tanh\alpha)^{-1/2}\exp[m(\tanh\alpha - \alpha)] \tag{11}$$

or

$$J_m(m\sec\beta) \sim (\tfrac{1}{2}\pi m\tan\beta)^{-1/2}\cos[m(\tan\beta - \beta) - \tfrac{1}{4}\pi] \tag{12}$$

0028-0836/81/020044—02$0

depending on whether ξ is greater or less than one. When the current density has limited total fluctuation in the radial direction, therefore, the rapid oscillation of the Bessel function in the interval $\xi > 1$ renders the magnitude of the power originating from $(r\omega_0/c)\sin\theta > 1$ negligible. According to the principle of stationary phase, the main contributions to the values of the integrals in equation (8) for $\xi > 1$ come from the neighbourhood of the surface where

$$\frac{\mathrm{d}}{\mathrm{d}\beta}[m(\tan\beta-\beta)-\tfrac{1}{4}\pi]=m\left[\left(\frac{r\omega_0}{c}\sin\theta\right)^2-1\right]=0 \qquad (13)$$

A similar conclusion in fact follows from the behaviour of the Bessel function in $\xi < 1$. Equation (11) in conjunction with the asymptotic value of the Bessel function at $\xi = 1$ (ref. 13) shows that the ratio

$$\frac{J_m(m\operatorname{sech}\alpha)}{J_m(m)} \sim \frac{3^{2/3}\Gamma(\frac{2}{3})}{2^{1/3}(2\pi)^{1/2}}\,\frac{\exp[m(\tanh\alpha-\alpha)]}{m^{1/6}\tanh\alpha} \qquad (14)$$

has a sharp peak in the neighbourhood of $(r\omega_0/c)\sin\theta = 1$. In this case, the order of magnitude $m^{-1/6}\exp(-\alpha m)$ of this ratio for $\alpha \gg 1$, that is for $r\omega_0/c \ll 1$, is small for the same mathematical reason that the power radiated by a particle in the non-relativistic as compared with that in the extreme relativistic regime is small. This mathematical similarity is, of course, not fortuitous (see ref. 11).

Equation (8) also shows that for a current density whose length scale of variation along z is c/ω_0, the main contribution to the values of $C_\parallel$ and $C_\perp$ is received from directions where $m\cos\theta \simeq 1$, because the integrals over z simply represent the Fourier amplitudes of the current density corresponding to the wave number $m\omega_0\cos\theta/c$. This beaming of the high-frequency radiation into $\theta \simeq \pi/2$, in turn implies that ξ attains the value unity in the neighbourhood of the light cylinder. Therefore I suggest that the higher the frequency, the closer the site of emission to the light cylinder. Because the quasistatic condition is associated with a rotating pattern for the source (see ref. 11 for a detailed discussion), it is not too surprising that the emission from inside the light cylinder should be much smaller than that from the vicinity of the light cylinder; the more unexpected outcome of the present analysis is that the emission from beyond the light cylinder is also relatively small.

Because it follows from a formalism in which the electric current is left unspecified, the present result is clearly independent of both the details of the mechanism by which the radiation is emitted and of the effects of the plasma through which it is propagated. The structure of the magnetosphere, moreover, has a bearing on this result only in that the plasma distribution is required to have a length scale of the order of c/ω_0. The validity of the quasistatic condition is, of course, implicitly dependent on the existence of an agent—such as a large scale magnetic field—which affects the coupling between the neutron star and the magnetosphere. However, imposing the quasistatic constraint can also be justified on independent observational grounds[11].

The present analysis clearly establishes that there is an inconsistency in those models which adopt the quasistatic constraint and at the same time identify the surface of the neutron star as the site of emission. According to equation (14), the power radiated into the mth harmonic $\omega = m\omega_0$ receives a contribution from the electric currents in the vicinity of the light cylinder which is by a factor of the order of $m^{1/3}\exp(2\alpha m)$ greater than that received from the vicinity of the neutron star. Thus, even for radio waves with $m \simeq 10^8$, the observed emission originates almost exclusively from the light cylinder when the electric currents are distributed throughout the magnetosphere.

The present discussion has centred on only one particular implication of equation (8), but in fact this equation, which incorporates the coherent character of the radiation automatically, also constitutes the departure point for a study of the polarization and the spectrum of the pulsar emission.

Photovoltaic properties of merocyanine solid-state photocells

G. A. Chamberlain & P. J. Cooney

Shell Research Ltd, Thornton Research Centre, PO Box 1,
Chester CH1 3SH, UK

S. Dennison

Department of Physical Chemistry, Lensfield Road, University of
Cambridge, Cambridge CB2 1EP, UK

Considerable progress has been made in improving the sunlight conversion efficiency of solid-state organic photovoltaic cells. Ghosh *et al.*[1] report a 0.7% efficiency for a merocyanine dye Schottky barrier cell. We expect that improvements in energy conversion efficiency may follow if merocyanines of low ionization potential are used in photovoltaic cells, in which the dye layer contains a strongly electronegative dopant such as iodine. To test these ideas we report here the photovoltaic quantum yields and sunlight conversion efficiences of a series of merocyanines in which the molecular properties have been varied systematically.

Ghosh *et al.*[1] used an evaporated thin film of the dye, sandwiched between thin Al/Al_2O_3 and silver layers and illuminated through the Al contact for maximum response. They proposed that charge carriers are generated by electron transfer from an exciton to unoccupied metal orbitals or oxide surface states at the aluminium/dye interface. The magnitude of the photocurrent at a given light intensity is then governed by the field dependence of geminate recombination between the transferred electron on the aluminium and its positive image charge in the dye layer. We have observed, however, that the photovoltaic response of this type of cell is extremely sensitive to the presence of added gases, for example, ambient air and particularly iodine vapour. By preparing and testing the cell in a vacuum of 10^{-6} torr we have found that the magnitude of the photovoltaic response increases by several powers of 10 when the dye is doped with iodine vapour; the dark conductivity of the dye, however, is unchanged. It seems likely, therefore, that charge carriers may be photogenerated by a charge transfer process from excited dye to iodine, possibly through an exciplex precursor. The undesirable back electron transfer reaction must then compete with charge carrier separation by hopping, which occurs in the built-in field in the region of the aluminium/dye interface. The extent of charge transfer from a donor (the dye) to an acceptor (iodine) in the ground and excited states of the complex increases as the ionization potential of the donor decreases[2].

In general terms[3], a merocyanine dye consists of an electron-donating group (the donor) linked by a conjugated polymethine bridge to an electron-accepting group (the acceptor). The intramolecular charge transfer that occurs in the ground and excited states depends on the relative strengths of the donor and acceptor groups. In addition, the stability and lifetime of the

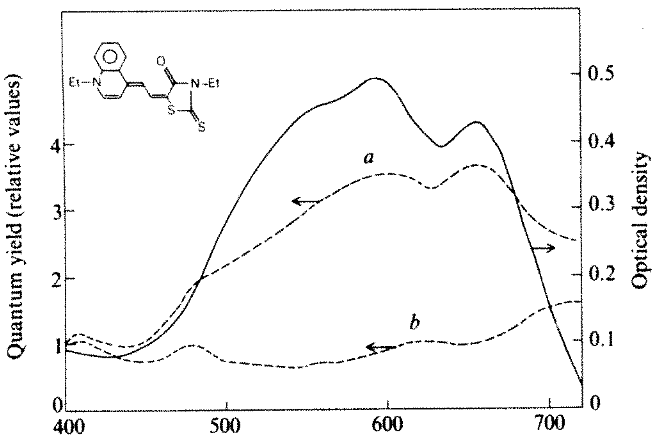

Fig. 1 Absorption spectrum and photocurrent action spectra for dye *E*-Ac, ~35 nm thick. *a*, Illumination through Al; *b*, illumination through Au.

cationic form of the dye that is produced after intermolecular charge transfer in photovoltaic cells depends on the ease with which the positive charge can be delocalized. This is determined to a large extent by the ionization potential of the dye, which in turn depends on the donating ability of the donor fragment. Therefore, to assess the effect of donor strength and bridge length on photovoltaic behaviour we have screened the responses of several merocyanines containing the same acceptor group (ethyl rhodanine). Some interesting molecular structure/photovoltaic activity relationships have emerged.

Solid-state sandwich cells were prepared by the sequential vacuum evaporation and deposition of thin films of aluminium, aluminium oxide, merocyanine dye and gold onto a quartz or Pyrex substrate supplied with two indium contacts. Active areas of about 5 cm^2 were readily obtained. The cells were then doped with iodine by vapour diffusion. An area of 0.064 cm^2 was illuminated with a single-strand Crofon fibre optic. Dark and photoelectric responses were monitored throughout the preparation of the cell and the apparatus was arranged such that the vacuum was maintained at about 10^{-6} torr. The thickness of each layer was controlled during evaporation by means of a Kronos quartz crystal thickness monitor. The metals used were at least 99.99% pure, and the purity of the dyes (~99%), prepared at Thornton Research Centre, was checked after double recrystallization by elemental analysis, IR spectroscopy and mass spectroscopy. Redox potentials were obtained from cyclic voltammograms of CH_2Cl_2 solutions of the dyes using Pt electrodes and tetrabutyl ammonium perchlorate as supporting electrolyte against a Ag/AgCl reference electrode.

The merocyanines and data obtained are shown in Table 1. For comparison, in the solid-state cells the thickness of each dye was maintained at about 35 nm, and quantum yields (ϕ_ε) based on photons absorbed by the dye (that is, correcting for transmittance of the aluminium layer) were measured at the peak of the absorption spectrum and in a range of light intensity where the photocurrent varied linearly. For donors A–E, ϕ_ε followed the ease of oxidation of the dye, which correlates well with the expected trends from charge transfer behaviour, resonance theory and the Brooker deviation[4], which give a qualitative measure of the relative donating ability of the donor residue.

Increasing the bridge length reduces the ionization potential and extends the chromophore; compare results for donors E, F and G. Unfortunately, merocyanine G-Ac became unstable during sublimation, and a thermal rearrangement to a non-coloured form, possibly a spiropyran[5], occurred. No photovoltaic effect was observed because the compound did not absorb in the visible portion of the spectrum. The original compound, however, could be regenerated by dissolving the thin film in ethanol, suggesting that a reversible tautomerization had occurred. Merocyanine F-Ac was tested in the hope that removal of the bridge between donor and acceptor groups would reduce the likelihood of tautomerization. However, no photovoltaic effect was observed, even though there was no evidence of oxetane formation. This result may be explained in terms of the excited-state lifetime of the dye. The steric hindrance between donor and acceptor groups leads to loss of coplanarity. Tredwell and Keary[6] have shown that twisting of heterocyclic rings about the polymethine bridge to relieve steric strain enhances the rate of internal conversion to the ground state, because excited state energy can then be efficiently dissipated by intramolecular vibration and rotation. We estimate from their results that the excited state lifetime $(\Sigma k)^{-1}$ for dye F-Ac is of the order of 1 ps. The charge generation process

$$(\text{dye})^* + \text{dopant} \xrightarrow{k_d} (\text{dye})^+ + (\text{dopant})^-$$

has a first-order rate constant[7] of about $10^7\ \text{s}^{-1}$ for a dopant concentration of 10^{19} molecules cm^{-3}. Thus, the quantum efficiency ϕ_d for excited state dissociation to charge carriers given by:

$$\phi_d = \frac{k_d[\text{dopant}]}{k_d[\text{dopant}] + \Sigma k}$$

has a value of about 0.001%, which is near the limit of detectability in our system. When combined with other energy dis-

* Tungsten-halogen lamp.

sipation processes, such as carrier recombination, this estimate accounts for the absence of detectable photocurrent.

The photocurrent action spectra for dye E-Ac are shown in Fig. 1. Good correspondence between action spectrum and absorption spectrum is observed for illumination through the aluminium electrode. However, an inverted behaviour is apparent when the cell is illuminated through the gold side. These results are consistent with the formation of a rectifying junction at the aluminium/dye contact. In the case of gold illumination, the dye itself acts as a filter of the strongly absorbed light, and weakly absorbed photons at the sides of the absorption peaks penetrate to the rectifying junction and make a major contribution to the photocurrent.

The dyes were tested for their photovoltaic power conversion efficiency, η_s, in simulated AM2 sunlight from a Thorn CSI lamp. η_s was calculated from the short-circuit current (I_{sc}), open-circuit voltage (V_{oc}) and fill factor (FF) at known incident light intensity (I_o) using the equation:

$$\eta_s = I_{sc} V_{oc} \mathrm{FF} / I_o$$

and the results are shown in Table 2. Efficiencies were dependent not only on donor type but also on the relationship between I_{sc} and I_o. The more efficient dyes, C-Ac, D-Ac and E-Ac, had linear photocurrent dependences up to and beyond the light intensities used. Taking the response for the most efficient dye, E-Ac, for a film of about 25 nm thickness, we have estimated the power conversion efficiency based on light absorbed, η_s', defined as:

$$\eta_s' = \frac{I_{sc}}{e\int_{E_g}^{E_m} A(E)N(E)\mathrm{d}E} \cdot \frac{eV_{oc}}{E_g} \cdot \mathrm{FF} \times 100\%$$

$$= [\text{average quantum yield}][\text{voltage factor}][\text{fill factor}] \times 100\%$$

where e is the electronic charge, E_m is the high-energy limit of the solar spectrum (taken as 3.1 eV), E_g is the absorption threshold for the dye (taken as 1.7 eV), $A(E)$ is a factor which accounts for the dye absorbance and $N(E)$ is the flux density of photons incident on the dye film per wavelength interval. From estimates of the average quantum yield (0.13), voltage factor (0.42) and measured fill factor (0.39) we calculate $\eta_s' = 2.1\%$.

Further exploitation of the relationship between molecular structure and photovoltaic behaviour should lead to further improvements in the conversion efficiency.

We thank G. Ellis for preparing pure samples of the merocyanine dyes.

Chemical changes during dyke metamorphism in high-grade basement terrains

Barry L. Weaver & John Tarney

Department of Geology, The University of Leicester,
Leicester LE1 7RH, UK

Trace element geochemistry is an important tool in deciphering the petrogenesis of igneous, and particularly basaltic, igneous rocks, and in assigning a possible tectonic setting to these rocks[1,2]. Studies of the trace element geochemistry of metamorphosed igneous rocks often implicitly assume element immobility during metamorphism even though recent studies[3–7] have demonstrated the sometimes quite extreme mobility of certain trace elements, and especially of the petrogenetically important rare-earth elements (REE), during low-grade (zeolite–greenschist facies) metamorphism. The mobility of trace elements at higher grades of metamorphism is poorly known, although there is some evidence[8] for the mobility of large ion lithophile (LIL—Rb, K, Th, Ba, Sr) elements, but not the REE, during amphibolite facies metamorphism. The REE also seem to be stable through the amphibolite to granulite facies transition[9,10]. We have studied a suite of ultramafic to mafic dykes (the Scourie dykes) cutting regrogressed Lewisian granulites in the Assynt region, north-west Scotland[11] and conclude that the mobility of trace elements is not controlled solely by the degree or grade of metamorphism, but more by the availability of a fluid phase for element transfer.

The intrusion of the Scourie dolerite dykes has been dated at 2,390 Myr (ref. 12). In the Assynt region, the dyke suite may have been intruded over a time span as great as 200 Myr (ref. 13), intrusion of the early dolerites being followed by intrusion of ultramafic dykes and later, rather minor, dolerites[11]. There is evidence for the injection and metamorphism of these dykes at depth in the crust (under pressures of 5–7 kbar) into hot (~500 °C) country rock gneisses, during the waning stages of the Inverian retrogression of Scourian granulites[11,14–16]. The dykes are variably metamorphosed, with the earlier dykes being in general more heavily metamorphosed[11,14]. The metamorphism of dolerite dykes from the Scourie area has been described by Sutton and Watson[17], who recognized six progressive stages of metamorphism. Metamorphic conditions in Assynt (of the lower amphibolite facies) were somewhat lower than at Scourie[11]. The metamorphism of Assynt ultramafic dykes has been detailed elsewhere[11].

The present study of the chemical changes associated with the metamorphism of Scourie dykes arises from the analysis of a large number of dykes from Assynt for a wide range of elements[18]. Amongst the trace elements, the incompatible elements are of most use in petrogenetic modelling, and it is important to assess the behaviour of these elements during metamorphism. As both fresh and variably metamorphosed dykes are present in Assynt, the behaviour of incompatible elements on metamorphism can be gauged by the normalization of the incompatible element abundances in an amphibolized dyke to those in a cogenetic fresh dyke. Ignoring possible effects due to phenocryst mineralogy, the resulting incompatible element pattern should be linear on such a plot if mobilization of trace elements has not occurred. The anomalous behaviour of an element on such a plot will, however, reflect, if phenocryst effects can be discounted, mobility of that element during metamorphism. It has been demonstrated[18] that during fractionation of the cogenetic fresh Scourie dolerites, the levels of incompatible elements increase steadily, with little change in incompatible element ratios, except for Sr, which has an approximately constant abundance due to the plagioclase fractionation which these dykes seem to have undergone. Bearing this in mind, the metamorphic effects on the chemistry of Scourie dolerites is illustrated in Fig. 1*a*, where the incompatible element abundances (arranged in the order given in ref. 19) in both a fresh and an amphibolized dolerite dyke have been normalized relative to a fresh dolerite. The fresh dolerite (sample 916) on this plot (Fig. 1*a*) displays an overall flat pattern, but with a negative Sr anomaly and a positive Ti anomaly which can be attributed to crystal fractionation effects[18]. On the other hand, the amphibolized dolerite (sample 689, Fig. 1*a*), in which pyroxene has been completely replaced by hornblende–quartz aggregates, the feldspar is altered and recrystallized, and the original texture of the rock has disappeared, displays significant relative depletion in Sr, Ba, K and Rb. The Sr anomaly can again be attributed to crystal fractionation[18], but the depletion in Ba, K and Rb is a direct result of amphibolite facies metamorphism. To assess at what stage in the metamorphic process appreciable K and Rb loss occurs, the analysed dolerites have been divided into three groups:

(1) those dykes which are fresh, with little or no replacement of pyroxene by secondary amphibole (nine samples);
(2) those dykes in which there is complete replacement of pyroxene, but with textural preservation (four samples);
(3) those dykes in which recrystallization of feldspar and the hornblende–quartz aggregates has occurred with destruction of the original texture (eight samples).

The average K_2O and Rb contents for the three groups are 0.82% and 18 p.p.m., 0.92% and 18 p.p.m., and 0.66% and 8 p.p.m. respectively, yielding average K/Rb ratios for each group, with 1σ standard deviations, of 392 ± 63, 422 ± 115 and 759 ± 356. Clearly then, substantial loss of K and Rb (and other LIL elements), and the consequent development of high K/Rb ratios, occurs only on recrystallization of the dykes.

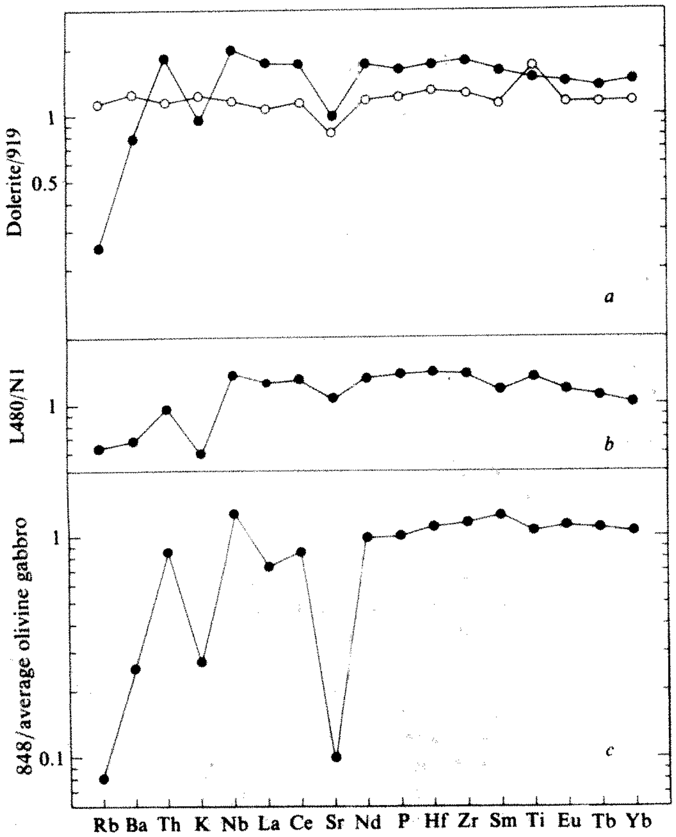

Fig. 1 Plot of incompatible element abundances in: *a*, fresh dolerite (○, 916) and an amphibolized dolerite (●, 689) normalized to a fresh dolerite dyke (919); *b*, an altered 'norite' dyke (L480) normalized to a fresh 'norite' dyke (N1); and *c*, an altered olivine gabbro dyke (848) normalized to the average of four fresh olivine gabbros.

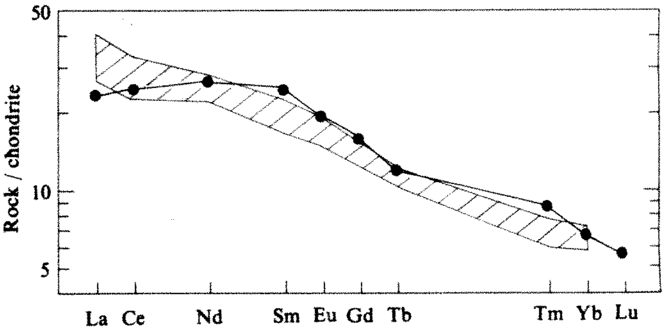

Fig. 2 Chondrite normalized plot of REE abundances in an altered olivine gabbro (●, 848) compared with the field for four fresh olivine gabbro dykes (from ref. 18). Chondrite normalizing values used are those of Nakamura[23].

Figure 1*b*, *c* investigates the metamorphism of ultramafic Scourie dykes. In Fig. 1*b*, sample L480 (the Loch Crocach 'norite' dyke[11]), which is heavily amphibolized throughout its length, has been normalized to a cogenetic fresh norite dyke from Scourie (dyke N1 of ref. 15). Here the LIL elements K, Rb, Ba and, less clearly, Sr seem to have been mobilized (Fig. 1*b*) during metamorphism of this ultramafic dyke. However, the depletion of these elements is not particularly severe, perhaps because sample L480 shows a considerable degree of textural preservation, with fresh primary feldspar and pseudomorphs after pyroxene still obvious. On the other hand, Fig. 1*c* illustrates the chemical effects of metamorphism of the olivine gabbro dykes from Assynt[11]. Sample 848 is, on the basis of most major and trace elements, clearly related to the olivine gabbro dykes[18], although the original olivine–augite–orthopyroxene–plagioclase–amphibole–mica assemblage[11] has been totally replaced by an amphibole–chlorite–ore mineralogy, with no textural preservation. This extreme metamorphism has caused severe depletion in Sr, Ba, K and Rb in the amphibolized olivine gabbro, while Th, La and Ce are less strongly depleted. The depletion in the light REE is perhaps better illustrated in Fig. 2, where the REE abundances in 848 are compared with the range in REE patterns for four fresh olivine gabbro dykes[18].

Apparently then, amphibolite facies metamorphism of Scourie dykes leads to appreciable mobilization of certain trace elements on recrystallization of the dyke. In this case, depletion in the LIL elements and the LREE is demonstrable, with mobility decreasing in the approximate order: $\mathrm{Rb} > \mathrm{Ba} \simeq \mathrm{K} \simeq \mathrm{Sr} \gg \mathrm{Th} \simeq \mathrm{La} \simeq \mathrm{Ce}$, although depletion in Th, La and Ce only becomes significant on extreme amphibolization. It would also seem reasonable that the mobility of Sr will depend on the stability of feldspar: in those rocks which retain feldspar on amphibolization (the dolerite dykes and the Loch Crocach norite), Sr is not particularly mobile, while in the amphibolized olivine gabbro, which contains no relict feldspar, Sr has been severely depleted. On the other hand, the elements Nb, P, Hf, Zr, Ti and the middle- and heavy-REE are immobile for all degrees of metamorphism observed in the Scourie dykes.

The critical factor seems to be not the grade of metamorphism, but the availability of a fluid agency for element transfer. During the amphibolite-facies retrogression of the enclosing granulite-facies gneisses (which largely preceded, but overlapped, the period of dyke injection), significant chemical changes as the gneiss compositions readjusted to their new equilibrium mineral assemblages have been recorded[20]. In this case, very considerable volumes of hydrous fluids were available to assist with element redistribution. The dykes, being intruded towards the end of this period of retrogression, were metamorphosed to a degree dependent on the availability of hydrous fluids. Thus they are metamorphosed progressively from their margins to their centres[11]. The dyke margins, which are often sheared, provided the means of access of these hydrous fluids from below[20]. High metamorphic temperatures alone were not sufficient to cause recrystallization, and only when the dykes had been thoroughly metamorphosed, implying a large fluid flux, are there significant chemical changes. Conversely, low-grade metamorphism of ocean-floor basalts is frequently associated with quite large chemical changes[21], even affecting rare-earth elements[22]; however, this is frequently related to the action of hydrothermal convection cells at mid-ocean ridges in which the fluid flux is of some magnitude[21], and high water–rock ratios are maintained for a considerable time[22].

Metamorphism alone is not sufficient to initiate chemical changes; the fluid flux is a much more important factor, but one which is rather more difficult to assess. The metamorphic grade does, however, control the mineral assemblages, which determines which elements may be mobile.

B.L.W. acknowledges the receipt of an NERC research studentship. The analytical data used in this study were obtained at the University of Birmingham (X-ray fluorescence data) and the Open University (NAA data), and the use of these facilities is gratefully acknowledged.

An unusual bed of giant pumice in Mexico

B. J. Clough, J. V. Wright*† & G. P. L. Walker*

Department of Geology, Imperial College, London SW7 2BP, UK

We report here that a remarkable bed of giant-sized pumice blocks occurs within an old caldera of the major late Quaternary rhyolitic volcano of Sierra La Primavera, Mexico (Fig. 1*a*). The bed lies within a 100-m thick sedimentary sequence distributed over a near-circular area 10 km across. The margin of this circular area closely parallels an incomplete ring of prophyritic comendite lava domes (Fig. 1*b*), some of which may be shallow intrusions emplaced into the sediments. The vents of these domes are believed to lie on a ring fault (Fig. 1*b*). The sedimentary sequence, now gently updomed (Fig. 1*c*), is believed to have accumulated in a caldera lake, the shoreline of which lay up to 1 km outside the ring fault.

The lake sediments are floored by an ignimbrite (Rio Caliente Ignimbrite) produced by the biggest explosive eruption of the volcano[1,2]; many of the deep gullies within the badland terrain, which characterize the area of lake deposits, cut down into the floor. The lake deposits have a maximum exposed thickness of ~100 m, and rest on top of the ignimbrite which was eroded before their accumulation. Locally, the non-welded top of the ignimbrite (at least 15 m) was stripped off and box canyons were incised into the incipiently welded zone. Some of these canyons are infilled with cross-stratified and pumice-rich fluvatile deposits.

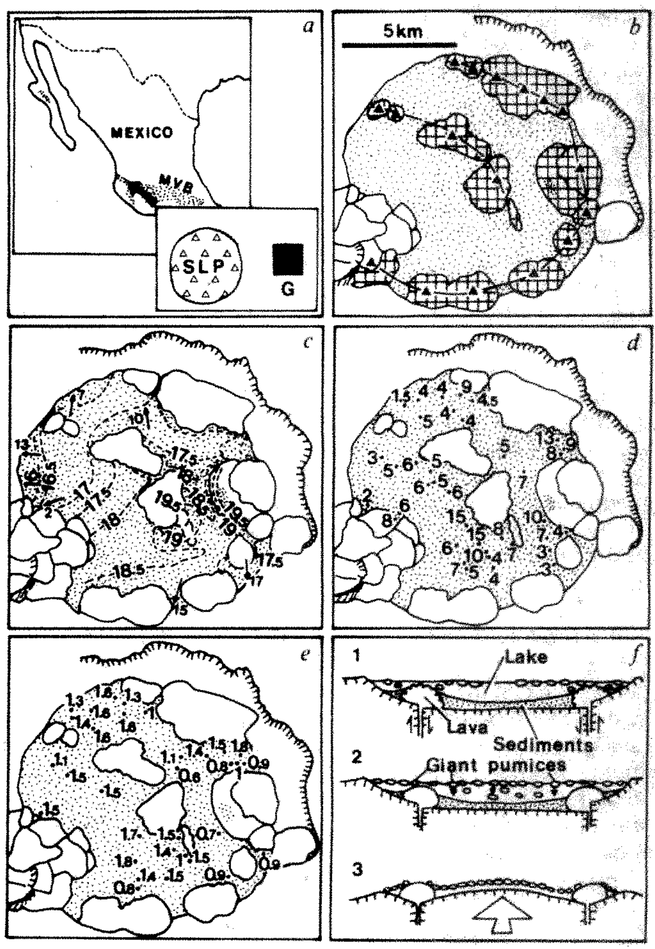

Fig. 1 The giant pumice block bed and lake sediments, and their relationships to the young rhyolite lavas of La Primavera volcano. *a*, Index map of study area: MVB is the Mexican Volcanic Belt which is a locus of Quaternary volcanism in Mexico; G is Guadalajara; SLP is the Sierra La Primavera. *b*, Distribution of the lake sediments and rhyolite lavas: stipple is lake sediments; cross-hatch is porphyritic comendite lavas lying on an 'inner-ring' with a transverse zone; triangles represent inferred vent positions; unornamented lavas are aphyric comendite lavas lying on an 'outer-ring' which is not fully shown or discussed here; hatched line is a low escarpment, possibly an embryo caldera rim. *c*, Altitude contours of the top of the giant pumice block bed in hundreds of metres above sea level. Heights were determined in the field using an altimeter. Dip of lake sediments is also shown (arrows). *d*, Thickness of giant pumice block bed in metres. *e*, Median diameter of giant pumice blocks in metres; 65–20 blocks were measured at each outcrop. *f*, Three stages in the envisaged formation of the giant pumice block bed.

The lake deposits are planar-laminated white vitric ashes and pumice layers. Some ash beds contain diatoms; discrete beds of diatomite also occur. The sediments commonly have current-ripple laminae and load casts indicative of deposition under water. Diatom assemblages indicate that the water was shallow (G. H. Evans, personal communication) and less saline than present-day lakes in this area (J. P. Bradbury, personal communication).

The most distinctive unit in the lake-sediment succession is the giant pumice block bed (Fig. 2*a*), which is 1.5–15 m thick and can be traced over practically the entire former lake area (Fig. 1*d*). It has an extreme bimodal size distribution, the coarse mode consisting of giant blocks of light grey porphyritic pumice averaging 1.3 m in size (Fig. 1*e*), commonly grain supported, with the finer mode consisting of fine white ash occurring

between the large blocks. The giant pumice blocks (Fig. 2) range in diameter from 0.2 to generally less than 6 m and are thus quite well sorted for their size; the maximum diameter measured of any block was 8.5 m. Locally, the giant pumice block bed is underlain by a thick accumulation of smaller-sized pumice. Near the northern edge of the lake area, the bed occurs as two or three beds separated by stratified reworked ash and pumice. The giant pumice blocks in the upper two beds are more matrix supported than is usual for this deposit, and may be reworked.

The ash matrix in the giant pumice bed is laminated, and the laminations are disturbed and contorted around the pumice (Figs 2*a*, 3); this is interpreted as gentle settling of the pumice blocks into waterlogged ash. However, the laminations are also disturbed above the pumice blocks, which is interpreted as a compactional feature. The pumice forms are oblate spheres and poorly rounded blocks (Figs 2*b*, 3). Some have a glassy, poorly vesicular outer sheath about 1 cm thick, but this is discontinuous. Many of the blocks have a crude prismatic jointing normal to their margins, most clearly developed in the outer part of the blocks; occasionally this jointing is very well developed (Fig. 2*b*). These features indicate that the giant pumice blocks have been chilled. A small amount of abrasion evidently took place before deposition.

Features such as relative uniformity of pumice size, relative uniformity in thickness (Fig. 1*d*), maximum pumice sizes (Fig. 1*e*) of the bed over practically the entire former lake area, and the lack of bomb sags make the giant pumice block bed sufficiently unique to demand an unusual mechanism of formation. Pyroclastic processes are inadequate to account for these features. The following mechanism (Fig. 1*f*), consistent with all the observed field relationships, envisages porphyritic comendite lava extrusions forming on the floor of a lake. It is common for the carapace of a silicic lava extrusion to be pumiceous, and in this case pumice blocks became detached from the carapace and floated to the lake suface. Eventually, the entire surface was covered with giant blocks of floating pumice, and these blocks became evenly distributed by jostling against one another. Size-sorting occurred as smaller pumice fragments rapidly sank close to the extrusions. Eventually, however, the largest pumice blocks became waterlogged and sank to generate the coarse mode of the bed. In places the bed mantles prophyritic lava, and here rests on a thick apron of less coarse pumice which sank earlier (if, indeed, it floated at all).

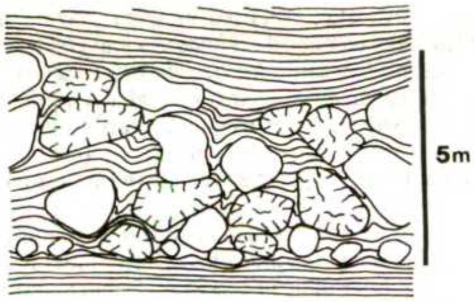

Fig. 3 Field sketch showing disturbed and contorted lake sediments with blocks of giant pumice. Some blocks show cooling joints normal to their margins.

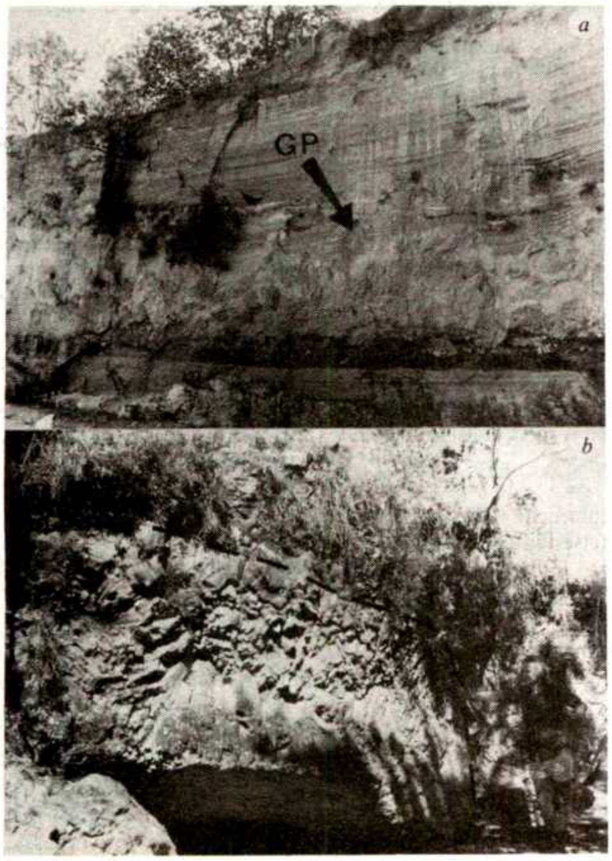

Fig. 2 *a*, Giant pumice block bed (GP), at this location approximately 5 m thick, and laminated lake sediments which are disturbed and contorted. *b*, Giant pumice block; this example has a largest diameter of ~6 m, and also has very well developed prismatic jointing normal to its margins.

Various lines of evidence indicate that the porphyritic lavas were emplaced in water or wet lake sediments. These include, (1) an unusually thick carapace of glassy rocks which is invariably present, (2) particularly well developed jointing (in places the rocks are extensively brecciated), (3) anomalously close spacing of microfractures and a resulting very pervasive perlitic alteration, and (4) an absence of spherulites and lack of post-eruption crystallization in general. In contrast, the aphyric comendite lavas of the volcano (Fig. 1*b*) are thought to have been erupted 'dry'. They have a carapace of fresh or slightly perlitized obsidian interbanded with stony and spherulitic rhyolite, and close-spaced foliation planes which are steeply inclined and intensely contorted.

The origin of the lake depression in which the sediments accumulated is not immediately apparent, because subsequent uplift of the central part of the volcano masks the original relationships (Fig. 1*c*). Geological relationships, however, suggest that the lake occupied a caldera. The sediments extend up to 1 km outside the limit of the rhyolitic ring, which conforms with observations that the topographic rim of a caldera commonly lies outside the ring fault[3] (as marked by lava extrusions or explosive vents). There is, in fact, a low escarpment 1–2 km outside the lava ring on the northern and eastern side (Fig. 1), but this could be a second outer embryo caldera of a nested pair. Resurgent updoming[4] has caused an inversion of topography so that the lake deposits now stand well above any possible shoreline. The updoming took place relatively late in the history of the volcano and did not follow closely on the climatic ignimbrite eruption. At La Primavera this could indicate the arrival of a new pluton beneath the volcano. If so, the apparently youthful age of the updoming indicates that possible future activity of the volcano should be considered seriously[2]. Numerous hot springs within the volcano point to the existence of a hydrothermal system driven by heat from a hot rock or magma body.

Microfossil-like objects from the Archaean of Greenland: a cautionary note

Recent reports[1–4] have described "yeast-like microfossils" (*Isuasphaera isua* Pflug[2]) in 3,800-Myr old[5] metaquartzites from the Isua supracrustal belt of south-west Greenland. A biogenic interpretation of these objects is inconsistent with the tectonic history of the Isua region[6–8], with the petrology of the metaquartzites, and with the morphology of the microstructures themselves. The putative microfossils are indistinguishable from limonite-stained fluid inclusions: microstructures which are demonstrably inorganic and post-depositional in origin. As such, we contend here that these objects should not be regarded as evidence of early Archaean life forms.

The geological history of the Isua supracrustal belt is summarized in Table 1. Several episodes of deformation, geochemical alteration and amphibolite-facies metamorphism have been recognized, in sharp contrast to slightly younger Archaean strata from which stromatolites[9,10] and apparently *bona fide* microfossils[11–13] have been reported.

Evidence of penetrative deformation is seen throughout the Isua succession where all lithologies record high strains. Few primary sedimentary and igneous structures are preserved apart from the gross lithological layering which allows a rudimentary stratigraphy to be described. Even in fold hinges or inclusions of competent material in a ductile matrix where strain is comparatively low a strong linear fabric is developed and primary features are only recognizable on surfaces normal to the maximum extension. Original discordant structures, such as the contacts between the supracrustal rocks and the intrusive Amîtsoq gneisses have been rotated to near-parallel. The absence of strain markers in the main quartzite horizon (from which the fossil-like microstructures were found), obscures evidence of deformation. Nonetheless, thin layers of magnetite and cummingtonite in the quartzites exhibit extension fabrics similar to those in neighbouring ironstones. There is no evidence that the quartzite horizon escaped the episode(s) of high deformation.

Large-scale geochemical alteration is inferred from rocks interpreted as volcanic in origin. Basic rocks record massive remobilization of alkalis, silica and CO_2 (ref. 14), whereas acid rocks are strongly enriched in K_2O (refs 6, 7) or carbonate minerals. Ultrabasic units (dunites and peridotites) are commonly transformed into schistose assemblages of talc, Mg-amphibole and carbonates. Sedimentary carbonate units display high initial Sr-isotope ratios (see W. Compston in ref. 15) attributed to massive metasomatic changes in constituents.

At least five regional metamorphic events occurred between 3,700 and 1,600 Myr (Table 1). The supracrustal rocks reached amphibolite-facies metamorphism twice: once associated with the emplacement of the Amîtsoq gneisses (~3,700 Myr), and again following the intrusion of the Ameralik dykes (before 3,000 Myr). Efforts to quantify temperatures and pressures attending these metamorphic events have been hampered by the

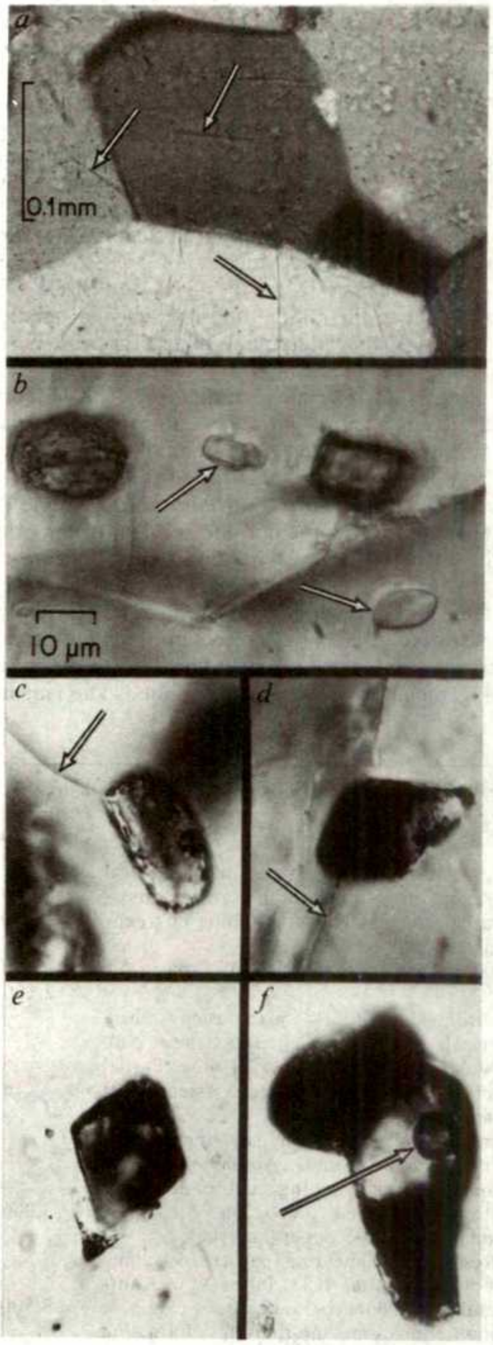

Fig. 1 Optical photomicrographs showing recrystallized, equigranular quartz grains (in plane polarized light; *a*) and non-biogenic, apparently limonite-stained microfossil-like objects (in transmitted white light; *b–f*) in petrographic thin sections of greenish-white quartzite from the 3,800 Myr Isua supracrustal belt of Greenland; *a*, arrows point to fine actinolite needles; *b*, arrows point to clear, ellipsoidal, fluid inclusions; *c*, *d*, arrows point to limonite-stained quartz grain boundaries (also visible in *b*); *f*, arrow points to gas bubble within an elongate, mineral-stained inclusion. *b–f* (scale as in *b*) are from thin section no. 60464, Paleobotanical Collections, Harvard University, Cambridge, Massachusetts.

polymetamorphic nature of the rocks and their common retrogression to chlorite-bearing greenschist facies assemblages. High-grade mineral assemblages recognized from different rock types are listed in Table 2. With specific reference to the pelitic units, the assemblage biotite + garnet + quartz + staurolite and the presence of kyanite[16] are consistent with temperatures of 500–600 °C and pressures of 200–500 MPa. Independent evidence of the temperatures of metamorphism is given by the oxygen isotope fractionation in quartz–magnetite pairs of the main quartzite horizon[17]. These ratios indicate a mean (and likely minimum) equilibration temperature of 390 °C, which we interpret as reflecting a late (post-3,000 Myr) event following regional amphibolite-facies metamorphism.

The 'fossiliferous' rock, specimen no. 2377, is a relatively coarse-grained, sugary, greenish-white quartzite. It is composed of quartz (95%), actinolite (4%) and talc (1%). The quartz is equigranular and totally recrystallized, with most grains clustering in the 0.2–0.3 mm size class. Neither the presence of "chalcedony" in the rock[1,3,4], nor its supposed "cherty" texture[1,2,4]. could be confirmed. Much of the actinolite $(Ca_{1.44}Na_{0.04}Mn_{0.07}Fe_{0.45})$ $(Mg_{3.79}Fe_{1.13}Al_{0.07})$ Si_8O_{23} is of a grain size similar to the quartz, and fine acicular needles can be found within many individual quartz grains (Fig. 1*a*). The talc $(Mg_{5.19}Fe_{0.87})$ $(Si_{7.90}Al_{0.07})O_{22}$ is seen as fine "beards" along quartz grain boundaries. The mineralogy of the quartzite does not contradict our conclusion that the quartzite unit was subjected to amphibolite-facies regional metamorphism.

Evidence of high grade metamorphism and extreme deformation does not entirely preclude the survival of microfossils, although the chances of preserving intact such delicate carbonaceous bodies as those described following complete recrystallization of their host rock seem to be remote. The morphology of the microfossil-like objects in thin section (including specimen no. 2377 from which *Isuasphaera* was first described[2]) convinces us that a biogenic interpretation is unfounded. The Isua microfossil-like objects are reported to "consist predominantly of carbon . . . characterized by a high degree of bitumunization"[1] preserved "partly in a charred condition, partly close to a final stage of graphitization"[4]; they have shapes ranging from ellipsoidal to elongate with "individuals . . . found in the assemblages which resemble a biscuit, a dumb-bell, or a pair of tears"[1]. The objects range in size from 10 to 40 μm (with "mature cells" said to occur towards the upper end of the size range[3]), and they are described as being "hollow" with their interiors "partly filled with organic matter or fine-grained pyrite" which is "dark brownish" in colour[1,3]. They are also reported to exhibit structures interpreted as "cell walls", "cell vacuoles", "gas vacuoles", "multilaminate sheaths", "budding structures", "bud scars", "cross walls", "remnants of protoplasm" and evidence of "filamental growth"[1,3]. By comparison with illustrations of dried, carbol fuchsin-stained yeast cells, and on the basis of the features noted above, these objects have been interpreted as representing carbonaceous cellularly intact remnants of "yeast-like organisms", possibly of "an evolutionary level which is far below that of yeasts of today" but which "may represent a half-way line between a microsphere-like protobiont and subsequent evolution"[1,3].

Table 1 Simplified table of events in the Isua area

Events	Time (Myr BP)
10. Resetting of K–Ar and Rb–Sr mineral ages[25] local granite intrusion[26] and static thermal metamorphism to approximately 300°, faulting in greenschist facies conditions.	1,600
9. Intrusion of E–W, N–S and NE–SW Proterozoic dykes.	2,100–
8. Transcurrent faulting juxtaposing Isua supracrustals and Amîsoq gneisses against Nûk (~3,000 Myr) gneisses in NW of area. Partial retrogression of amphibolite-facies assemblages in supracrustals.	
7. Deformation with local strong shearing concentrated in supracrustal units. Amphibolite-facies metamorphism and strong deformation of Ameralik dykes within supracrustals.	3,000–
6. Intrusion of E–W, N–S Ameralik dykes.	
5. Retrogression and shearing particularly along contact of supracrustal rocks. Intrusion of Amîtsoq pegmatites and leucogranites.	3,500–
4. Amphibolite-facies metamorphism, deformation to produce major stretching fabric in supracrustals.	
3. Intrusion of Amîtsoq tonalitic and granodioritic gneisses.	3,700–
2. Deformation of supracrustals. Fabric locally preserved, mineral assemblages commonly retrogressed during later events.	
1. Deposition of Isua sediments, volcanism, post-depositional hydrothermal activity.	3,800–

Ages quoted are rounded to the nearest 100 Myr. Based on published and unpublished Rb–Sr, Sm–Nd, Pb–Pb whole-rock, Pb–Pb, U/Pb, Rb–Sr and K–Ar mineral determinations. See refs 5–8 for original refs.

Table 2 Amphibolite-facies mineral assemblages* in the Isua supracrustal rocks

Rock type	Assemblage
Ironstones (and Mg-rich analogues)	Quartz, magnetite, grunerite/cummingtonite
Basic volcanic rocks	Hornblende, plagioclase (andesine–labradorite), quartz, magnetite, sphene (diopside)
Mg-rich and ultrabasic volcanic rocks	Talc, anthophyllite, carbonate minerals (quartz, plagioclase)
Carbonate rocks and calc-silicates	Diopside, anthophyllite, Fe-carbonate, calcite
Pelites	Biotite, quartz, garnet, magnetite (staurolite, kyanite)

* Minerals in parentheses are only sporadically preserved.

Our thin sections contain microstructures which conform in size, shape and all other optically detectable properties to the putative microfossils previously described, leaving no doubt that our material is identical to that previously interpreted as biogenic. We find, however, that the populations of these objects span a decidedly broader size-range than that previously reported: measurements of 250 such objects (in three thin sections) show that they range in length between 2 and 115 μm, with a mean length of ~23 μm (and a variance, s^2, of 38.2).

Two principal categories of fossil-like objects occur in the thin sections: (1) clear, spherical to ellipsoidal structures (Fig. 1*b*) occur only within quartz grains (rather than at grain boundaries); these structures are comparable to fluid inclusions: inorganic, metamorphically produced micro-structures that are of well known and relatively common occurrence in other, similarly altered metasediments[18]; (2) yellowish to reddish-brown (apparently limonite-stained) structures that exhibit a continuum of shape from spheroidal to ellipsoidal to subangular to completely euhedral (Fig. 1*b–f*).

With the apparent exception of the occurrence of "multilaminate sheaths" (of which we find no evidence) members of this second category are identical to forms described as *Isuasphaera*[1–4]. However, the population includes rhombohedral (Fig. 1*e*) and obviously crystalline individuals (see also ref. 1 Fig. 3, parts 2, 4, 11, 12) which do not exhibit the pattern of morphological consistency characteristic of fossilized microorganisms[19]. Furthermore the objects show a marked concentration at quartz grain boundaries (Fig. 1*c*, *d*), a feature commonly observed in fluid inclusions in recrystallized granites[20] and not likely to be the result of a primary sedimentological distribution. The reported "budding", which has previously been attributed to a biological origin, we interpret as a 'necking-off' process commonly occurring during recrystallization of multiphase inclusions[21], while the reported "gas vacuoles" are bubbles trapped within the objects during their formation and recrystallization[18]. Other suggested biological features (bud scars, cross walls, and so on) are more consistent with an inorganic origin, for example, the staining of the surfaces of fluid inclusions and negative crystals by secondarily mobilized limonitic iron oxides which were also deposited along grain boundaries. Many of the quartz grain boundaries are, in fact, stained with limonite and are indistinguishable in colour and texture from the coating that outlines the fossil-like objects (see ref. 4, plate 2, Figs 2, 5, 6).

Thus consideration of the geological, petrological and morphological evidence leads us to conclude that the fossil-like microstructures (*Isuasphaera isua*) described from the 3,800-Myr old Isua supracrustal rocks are in fact non-biogenic artefacts of inorganic, post-depositional origin. Their reported "yeast-like" morphology and fine structure are inconsistent with the tectonic history of the rocks in which they occur and are at variance with the remainder of the Precambrain fossil record as now known[22]. The occurrence of hydrocarbons within these microstructures[3], if confirmed, would be equally consistent with both a biological and non-biological origin of these compounds. We believe that the microstructures are non-biogenic, and while graphitic carbonaceous matter occurs in the Isua metasediments[4,23,24] it remains to be established whether this is biogenic or abiogenic in nature and to what extent it may be of postdepositional rather than solely syngenetic origin.

We thank M. Schidlowski for providing sample no. 2377 and P. Appel and C. Walters for additional material, and W. S. Fyfe, G. Perry, R. Dymek, R. Kerrich and J. D. Meloche for information and discussion. Mapping at Isua (D.B. and J.H.A.) is part of the programme of the Geological Survey of Greenland. Field work was supported by NATO research grant no. 949 and by a NSERC (Canada) grant to W. S. Fyfe (B.E.G.). We thank other members of the NATO supported research group[8] for discussion. Laboratory work was supported by NSF grants 77-22518 and 79-21777 and by NASA grants NGR 05-007-407 and NSG 7489 (to J.W.S.); by NASA grant NGL 22-007-067 and by NSF grant EAR 78-24237 (to E.S.B.) by NSF grant EAR 76-11740 (to C.K.).

Amino acids and hydrocarbons $\sim$3,800-Myr old in the Isua Rocks, southwestern Greenland

Bartholomew Nagy*, Michael H. Engel*‡, John E. Zumberge*§, Hiroshi Ogino* & Sai Y. Chang†||

* Laboratory of Organic Geochemistry, Department of Geosciences, The University of Arizona, Tucson, Arizona 85721
† Department of Pharmacology, The University of Arizona, Tucson, Arizona 85721

The Isua supracrustal belt consists of metamorphic rocks, including metamorphosed sediments, and are the oldest known rocks on Earth. It has been postulated[1,2] that hydrocarbons recently detected in these rocks are remnants of organisms that lived $\sim$3,800 Myr ago. This popular interpretation is inconsistent with the high-temperature history of the Isua rocks. Various types of hydrocarbons were liberated from these rocks after repeated solvent extraction by matrix dissolution or pyrolysis. However, the Isua rocks have been metamorphosed to the upper greenschist or amphibolite facies (400–600 °C); the metamorphic episodes lasted $>10^6$ yr. Consequently, it is very important that the origins of the key organic constituents be established. In the study reported here both hydrocarbons and amino acids were detected in Isua rock samples. In addition to the common biological amino acids, geologically unstable amino acids and biologically uncommon ones were detected (such as sarcosine). The extent of amino acid racemization suggests the apparent continuous diffusion of biochemicals into the Isua rocks from encrusting lichens since the end of the last ice age. Also, the cold-temperature history (which retards racemization) suggests that the amino acids may be modern to a few tens of thousands of years old. *n*-Alkanes lacked odd/even carbon chain preference which may indicate some antiquity. However, the hydrocarbons also resemble a recent petroleum distillate fraction. Laboratory experiments, supported by kinetic and thermodynamic calculations, show that amino acids and aromatic and saturated aliphatic hydrocarbons, including pristane, could not have survived the known metamorphic history of the Isua rocks.

Samples from the Isua banded iron formation ($\sim$150 km north-east of Godthåb) were analysed. Sample 155782 was an interior portion of the banded ironstone ($\sim$50 g) that contained a limonite-filled microcrack. Samples 3015, 3016, 3022 and 3028 ($\sim$50 g each) had weathered surfaces. Porosity, air and water permeabilities of samples 3015 and 3016 were 2.3%, 1.0×10^{-2} mdarcies and 1.2×10^{-6} mdarcies; and 2.2%, 4.6×10^{-1} mdarcies and 1.3×10^{-1} mdarcies, respectively[3]. Isua sample 3015 was less extensively weathered than Isua 3016 and thus had a lower water permeability.

To minimize laboratory contamination, all glassware was acid cleaned, solvents and acids were redistilled from reagent or spectral grade, water was triple distilled in glass and so on[4,5]. The rock surfaces were drilled off and the samples pulverized. Excessive ball milling (>20 h) was avoided because it caused some racemization of amino acids. The pulverized samples and corresponding blanks were refluxed with water for 8 h. The filtrate residues were hydrolysed for 24 h at 100 °C in 6 M HCl. The samples were then desalted by ion exchange chromatography[4,5] and the *N*-PFP-(+)-2-butyl amino acid diastereomers were prepared[4,5] and analysed for their D/L amino acid ratios by gas chromatography. Amino acids in the water extract of sample 3028 were analysed by combined gas chromatography–chemical ionization mass spectrometry (GC–CIMS). Part of the water extract of Isua sample 3016 was analysed by an amino acid analyser.

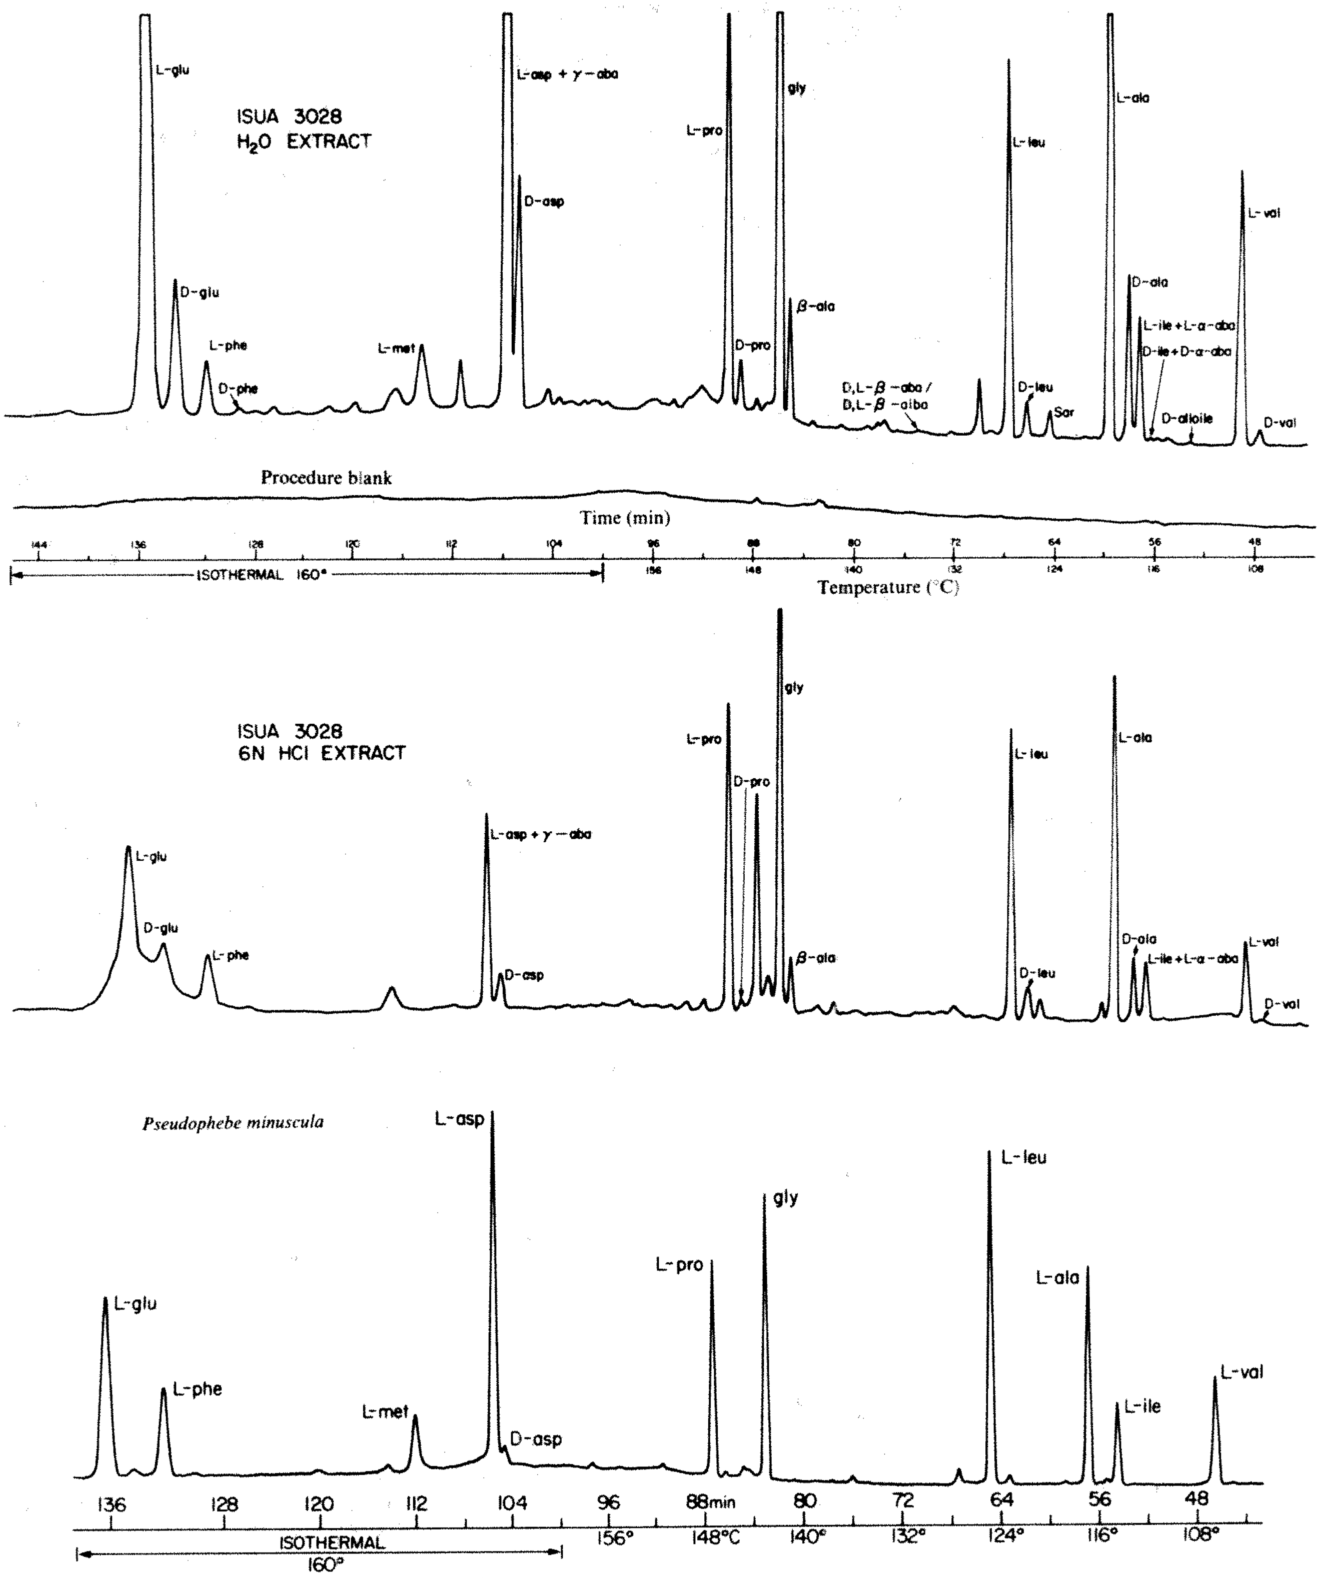

Fig. 1 Gas chromatograms of the water extract, procedure blank and HCl acid extract of Isua sample 3028 and of the 6M HCl extract of the lichen *Pseudophebe minuscula*. A Perkin-Elmer model F-11 gas chromatograph coupled to an Infotronics CRS-208 integrator was used with a Carbowax-20M 61m × 0.5 mm i.d. WCOT nickel capillary column. The He flow rate was 11.5 ml min^{-1}. The inlet temperature was 150 °C. The oven programme was 80 °C isothermal for 20 min; then 80 °C to 160 °C at 1 °C min^{-1}. The programmes were finished isothermal at 160 °C. In addition to co-injection of amino acid standards and retention times, all amino acid identifications in the water extract of sample 3028 were confirmed by GC–CIMS. A Finnigan 9500 gas chromatograph coupled to a Finnigan 3300 mass spectrometer (quadrupole) equipped with a 6110 series data system was used. CH_4 served as both carrier gas and reactant for chemical ionization. A Carbowax-20M 46 m × 0.5 mm i.d. SCOT stainless-steel capillary column was used for GC–CIMS. The carrier gas flow rate was ~8.5 ml min^{-1}. The oven programme was 90 °C to 150 °C at 2 °C min^{-1}. The programme was finished isothermal at 150 °C. The ionization chamber temperature and pressure were 150 °C and 1.0 Torr, respectively. The emission current was 1.0 mA. 150 eV was used to generate the methane ions. Valine, val; alloisoleucine, alloile; α-amino-*n*-butyric acid, α-aba; isoleucine, ile; alanine, ala; sarcosine, sar; leucine, leu; β-amino-*n*-butyric acid, β-aba; β-aminoisobutyric acid, β-aiba; β-alanine, β-ala; glycine, gly; proline, pro; γ-amino-*n*-butyric acid, γ-aba; aspartic acid, asp; methionine, met; phenylalanine, phe; glutamic acid, glu.

Approximately 2.0% of the D-amino acids used to obtain the D/L ratios may be attributed to (−)-2-butanol impurities and racemization during 6M HCl hydrolysis. Average instrumental error of three gas chromatographic determinations for each D/L ratio = ±0.011. Asp D/L ratios could not be corrected for minor γ-aba interference.

* This rock specimen is another portion of the sample on which the original Pb/Pb date of the Isua rocks was determined[30]. This age has been confirmed by other methods, see ref. 31.

† These values are total concentrations of the amino acids detected in the samples. The Isua extracts = nmol g^{-1}; the lichen extracts = nmol $mg^{-1} \times 10^{-2}$. The experimental error for the amino acid concentration is ±20%.

‡ D peak and/or L peak too small to determine D/L ratios. The two values reported are based on only single gas chromatographic determinations.

§ Interference of D peak and/or L peak.

‖ Glu and Phe were not included in this value because of gas-chromatographic peak interference.

The water-extracted rock residues were digested for 24 h at 100 °C in 6M HCl. The HCl solutions were analysed by the same procedure as above. During the HCl digestion the possibility arose that release of ferric iron or other substances may have oxidized the amino acids. To test this, an 8.1-g portion of sample 155782 was mixed with L-norvaline (1.7 mg) and L-norleucine (1.9 mg), two amino acids not originally detected in 155782. The mixture was digested and analysed as before. Approximately 75% of these amino acids were recovered after HCl digestion. No racemization was noted. 6M HCl extracts of two lichen species from the surface of sample 3016 (*Rhizocarpon* sp., *Dermatocarpon* sp.) and one lichen species from 3028 (*Pseudophebe minuscula*) were analysed for amino acids. Before acid hydrolysis *P. minuscula* was sonicated for 30 min with 1.5 M HCl to liberate non-bound amino acids and/or peptides. This free fraction was hydrolysed separately.

Figure 1 shows the results of the analysis of sample 3028 and of the 6M HCl extract of *P. minuscula*. Notable similarities exist between the relative abundances of amino acids in the lichens and in the Isua rocks. Glutamic acid, aspartic acid and glycine, the most abundant amino acids in the three lichen species analysed, were also the most abundant amino acids in the Isua rocks. Co-injection and GC–CIMS confirmed the presence of small quantities of four uncommon non-protein amino acids (α-amino-*n*-butyric acid, β-amino-*n*-butyric acid and/or β-aminoisobutyric acid, γ-amino-*n*-butyric acid and sarcosine) in the 3028 water extract. Three of these amino acids have been detected in biological systems[6]; β-amino-*n*-butyric acid and β-aminoisobutyric acid can also be derived biologically. α-Amino-*n*-butyric acid and γ-amino-*n*-butyric acid can evolve by the decomposition of threonine and glutamic acid, respectively[7–9].

D/L ratios and the abundances of the amino acids from the Isua rocks and lichens were determined by gas chromatography and are listed in Table 1. Part of the Isua 3016 water extract that was analysed on an amino acid analyser revealed the presence of threonine, serine, tyrosine, histidine, arginine and lysine (P. E. Hare, personal communication), in addition to the amino acids listed for sample 3016 in Table 1. In temperate environments containing moisture, syngenetic amino acids should be substantially racemized (or epimerized) after ~a few hundred thousand to a few million years[10–13]. The amino acids found in the ~3,800-Myr-old Isua metamorphosed sedimentary rocks were not racemic. The high L-amino acid abundances introduced by modern lichens may have lowered the D/L ratios of older amino acids in the Isua rocks. Amino acids extracted from the Isua rocks with 6M HCl seem to be more tightly bound to the organic and/or inorganic rock matrices than the water-extractable amino acids; they yielded lower D/L ratios. This is not surprising considering recent reports on the adsorbtion of amino acids by organic and inorganic rock constituents and their concomitant effects on amino acid racemization rates[14–17].

After deposition, the Isua rocks experienced episodes of metamorphism. During the metamorphic events temperatures were 400–600 °C (refs 18, 19). Elevated temperature experiments have demonstrated that amino acids and peptides rapidly decompose when exposed to temperatures within the range of the Isua metamorphism[20,21]. Serine, threonine and tyrosine are particularly unstable at elevated temperatures and in geological environments[22,23]. Their presence further precludes an elevated temperature history for the amino acids in the Isua rocks.

To test the possibility of diffusion of amino acids from the lichens into the rocks, fragments of samples 3016 and 3015 were

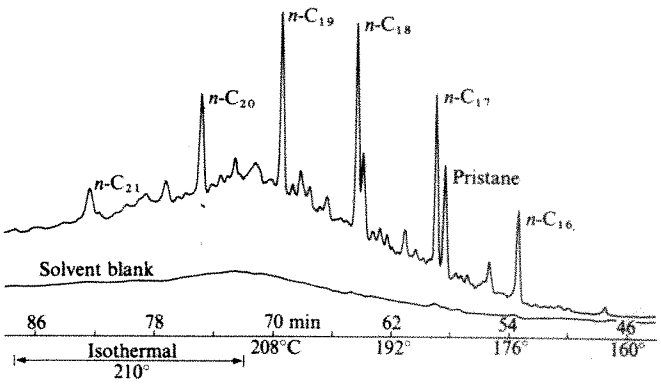

Fig. 2 Gas chromatrograms of the procedure blank and the saturated hydrocarbons in sample 3016. The alkane distribution pattern may suggest some antiquity and/or contribution from a petroleum distillate fraction. For gas chromatography, an Apiezon L 15 m × 0.5 mm i.d., WCOT stainless-steel column was used. The GC programme was 80 °C isothermal for 6 min; then 80–210 °C at 2 °C min^{-1}. The He carrier gas flow rate was 3.5 ml min^{-1}. The inlet temperature was 195 °C. The chromatograms shown above were obtained using a Perkin Elmer F-11 gas chromatograph. In addition to co-injection of standards, the major hydrocarbon components in samples 3016 and 3028 were identified by GC–MS.

placed in aqueous solutions of D-amino acids for 1,321 h at 36 °C. After soaking, the concentrations of the D-amino acids in the rock interiors were 1 or 2 orders of magnitude higher than before exposure. Some amino acids present in the Isua rocks were probably introduced by encrusting lichens. However, the lichens chosen for analysis in this study were apparently not the direct source of the less common amino acids such as α-amino-n-butyric acid, β-amino-n-butyric acid/β-aminoisobutyric acid and sarcosine which were present in low concentrations in the Isua rocks.

Comparisons of the Isua rock amino acid D/L ratios with amino acid D/L ratios reported for samples from other regions that have experienced comparable cold-temperature histories, such as the late Pleistocene fossil shells from the eastern Canadian Arctic[24] and shells from a Carribean core (bottom water = 4 °C)[25], indicate that some of the Isua amino acids may be several tens of thousands of years in age; although comparisons of amino acid D/L ratios in rocks with fossil shells are tenuous. Comparisons of the amino acid D/L ratios of the Isua rocks with those reported from clay-rich (low-carbonate) sediments from Leg 15, Site 148, of the Deep Sea Drilling Project[26] and with amino acid D/L ratios reported for siliceous oozes from a core taken from the southern Atlantic Ocean (lat 56°34.7′ S, long 20°17.2′ W; bottom water, −0.2 °C)[27] further suggest that none of the amino acids in the Isua rocks are older than a few tens of thousands to possibly a few hundreds of thousands of years.

Interior portions of Isua samples 3016 and 3028 were also analysed for saturated hydrocarbons. The rock powders were first extracted with H_2O at 100 °C followed by $CHCl_3/CH_3OH$ (87/13, v/v) at room temperature. Two alumina columns (Woelm Neutral, Waters Associates) were prewashed with distilled n-hexane. Procedure blanks and sample extracts were eluted from the alumina columns with n-hexane. The samples and blanks were analysed by gas chromatography and GC–MS.

Gas chromatograms of the procedure blank and hydrocarbon extract of sample 3016 are shown in Fig. 2. A similar hydrocarbon envelope was detected from sample 3028. The aliphatic hydrocarbons in samples 3016 and 3028 ranged from n-C_{16} to n-C_{21}. Pristane was present in both samples. No odd carbon number preference was found for these Isua hydrocarbon extracts, indicating that these hydrocarbons were old or were introduced more recently from some organisms lacking odd carbon preference. Alternatively, they may have been derived from older materials brought into contact with the rocks by glacial action or by contamination with petroleum products.

It may clarify the origin of the hydrocarbons found in the Isua rocks[1] if pertinent laboratory experiments and related kinetic and thermodynamic calculations are considered. Elevated temperature experiments have shown that, at 375, 400 and 600 °C, the temperature range of the Isua metamorphic episodes, straight chain aliphatic hydrocarbons decompose in ~$6\frac{1}{4}$ days, ~5 days and in ~10 s, respectively[28,29]. In experiments conducted in this laboratory, pristane (10 μl); pristane (7 μl) and graphite (10.2 mg); and pristane (6 μl) and a Santa Barbara Basin Recent marine sediment (3.7 mg) were heated in glass tubes under He at 520 °C for 2,924, 1,891 and 2,107 h, respectively. Next, the samples were extracted with n-hexane by ultrasonication and analysed by GC–MS. Pristane was destroyed in all three samples. ΔG for the decomposition of nonadecane ($C_{19}H_{40} \rightarrow 19C + 20H_2$) at 427 °C is −212.68 kcal mol^{-1}, (S. L. Miller, personal communication). ΔG for the decomposition of naphthalene ($C_{10}H_8 \rightarrow 10C + 4H_2$) at 427 °C is −79.45 kcal mol^{-1}, and for biphenyl ($C_{12}H_{10} \rightarrow 12C + 5H_2$) at 427 °C is −101.63 kcal mol^{-1}. This indicates that even aromatic hydrocarbons, if initially present, may not have survived prolonged Isua metamorphic episodes. Thus the limited thermal stabilities of alkanes, these aromatic hydrocarbons, amino acids, and the low amino acid D/L ratios, probably preclude a very great age.

We thank S. Moorbath for a rock sample and for reviewing the manuscript, and M. Schidlowski for rock samples and helpful comments, T. Nash for identifying the lichen species. P. E. Hare for help with the amino acid analyser analyses, E. S. Barghoorn for helpful comments and J. L. Bada and G. Eglinton for reviewing the manuscript. This research was supported by NASA grant NGR 03-002-171.

In spite of recent progress towards an understanding of prehispanic Maya agriculture, relatively little is known about plants grown prehistorically in the Petén, Belize and the Yucatan Peninsula. Little plant material has been reported from Maya sites, and almost no detailed archaeobotanical analyses have been done. The Cuello site (18°05′N, 88°35′W) in northern Belize is unique in having numerous intact floors of very early ceremonial structures which separate plant remains into clearly defined units. Flotation of soil samples has yielded a wide range of carbonized plant material including many maize cupules (cob fragments) and kernels. As we report here, these can be classified into several types which seem to relate to a range of archaeological types of maize found elsewhere.

All measurements except row no. are in mm, not corrected for carbonization. Means and standard deviations of five measurements and two estimates for six Preclassic Cuello cupule categories. All the measurements (mm) are from carbonized specimens, so for comparison to uncarbonized specimens, about 25% needs to be added to the values.

* Row no. estimated: 360°/cupule angle, rounded off, multiplied by 2.

† Rachis diameter estimated by law of cosines: rachis diameter = cupule width × 1.414 $(1\text{-cosine cupule angle})^{-0.5}$.

Excavations at Cuello during 1976–1980 revealed superimposed early structures, some of probably ceremonial function[1-3]. The overall chronology of the site is from about 2000 b.c. in radiocarbon years to about AD700 in calendar years, the early part of the Late Classic period of historically dated Maya civilization[4,5]. (The Preclassic or Formative period before AD 250 is dated by a suite of 20 radiocarbon dates from the Cambridge (Q) and Los Angeles (UCLA) laboratories provided by V. R. Switsur and R. Berger; further samples are being processed by these two laboratories and also that at La Jolla (LJ) by H. Suess. (Lower case b.c. and a.d. indicate radiocarbon years with no correction for the bristlecone pine chronology, geomagnetic curve, or other factors.) The occupation of Cuello is formally divided into five successive phases, three in the Formative and two in the Classic period, based on the stratigraphy, pottery and radiocarbon dates from excavations principally in Platform 34 at the site. The Early Formative Swasey phase (2000–1000 b.c.) is succeeded by the Middle Formative Lopex Mamom phase (1000–400 b.c.) and the Late Formative Cocos Chicanel phase (400 b.c.–AD 250), then by the Early Classic Nuevo Tzakol (AD 250–600) and Late Classic Santana Tepeu (AD 600–700). Classic period deposits consist of superficial architecture and do not feature in the sampling programme reported here.

For the entire Formative period a succession of plaster floors define and separate layers of occupational material and fill. The possibility of vertical displacement of plant remains after deposition is minimal, although some animal and insect burrows were noted in the excavation and some root penetration was also present. The recycling of earlier material in later construction fills is, on the other hand, a reality attested to by abraded sherds of Swasey pottery occurring in Mamom and Chicanel contexts.

From 1978 to 1980 we carried out an intensive programme of sampling for plant remains by water flotation[6], processing 250 50-l samples representing more than 10 metric tons of earth. Soil samples were sealed into plastic bags and before flotation were partially air-dried to enhance recovery of carbonized plant parts, mollusc shells and bones. The smallest materials were land snails and seeds whose longest dimensions are 0.5 mm, so that little recoverable and identifiable material was missed. We recovered *Zea mays* kernel, cupule and glume fragments from all contexts including the earliest occupation on the old land surface dated at 1950±65 b.c. (Q-1571)[1]. From the samples analysed so far, 141 cupules (of a total of 329) and 56 kernels (of 821) were complete enough to measure in several ways. The lack of intact maize cobs may be due to breakage during construction of the platforms, predepositional handling including burning, and a low level of cob induration.

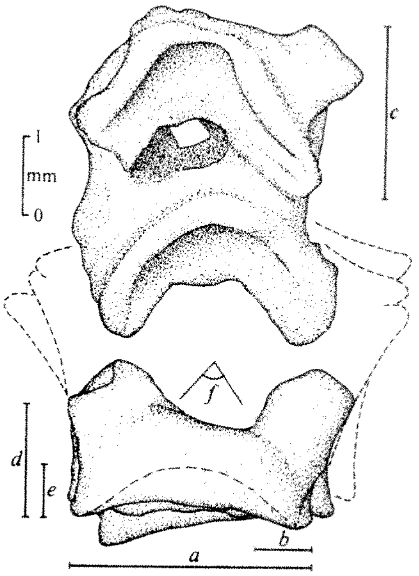

Fig. 1 A cob fragment with two almost complete cupules and one partial cupule to each side, similar to some Swasey type 2 cupules, dating to about 1000 b.c. Upper, side view; lower, end view (apical) demonstrating that the whole cob had five ranks of cupules, each subtending two fertile spikelets, giving ten rows of kernels. An estimate of the rachis outline and the interior of one cupule are indicated by dashes on the lower part of the fiugre. The measurements indicated are *a*, cupule width; *b*, cupule wing width; *c*, cupule length; *d*, cupule thickness; *e*, cupule depth, and *f*, cupule angle (used for estimating row number). (Drawn by R.McK.B.)

The variables we used to measure the cupules (Fig. 1) have been applied to a wide range of prehistoric and modern cobs[7–11]. Cupule angle has been used by Cutler to estimate row number[12]. Usually several measurements need to be used simultaneously to distinguish types of maize because races overlap in many metric values, often being differentiated by only one of the available variables. Several characters that are not easily quantifiable, such as cupule shape, may also aid in separation. Cuello maize types are named according to the phases in which they first appear.

The classification of extant races of maize is based on a broad spectrum of variables: morphology of the plant, tassel and ear; physiology; cytology; and most recently, isozymes of the coleoptile[13–16]. Because the Cuello collection consists of only charred kernel and cob fragments, much of the necessary evidence for complete racial classification is lacking. Nevertheless, it is important to attempt to understand the relationships of the Cuello maize to existing modern races and other archaeological collections.

The smallest type of Cuello maize is Swasey type 1 (SW-1). It has small elliptical to rectangular cupules with narrow cupule wings (Table 1), and 10–16 rows of grains, as estimated by cupule angle. The smallest kernels from Cuello, probably associated with this type, all have hard endosperm and probably represent a popcorn. They measure 4.2×3.2 mm (kernel width × kernel thickness, charred). Allowing for 20% shrinkage on carbonization, and estimating rachis diameter using the law of cosines (equation, Table 1), we believe that the intact ear would have been about 22 mm in diameter, about the size of a modern US popcorn called Ladyfinger. Without an entire cob, it is impossible to estimate length. SW-1 is more like early types of maize from South America (Cupisnique types 3 and 4, Gallinazo types 1 and 3) than any reported Mexican archaeological collections (Table 2).

Swasey type 2 (SW-2) and Swasey type 3 (SW-3) are somewhat similar, but can be distinguished by cupule width and shape. In outline SW-2 cupules are trapezoidal, chevron-shaped (Fig. 1) or B-shaped. SW-3 cupules tend to be more rectangular with wide wings, some of which resemble small 'ears'. The cupules of SW-2 often have slight apical protrusions resembling the toe of a boot. This configuration (sometimes called 'shoe-shaped' or 'Spanish stirrup') is present in some Tehuacán specimens, as well as modern Chapalote and many South American races. SW-2 has 10–16 rows of kernels averaging 5.6×4.2 mm (charred) which resemble a rounded popcorn. SW-3 has a slightly lower mean row number (with a range of 8–16) and kernels measuring 6.2×4.8 mm (charred) which seem to represent both popcorn and hard flint types. SW-2 is somewhat like Abejas maize but is very like Gallinazo types 1 and 4 from the north coast of Peru and Guadalupe-Largas maize from Oaxaca. SW-3 also resembles Guadalupe-Largas but is more like Early Nal Tel B and Pre-Chapalote (Table 2).

Mamom type 1 (MA-1) is larger than Swasey maize groups. It has wide, but comparatively short, rectangular to 'eared' cupules with broad wings. Charred kernels apparently associated with this type are all flinty (probably a soft flint), measuring 6.4×4.6 mm (charred). Uncarbonized MA-1 cobs would have been about 16 mm in diameter and, with kernels, the ears may have been about 28 mm in diameter. MA-1 is almost identical to Early Nal Tel B from La Perra Cave (Table 2) and is similar to Early Teosintoid, Late Nal Tel and Early Chapalote. With the appearance of MA-1, the resemblance between the Cuello material and the listed Peruvian maize types diminishes. MA-1 was probably very similar to a previously undescribed Central American race which we have collected from Santa Cruz, August Pine Ridge and Rancho Creek (Orange Walk District) and Aguacate (Toledo District) in Belize. This race has 10–14 rows of soft flint or semi-hard dent kernels with white, purple, yellow or pale red aleurone. The ears average 32 mm in diameter and 106 mm long. Although local Mayan farmers refer to this race as 'Dzit Bacal', it bears no resemblance to published descriptions of Dzit Bacal from Guatemala or the Yucatan[15,16].

Mamom type 2 (MA-2) is the largest of all Preclassic Cuello maize varieties. MA-2 has deep, wide trapezoidal or chevron-shaped cupules with 8–12 rows of flinty kernels measuring 6.8×4.3 mm (charred). It resembles Early Nal Tel B and Late

Table 2 Formative period maize from Latin America

Measurement means for early maize types from eight archaeological sites in five areas of Latin America. The data from Tamaulipas are taken from photographs and published information. The Tehuacán Valley (Puebla, Mexico) sites are the Coxcatlán and San Marcos Caves[8]; the Sierra de Tamaulipas (Mexico) site is La Perra Cave[17]; the Infiernillo Canyon (Mexico) sites are Romero's Cave, Valenzuela's Cave and Ojo de Agua[18]; the Oaxaca Valley (Mexico) site is Fabrica San José[19]; the Chicama Valley (Peruvian north coast) site is Huaca Prieta, including an associated area 150 m north[8]. The maize comes from two or more cultural phases at each site. An asterisk indicates that the value for rachis diameter is estimated as explained in Table 1, or that cupule width is estimated from rachis diameter. Figures in parentheses are from carbonized specimens with about 20% shrinkage. Cupule depth for the five Coxcatlán cobs is 0.7 mm, and for the four Abejas cobs is 1.1 mm. Cupule thickness for Coxcatlán maize averages 1.7 mm. The index of similarity is calculated by adding 25% to the values for carbonized Cuello specimens, then establishing a ±20% range around these adjusted values, counting overlaps of this range with the mean values per type, and dividing by the number of possible comparisons.

Nal Tel from La Perra Cava and Early Teosintoid maize from Tehuacán (Table 2). Before carbonization, the cobs of MA-2 would have been about 20 mm in diameter and with kernels the ears would have measured about 30 mm in diameter. It was probably quite similar to the Tuxpeño-introgressed Nal Tel grown by traditional *milperos* throughout Belize today.

Approximately three-quarters of the Cuello Chicanel-1 material comes from Square 45/35 Layer 1597, a burnt house (apparently with a corn crib) dating to the early Chicanel phase, about 250 b.c. Because all the maize from this context was quite similar, it probably represents a single type from one harvest. CH-1 has open, trapezoidal, 'Spanish-stirrup' cupules with broad cupule wings and 8–16 rows of flinty kernels measuring 6.5 × 5.0 mm (charred). It is almost identical to Early Chapalote from Tamaulipas and is quite similar to Early Teosintoid and Early Nal Tel B (Table 2).

Because they lack all but cob and kernel fragments, we know nothing about ear length, plant form, productivity or other characters of these early lowland maize types. Although the general increase in rachis diameter and kernel size through time suggests an increase in productivity, we must be cautious in making this assumption. A single plant with many small ears (which is true of many popcorns and primitive maize types) could produce as much food as a plant with one or two larger ears. Perhaps evidence for other plant characters and the early adaptation of maize to the lowlands will be found in dry caves in arid valleys along the upper Motagua drainage in southeastern Guatemala.

The earliest domesticated maize was probably adapted to the semi-arid highlands of central and southern Mexico. By at least 2000 b.c. a distinct lineage including SW-1 and SW-2 was developed which was more adapted to the humid lowlands. This lineage probably spread throughout tropical Central America and into coastal South America and contributed to the development of sedentary horticulturalists such as the Swasey people at Cuello. After 1000 b.c. the relationship of Cuello maize to highland Mexican types is more pronounced. The improvement of earlier Swasey maize and hybridization with highland germplasm (and possibly teosinte) produced new varieties which eventually helped to support a dense population and the complex culture of the Maya lowlands.

Major funding for this field work came from the National Geographic Society, the British Museum, the Society of Antiquaries of London, the Wenner-Gren Foundation for Anthropological Research Inc. and Rutgers University. Valuable field assistance was given by Ingrid Wuebber, Kathryn Elsesser, and other members of the Cuello Project Staff; John Masson and Richard Wilk assisted with ethnobotanical collection of modern Maya maize. We thank the Director of the Museo Regional de Puebla and Mario Camacho Robles, Curador General, for access to collections of archaeological maize from the Tehuacán Valley, Puebla, Mexico.

Received 4 February, accepted 31 October 1980.

The sea anemone *Anthopleura elegantissima* lives in clonal colonies[1–3] and possesses a cellular recognition system of remarkable specificity[4], by which it can recognize members of its own clone; other anemones, including individuals of the same species which are not syngeneic, are attacked. Attack is initiated by contact with a foreign anthozoan and involves the inflation of specialized tentacle-like structures known as acrorhagi, which contain numerous stinging cells[1,2]. These stinging cells only discharge when the tip of the acrorhagus is in physical contact with the surface of a foreign anthozoan; contact with syngeneic individuals, organisms other than anthozoans and inanimate objects does not elicit discharge[4]. We show here that the recognition of allogeneic tissue is accompanied by a novel form of local electrical activity in the acrorhagus that is usually, but not invariably, followed by nematocyst discharge. This type of electrical activity was not found during contact with syngeneic tissue or inanimate objects and seemed to be a consequence of the recognition of allogeneic surface markers by cells at the tip of the acrorhagus.

Clones of *A. elegantissima* were maintained in several 150–400 l aquaria containing artificial sea water (Tropic Marin Neu; relative density 1.025) at 23 °C. Before experimentation, an anemone was placed in a small bowl of sea water and induced to inflate its acrorhagi by contact with an allogeneic individual. Extracellular suction electrodes[5,6] (tip diameter 200 μm) were applied to a point about half way along the inflated acrorhagus; signals were amplified by Tektronix Type FM 122 differential preamplifiers and displayed on a Tektronix Type 5111 storage oscilloscope and a Washington curvilinear pen recorder. Care was taken to maintain the electrodes in a single position when comparing responses. Discharge of nematocysts was observed using a binocular microscope, usually with dark ground illumination.

Touching the acrorhagus with the intact surface of excised syngeneic tentacles consistently failed to induce either nematocyst discharge or any recordable electrical excitation; in addition, no detectable activity could be produced by touching the acrorhagus with inanimate objects (metal forceps or glass rod). On the other hand, contact of the acrorhagial tip with an allogeneic tentacle required only a short delay before it produced massive, simultaneous nematocyst discharge, including numerous nematocysts remote from the point of contact (Fig. 1*a*, *b*); discharge was accompanied by a triphasic spike up to 50 μV in amplitude and about 350 ms in duration (Fig. 2). The precise timing of this spike in relation to that of nematocyst discharge was not established and it was therefore unclear whether the spike initiated discharge or was a consequence of it. Of greater interest in the present context was the occurrence of a variable number of much smaller impulses of up to 10 μV and up to 50 ms duration, which preceded the spike. It was particularly notable that these small impulses could also be evoked by brief contact with allogeneic material, even though no discharge of acrorhagial nematocysts and no spike occurred (Fig. 2). These impulses could not be ascribed to any of the known sea anemone electrical conduction systems[7]; they were distinctive in that they seemed to be confined to a single acrorhagus and could be

0028-0836/81/020059—02$01.00

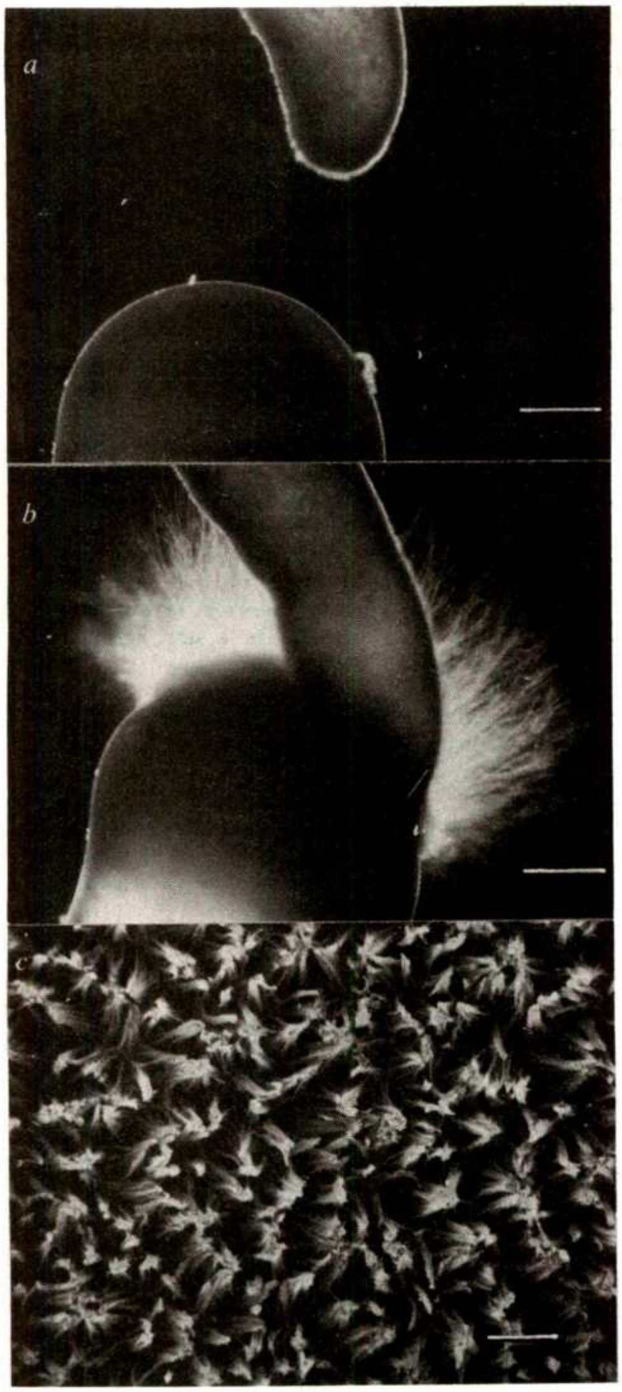

Fig. 1 *a*, Acrorhagus (below) and allogeneic tentacle (above) before contact. Scale bar, 300 μm. *b*, Massive, simultaneous discharge of acrorhagial nematocysts after contact between acrorhagus (below) and allogeneic tentacle (above); discharge usually occurred within 0.5–3 s of contact. Scale bar, 300 μm. *c*, Scanning electron micrograph of ciliary cones on the tip of an inflated acrorhagus. Scale bar, 5 μm.

shown, using two electrodes, to decrease rapidly in amplitude at increasing distance from the acrorhagial tip. They were clearly not the result of the foreign tentacle stinging the acrorhagus: the impulses could also be obtained using fresh pieces of allogeneic column tissue (largely devoid of nematocysts), as well as washed foreign tentacles previously fixed in formalin. It thus seemed that the small impulses were a consequence of cells at the acrorhagial tip recognizing allogeneic markers on the foreign tissue.

The receptors associated with recognition were presumed to reside on the ciliary cones that densely cover the distal portion of the acrorhagus (Fig. 1*c*); it was notable that touching the unciliated sides and base of the acrorhagus with allogeneic tissue failed to produce any detectable electrical activity.

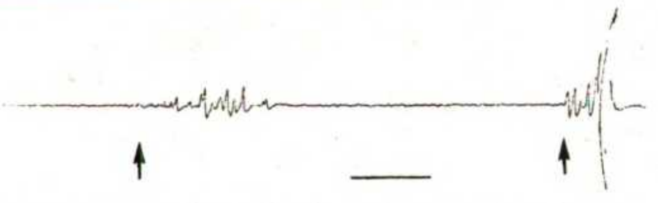

Fig. 2 Pen recording showing electrical response of acrorhagus to contact with an allogeneic tentacle. The beginning of each period of contact is indicated by an arrow; duration of contact was ~1 s. The first period of contact (left-hand arrow) evoked small impulses but no nematocyst discharge. The second period of contact (right-hand arrow) evoked small impulses which were succeeded by a large triphasic spike; the spike was accompanied by massive nematocyst discharge. Scale bar, 1 s.

We suggest the following hypothesis of the means by which recognition of a foreign anemone leads to nematocyst discharge: specific molecules on the surface of the allogeneic tissue bind to surface receptors on cells at the tip of the acrorhagus, inducing electrical excitation; local events of this kind summate until a threshold is reached, at which point massive nematocyst discharge occurs. The fact that electrical activity was recorded on contact with allogeneic tissue, but not with syngeneic tissue of inanimate objects, is consistent with the previously advanced theory[8] that self recognition in anemones is an essentially passive process, with specific receptors failing to be excited, whereas non-self recognition is an active process involving receptor excitation.

We thank W. B. Amos and G. Koch for commenting on the manuscript.

The fusion of mononucleate myoblast cells into multinucleate myotubes (myogenesis) has often been studied as a model system of terminal cellular differentiation[1]. Although cell-surface changes during myogenesis have attracted much attention and a variety of surface antigens including the nicotinic cholinergic receptor[2], acetylcholinesterase[3] and muscle lectins[4,5] have been shown to be present on muscle cells, a detailed identification of markers specific to the various cell types has not been attempted. This is mainly because fibroblasts are a major contaminating cell type in primary muscle cultures and these cells have no known distinctive cell-surface antigen(s). For instance, surface fibronectin has been used to distinguish fibroblasts in the rat peripheral nervous system *in vitro*[6] but has proved ineffective in the human muscle cell system[7]. In addition, Lesley and Lennon[8] found that Thy-1 antigen was present on myoblasts but not myotubes of the rat L6 muscle cell line and primary cultures. However, Thy-1 antigen is also present on

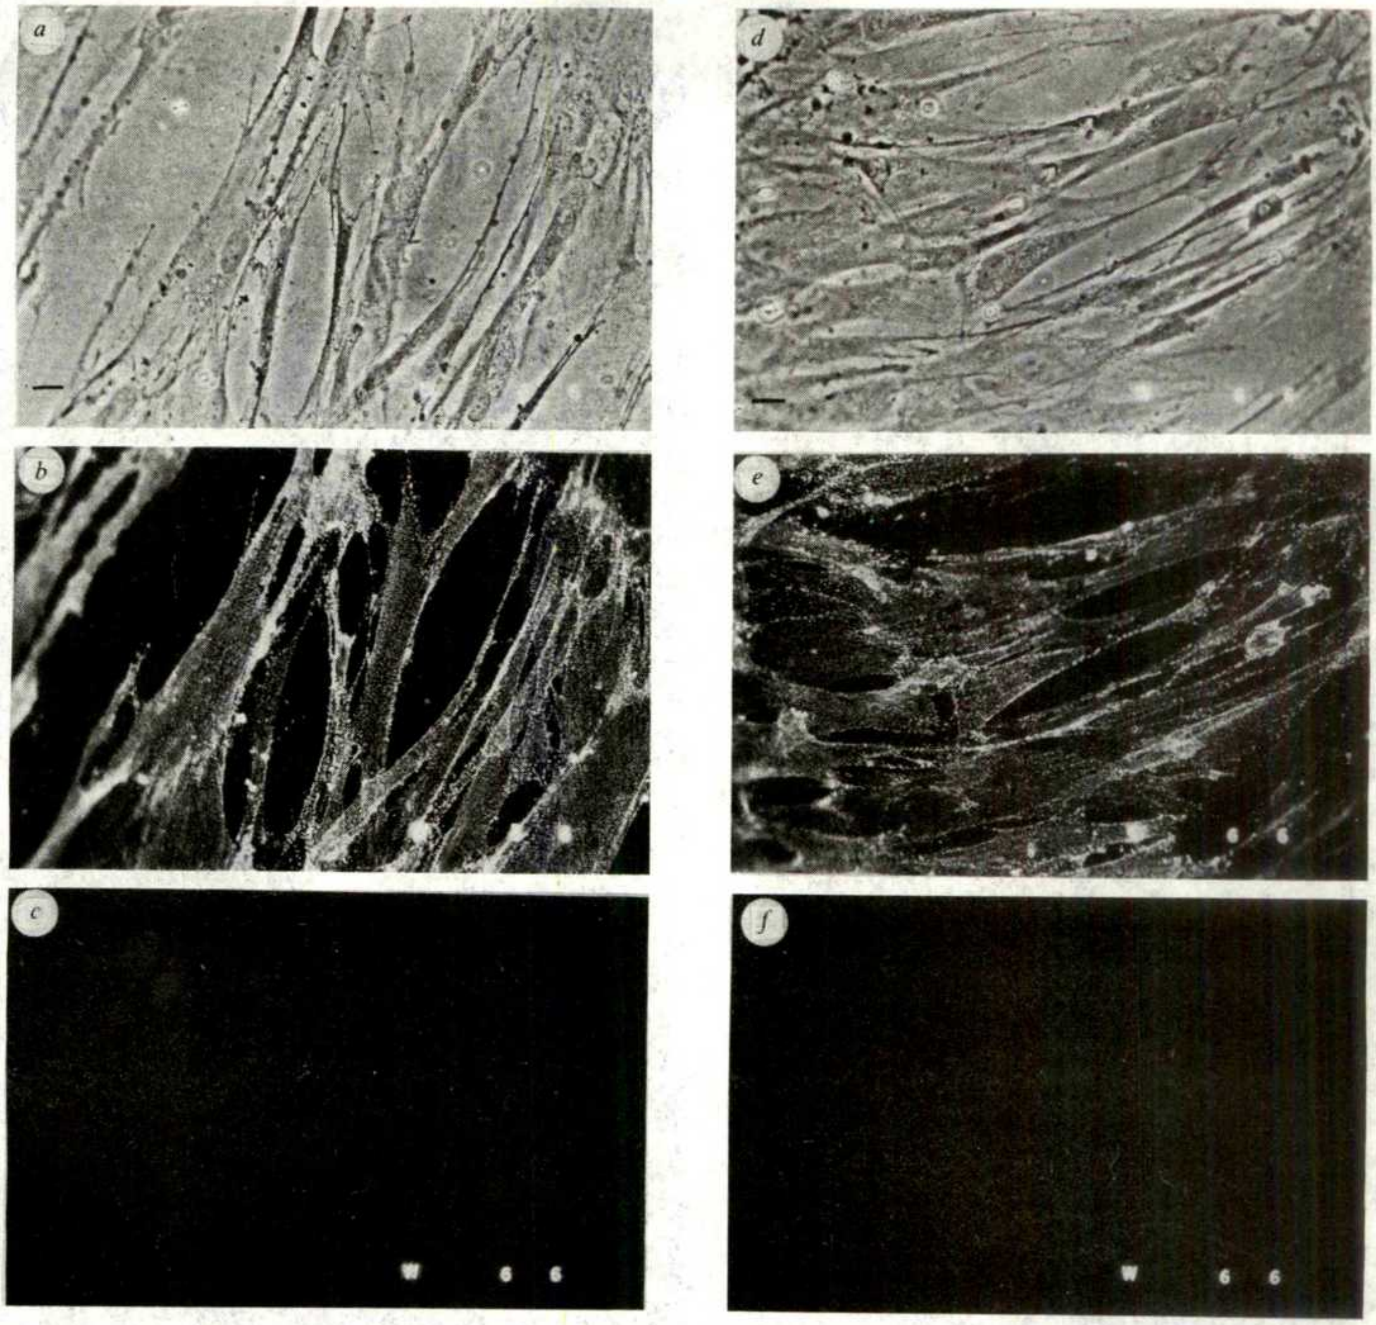

Fig. 1 Double immunofluorescent staining of fetal human skin fibroblast or muscle fibroblast cells with rabbit anti-rat Thy-1 antibody and 5.1 H11 monoclonal antibody. Fibroblasts were prepared from fetal skin by dissociating with trypsin and collagenase, using the procedure previously described for muscle[17]. The cells were grown on 60-mm Petriperm plates (Heraeus) in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf serum (FCS). Fetal human muscle fibroblasts were prepared by preplating[14] a single-cell suspension of enzymatically dissociated skeletal muscle. The cells that adhered to uncoated 100-mm Lux Petri dishes after 30 min incubation were regarded as muscle fibroblasts. These cells were grown to confluence in DMEM, 10% FCS, at least twice before use to allow any residual myoblasts to fuse into myotubes. These cultures express negligible activity of the muscle enzymatic marker creatine phosphokinase when grown to confluence. Immunofluoroescent staining of skin or muscle fibroblast cultures was carried out on subconfluent cultures. The Petriperm plates were cut into 10-mm^2 pieces and 10 μl of an F(ab')$_2$ preparation of rabbit anti-rat Thy-1 antibody (24 μg ml^{-1}) in phosphate-buffered saline (PBS, 10 mM Na phosphate buffer, 0.15 M NaCl, *p*H 7.3) and 10 μl of 1 : 100 dilution of 5.1 H11 antibody (ascitic fluid) in PBS added for 45 min at 20 °C. The cells were washed in PBS and 10 μl of an F(ab')$_2$ fragment of sheep anti-rabbit IgG antibody (60 μg ml^{-1}) labelled with rhodamine plus 10 μl of a 1 : 10 dilution of goat anti-mouse IgG antibody labelled with fluorescein (Meloy) added for 45 min at 20 °C. The cells were washed extensively in PBS, fixed in 3.5% formaldehyde in PBS for 5 min followed by 5% acetic acid in ethanol for 5 min at 20 °C. The samples were mounted on glass slides in glycerol and sealed with nail varnish. Samples were examined with a Leitz dialux 20 microscope equipped with phase contrast fluorescein and rhodamine optics and epi-illumination. *a*, Phase-contrast view of skin fibroblast culture; *b*, positive Thy-1 staining viewed with rhodamine optics; *c*, negative 5.1 H11 staining with fluorescein optics; *d*, phase-contrast view of muscle fibroblast culture; *e*, positive Thy-1 staining viewed with rhodamine optics; *f*, negative 5.1 H11 staining with fluorescein optics. rat fibroblasts[8,9]. Thus, unequivocal identification of the major mononucleate cell types in muscle cultures, fibroblasts and myoblasts has not been possible. We report here the use of two surface antigens, Thy-1 and a muscle-specific antigen recognized by a monoclonal antibody, to identify unambiguously the four major types of cells present in human muscle cultures and to propose a model of cell-surface differentiation during human myogenesis.

Two antibodies were used in this study. The first is a rabbit antibody to purified rat brain Thy-1 (refs 10, 11) which we have used to detect the human homologue of Thy-1 (refs 12, 13). Preabsorption of this antibody with pure rat brain Thy-1 (1:3 molar ratio) abolished all immunofluorescence on human muscle cells (see below), showing the staining to be specific for the Thy-1 molecule. In addition, because previous absorption of the anti-Thy-1 with Thy-1.2 mouse thymocytes also abrogated

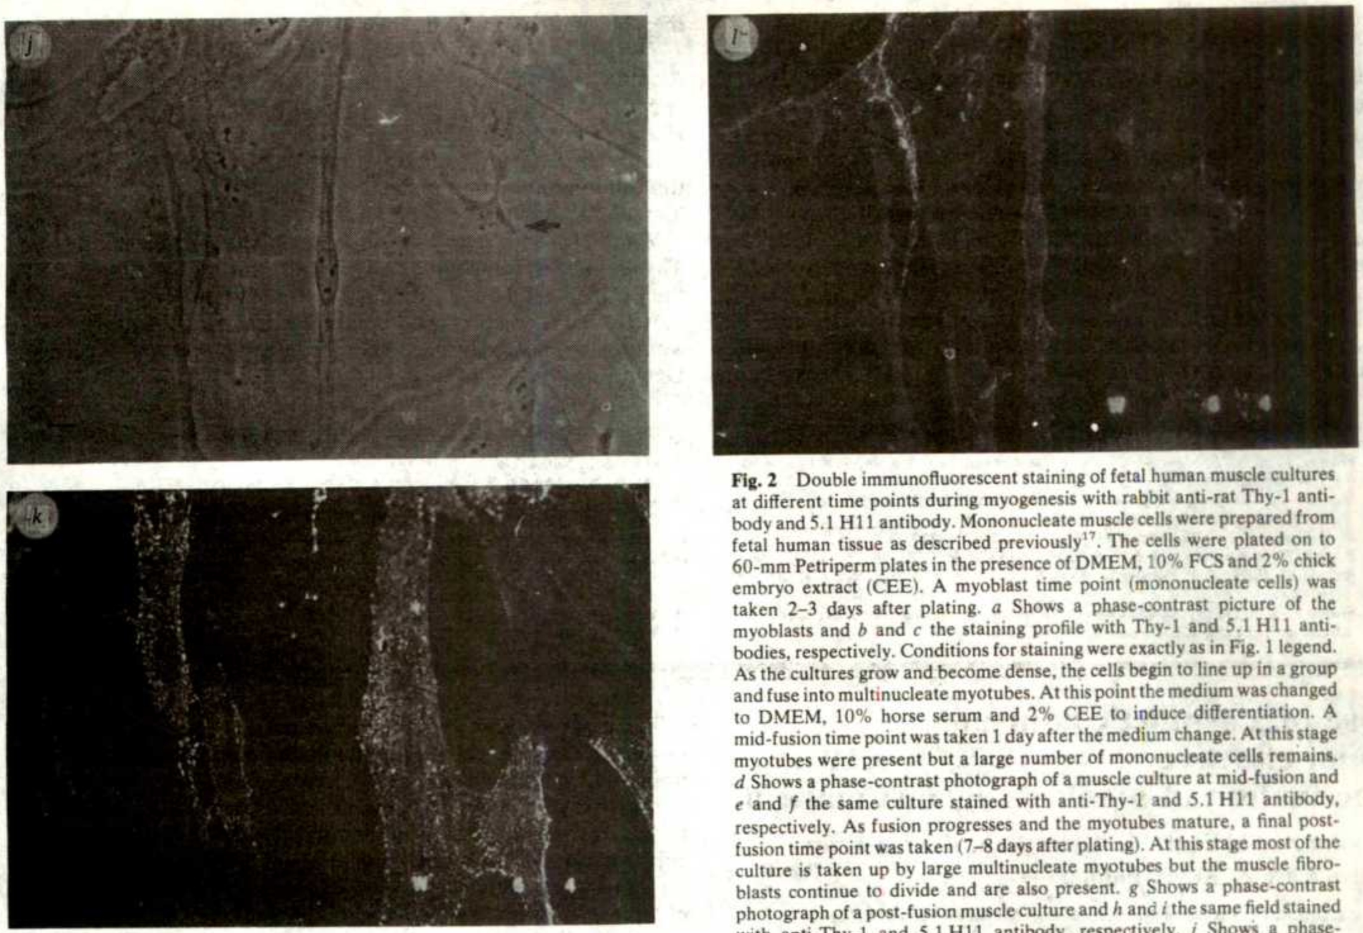

Fig. 2 Double immunofluorescent staining of fetal human muscle cultures at different time points during myogenesis with rabbit anti-rat Thy-1 antibody and 5.1 H11 antibody. Mononucleate muscle cells were prepared from fetal human tissue as described previously[17]. The cells were plated on to 60-mm Petriperm plates in the presence of DMEM, 10% FCS and 2% chick embryo extract (CEE). A myoblast time point (mononucleate cells) was taken 2–3 days after plating. *a* Shows a phase-contrast picture of the myoblasts and *b* and *c* the staining profile with Thy-1 and 5.1 H11 antibodies, respectively. Conditions for staining were exactly as in Fig. 1 legend. As the cultures grow and become dense, the cells begin to line up in a group and fuse into multinucleate myotubes. At this point the medium was changed to DMEM, 10% horse serum and 2% CEE to induce differentiation. A mid-fusion time point was taken 1 day after the medium change. At this stage myotubes were present but a large number of mononucleate cells remains. *d* Shows a phase-contrast photograph of a muscle culture at mid-fusion and *e* and *f* the same culture stained with anti-Thy-1 and 5.1 H11 antibody, respectively. As fusion progresses and the myotubes mature, a final post-fusion time point was taken (7–8 days after plating). At this stage most of the culture is taken up by large multinucleate myotubes but the muscle fibroblasts continue to divide and are also present. *g* Shows a phase-contrast photograph of a post-fusion muscle culture and *h* and *i* the same field stained with anti-Thy-1 and 5.1 H11 antibody, respectively. *j* Shows a phase-contrast photograph of a mid-fusion culture, and *k* and *l* the same field stained with anti-Thy-1 and 5.1 H11 antibodies, respectively. Note the mononucleate cell (see arrow) stained by 5.1 H11 antibody but not anti-Thy-1. Scale bar, 20 μm.

all immunofluorescent staining on human cells, it must be the rat–mouse cross-reacting antigenic determinant that is shared by rat and human Thy-1. The second reagent, 5.1 H11 monoclonal antibody[7], was produced from a cell fusion involving P3X63 Ag8 mouse myeloma cells and spleen cells from a BALB/c mouse immunized with human myotube cells. It reacts with human myoblasts and myotubes but not with fibroblasts and is human muscle cell specific[7].

Human fetal skin fibroblasts, muscle fibroblasts and muscle cultures at different stages of myogenesis were grown and tested for reactivity with these antibodies by indirect immunofluorescence. Figure 1 shows that Thy-1 antigen is present on all cells in human skin and muscle fibroblast cultures; neither of these cell types showed detectable reactivity with 5.1 H11 antibody. The results with anti-Thy-1 antibody agree with data from rats that show Thy-1 antigen is expressed on fibroblasts[9].

The distribution of Thy-1 and 5.1 H11 antigens in cultures of mononucleate muscle cells is shown in Fig. 2*a–c*. In contrast to the results with skin or muscle fibroblasts, the majority of the cells in the myoblast culture are labelled by both anti-Thy-1 and 5.1 H11 antibodies. A few (10%) of the cells were found to be Thy-1$^+$/5.1 H11$^-$. These muscle cultures have been significantly depleted of fibroblasts by preplating[14]; we therefore believe that the Thy-1$^+$/5.1 H11$^-$ cells are muscle fibroblasts, because these cells express the same antigenic phenotype as the fibroblast cultures. At the mid-fusion stage of growth and differentiation (Fig. 2*d*), the mononucleate myoblast cells have started to fuse into multinucleate myotubes, although some mononucleate cells remain. All the multinucleate myotubes in the cultures are stained by 5.1 H11 antibody (Fig. 2*f*) but not by anti-Thy-1 antibodies (Fig. 2*e*). Multinucleate myotubes are therefore Thy-1$^-$/5.1 H11$^+$. As the myoblast population has mostly fused to form myotubes, there are few myoblasts of Thy-1$^+$/5.1 H11$^+$ phenotype at this time. Most of the mononucleate cells in these cultures are Thy-1$^+$/5.1 H11$^-$ and, we believe, fibroblasts. At a later stage in muscle differentiation, post-fusion, the fibroblast population has enlarged and the majority of the mononucleate cells are Thy-1$^+$/5.1 H11$^-$. The myotubes here are still Thy-1$^-$/5.1 H11$^+$. In general, the strength of 5.1 H11 staining is much higher in post-fusion than in mid-fusion cultures so it is possible that the level of the antigen increases during differentiation. Two further points deserve comment. First, in mid-fusion and post-fusion cultures a small percentage of mononucleate cells is often found expressing the phenotype Thy-1$^-$/5.1 H11$^+$. Figure 2*j, k, l* shows an example of this behaviour and it seems likely that these cells are post-mitotic myoblasts which do not fuse to myotubes[15].

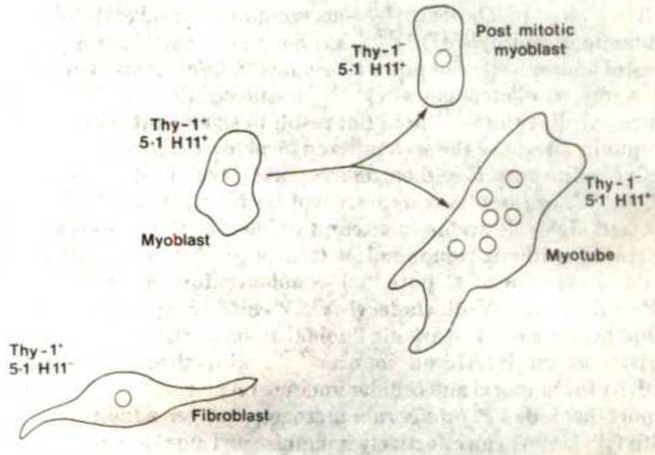

Fig. 3 A scheme for cell-surface differentiation during human myogenesis.

Second, we have confirmed the conclusions presented for the primary muscle cultures in experiments carried out on myogenic single-cell clones derived from human skeletal muscle.[16] Thus, the pure populations of myoblasts in these clones are all Thy-1$^+$/5.1 H11$^+$ and multinucleate myotubes are Thy-1$^-$/5.1 H11$^+$. No Thy-1$^+$/5.1 H11$^-$ cells were found in either pre- or post-fusion cultures.

Thus, we have found a distinctive phenotype for each of the main cellular populations in human skeletal muscle cultures. It is therefore possible to construct a model of surface membrane changes during myogenesis incorporating these results (Fig. 3). 5.1 H11 is present throughout myogenesis, whereas Thy-1 is lost from the cell surface as myoblasts fuse to form multinucleate myotubes (a similar situation is found with rat Thy-1[8]) or when they become post-mitotic myoblasts. Fibroblasts remain Thy-1$^+$/5.1 H11$^-$ throughout culture. Hence, it should be possible to separate out the various muscle cell types for biochemical analysis. A number of interesting points remain to be resolved. Exactly when is Thy-1 lost: before or after myotube formation? Could cell-surface Thy-1 be involved in the fusion process and is this differentiation pattern altered in diseases such as Duchenne muscular dystrophy? These aspects are now being investigated.

We thank Dr Roger Morris for the gift of the rabbit anti-rat Thy-1, rhodamine-conjugated sheep anti-rabbit antisera and the purified rat Thy-1 antigen, Dr Rose Yasin for the human muscle clones and Susheela Dhut for technical assistance. This work was supported by a special project grant from the Muscular Dystrophy Group of Great Britain to F.S.W.

Research towards the development of a vaccine against malaria has recently accelerated[1], mainly because of a resurgence in the worldwide incidence of the disease[2]. These investigations have been aided by the use of the owl monkey for direct experimentation with human malaria[3–5], techniques for producing *Plasmodium falciparum* antigen through continuous or short-term *in-vitro* cultivation[6,7], and the recent demonstration of effective immunization of owl monkeys against *P. falciparum*[8,9]. However, the inclusion of a strong adjuvant in the vaccines seems to be required for the development of protective immunity. Thus, inclusion of the whole mycobacterial cell wall/mineral oil adjuvant (Freund's complete adjuvant: FCA)[8,9] or a semi-synthetic derivative of the active component of that cell wall (6-*O*-stearoyl-*N*-acetylmuramyl-L-alanyl-D-iso-glutamine: stearoyl-MDP)[10,11] has been necessary for the successful immunization of primates against *P. falciparum*. The use of X-ray irradiated parasites[12–14] or substitution of FCA by muramyl-dipeptide[15,16] does not result in significant protective immunity. Because the systemic and local toxic responses to the active adjuvants is either unacceptable (as in the case of FCA)[10,11], or essentially undescribed (as for stearoyl-MDP), it seemed highly desirable to attempt to identify alternative, well tolerated synthetic compounds with strong adjuvant activity for malarial vaccines. A potential candidate for this role was CP-20,961 (*N, N*-dioctadecyl-*N′*, *N′*-bis (2-hydroxyethyl)-propanediamine), a synthetic lipoidal amine, originally characterized as an interferon inducer[17–20], with strong adjuvant activity for humoral and cellular immune responses[21,22]. We now report that killed *P. falciparum* merozoite antigen administered with CP-20,961 can effectively immunize owl monkeys against a lethal *P. falciparum* infection.

The adjuvant action of CP-20,961 derives from an enhancement of leukocyte traffic through antigen deposits and into the draining lymph nodes, potentiating the expansion of immunoreactive clones[23]. Immunizations of guinea pigs[21], mice[23], rats, cows and horses (unpublished data) with intramuscular vaccines adjuvanted with CP-20,961 in aqueous soybean oil emulsions result in elevated immune responses, with only mild, transient swelling at the site of injection. The nature and extent of the cellular reactions induced at the site of CP-20,961 injection and in the draining lymphatics has been well characterized and seems to be quite benign, in contrast to reactions noted with equipotent doses of FCA[23]. Systemic toxicity of CP-20,961 also seems quite low when assessed either acutely ($LD_{50} > 2{,}000$ mg per kg, mice, intraperitoneally i.p.), or chronically (unpublished data). It was these characteristics which prompted our investigation of CP-20,961 as a substitute for FCA in an experimental malaria vaccine.

The Uganda-Palo Alto strain (FUP) of *P. falciparum* has been maintained in our laboratory by serial passages of blood-induced infections in owl monkeys (*Aotus trivirgatus griseimembra*)[24]. The immunizing antigen (mature segmenters containing individual merozoites) was obtained through short-term *in vitro* cultivation of owl monkey-derived *P. falciparum* parasites[11,25], and was concentrated and collected relatively free of other cellular elements[26]. The antigen preparation was stored at −20 °C for 2 months.

CP-20,961 was prepared with carrier soybean oil emulsion (Intralipid, Cutter Laboratories) as previously described[21]. The adjuvant stearoyl-MDP was used with carrier liposomes[10,27] and the method of malaria vaccine preparation using this adjuvant has been described earlier[11], as have the techniques for preparing malaria vaccine with FCA[8].

Nine owl monkeys were used, indicated by physical characteristics and fur coloration[28] to be of phenotype B. Using the standard chromosome preparation method[29] and well established classification criteria[28], six monkeys (A299, A304, A300, A297, A310 and A321) were found to belong to karyotype II and the remaining three (A320, A322 & A301) to karyotype III. Monkeys of both these karyotypes, originating in Columbia, South America, were found to be highly susceptible to blood challenge from a patent *Aotus* monkey infection of the FUP strain of *P. falciparum*[30].

Table 1 summarizes the composition of the vaccine and the vaccination schedule. Three monkeys were used as controls: A299 and A305 received parasite antigen only and A300 CP-20,961 adjuvant only. Of the six vaccinated monkeys,

0028-0836/81/020064—03$01.00

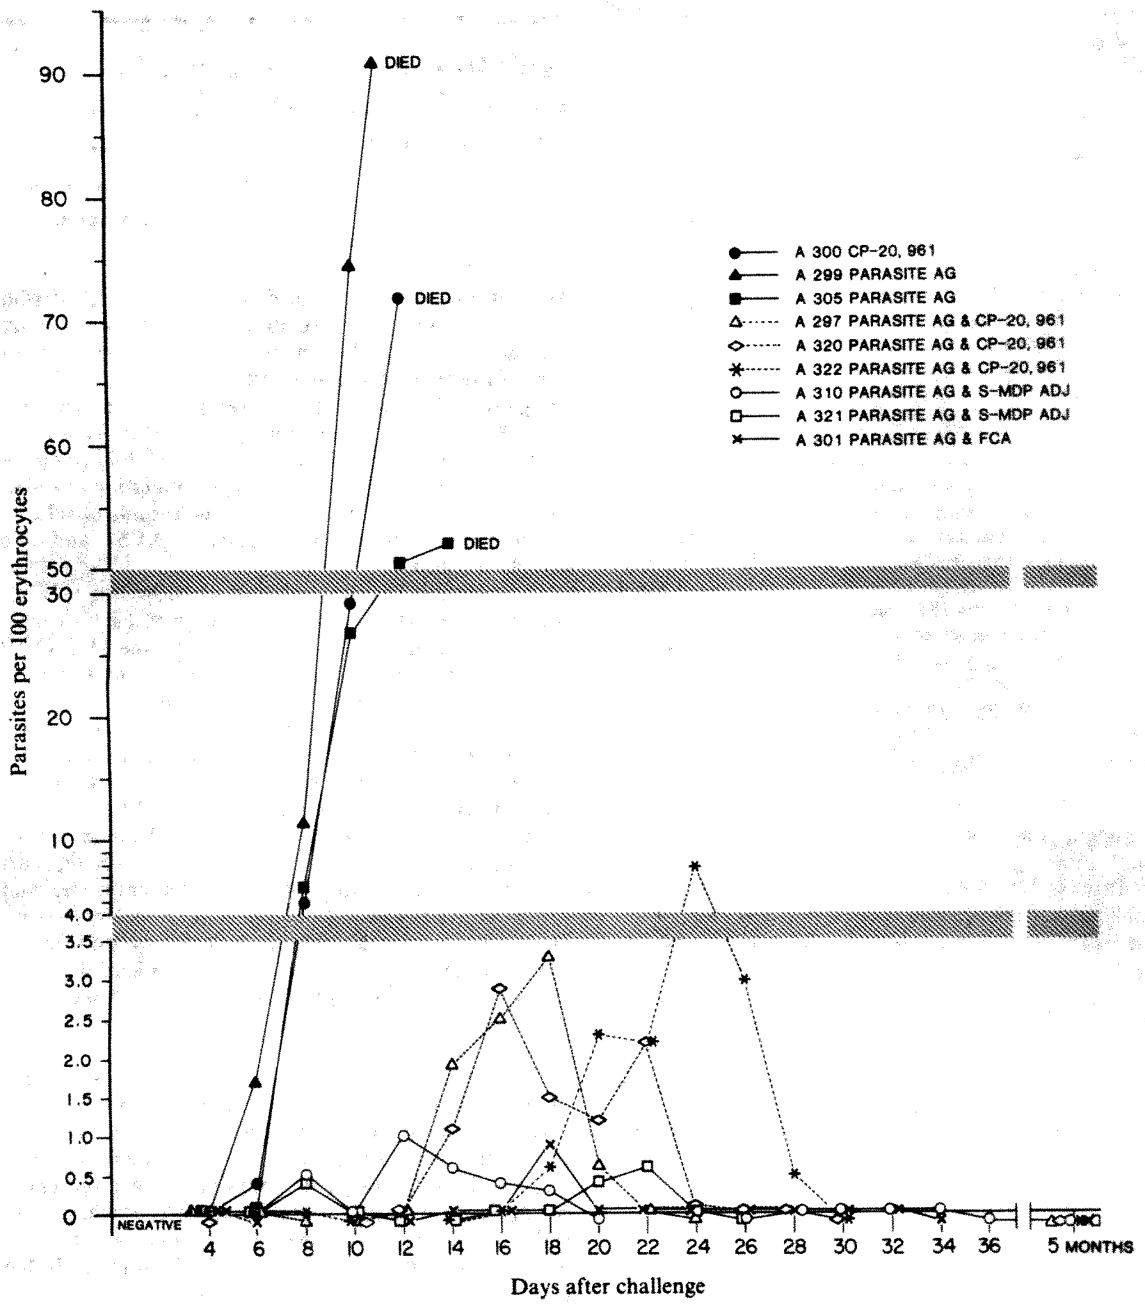

Fig. 1 Course of infection of *Plasmodium falciparum* (FUP strain) in control and vaccinated monkeys (*Aotus trivirgatus griseimembra*).

A297, A320 and A322 received vaccine composed of parasite antigen plus CP-20,961 adjuvant; A310 and A321 were vaccinated with parasite antigen mixed with stearoyl-MDP; A301 received parasite antigen with FCA. Two intramuscular injections of vaccine were given in alternate thighs at a 3-week interval. Immunization never produced a detectable infection. On day 51, all nine monkeys were challenged with an intravenous injection of 7.5×10^5 parasites (FUP strain of *P. falciparum*) derived from a current infection in an owl monkey. Thick and/or thin blood films were made daily to follow the course of infection (Fig. 1). All three control monkeys died within 2 weeks of challenge: A300 and A299 died on day 12 with parasitaemias of 72.0 and 91.0%, respectively, and A305 died on day 14 with 52.2% parasitaemia. In contrast, all six vaccinated monkeys survived challenge, exhibiting only low grade infections. The duration of patency was longest in A310, which experienced a maximum parasitaemia of 1.6% and a very mild recrudescence. The duration of parasitaemia was similar in the other five vaccinated animals. Peak parasitaemias of 4% occurred in A297 and A320 and 8% in A322, and lasted for 3 days only. In general, the level of parasitaemia remained below 0.5% in A301 and A321. Full recovery from *P. falciparum* infection began on day 24 for A297, on day 32 for A320, A321, A322 and A301, and on day 36 for A310. Although the number of monkeys used in this experiment was small, the difference between the course of infection in immunized and non-immunized monkeys is indeed very significant considering the high virulence of *P. falciparum* (FUP) for owl monkeys. The FCA-immunized monkeys displayed the usual granulomatous abscesses at the injection site, but only minimal side reactions were observed in the owl monkeys immunized with the synthetic adjuvants: stearoyl-MDP induced a temporary anorexia and CP-20,961 produced a slight, transient swelling at the site of injection.

Our results confirm previous findings of protective immunity conferred by merozoite vaccines containing stearoyl-MDP[11] and FCA[8,9], and further demonstrate that the novel synthetic adjuvant CP-20,961, when combined with *P. falciparum*

Table 1 Use of synthetic adjuvants in vaccination of Aotus monkeys against *Plasmodium falciparum* (Uganda-Palo Alto strain)

	Composition of vaccine		
Monkey no.	Adjuvant	Parasite antigen (1.4 mg protein per injection)	Challenge inoculum (7.5×10^5 infected erythrocytes)

A305	None	+	+
A300	Pfizer, CP-20,961*	None	+
A297	Pfizer, CP-20,961	+	+
A320	Pfizer, CP-20,961	+	+
A322	Pfizer, CP-20,961	+	+
A310	S-MDP†	+	+
A321	S-MDP	+	+
A301	FCA‡	+	+

The vaccine consisted of adjuvant plus antigen mixed using a 3-way stopcock and two syringes, administered intramuscularly in alternate thighs. Vaccination was on days 0 and 21. Parasite antigen consisted of >50% mature schizonts with individual merozoites, freed by saponin lysis, 0.5 ml per dose[21]. Challenge inoculum was with parasitized blood obtained from a current infection (FUP strain of *P. falciparum*) in an *Aotus* monkey. Inoculum was given intravenously on day 51.

* Pfizer adjuvant containing 3 mg of CP-20,961 dispersed in Intralipid in 1.0 ml volume per dose[22].

† 0.25 mg of 5-*O*-stearoyl-*N*-acetylmuramyl-L-alanyl-D-isoglutamine plus liposomes in 1.0 ml volume per dose[21].

‡ 0.5 ml Freund's complete adjuvant (Difco) per dose.

merozoite antigen, fully protects owl monkeys against a normally lethal homologous challenge of intra-erythrocytic *P. falciparum* parasites. Although the duration of immunity conferred by malaria vaccines containing CP-20,961 or other adjuvants has not been fully assessed in the present model, antibodies against Rift Valley fever virus produced in *Macacca fascicularis* with a CP-20,961-adjuvanted vaccine persist at high levels for at least 6 months (J. A. Reynolds, personal communication).

Isolation of a cloned cell line expressing variant H–2K^k using fluorescence-activated cell sorting

B. Holtkamp, M. Cramer, H. Lemke* & K. Rajewsky

Institute for Genetics, University of Cologne, Weyertal 121,

We describe here a method for the isolation of somatic cell variants that express a structurally altered gene product on their cell surface. The method makes it possible to select positively for cells of the variant phenotype which is defined by loss of a given antigenic determinant. As an example, we present the isolation of a cloned cell line expressing a structurally altered H–2K^k molecule, designated H–2K^{kS1}. Cells of this phenotype were found to be present in the wild-type population at a frequency of 10^{-5}–10^{-6} and were isolated in three rounds of selection in the fluorescence-activated cell sorter (FACS) and subsequent growth *in vitro*.

Our method for the isolation of structural H–2K^k variants requires a set of monoclonal antibodies, each of which reacts with a single antigenic determinant on the H–2K^k molecule[1]. The antigenic determinants recognized by these antibodies can be distinguished from each other by genetic analysis in which the antibodies are reacted with a set of cells expressing different H–2 haplotypes[2]. Imagine a pair of monoclonal anti-H–2K^k antibodies, each of which binds to a different H–2K^k determinant. If one antibody is labelled with a green and the other with a red fluorescent dye and the cells stained with a mixture of the two, we could in principle directly isolate, by cell sorting, variant cells that have lost reactivity with one of the antibodies but not the other. Such cells would be expected to continue expressing an H–2K^k-like molecule, but this molecule would lack at least one antigenic determinant. Because of technical limitations of the FACS I (Becton-Dickinson), we have not yet been able to apply this simple principle directly, but have used a similar, though less general, approach (Fig. 1).

We used a pair of monoclonal antibodies which mutually inhibit their binding to the H–2K^k target, presumably by steric hindrance. Such pairs of antibodies have been shown to exist[3]. One of the two antibodies is labelled with a fluorescent dye and incubated with cells in the presence of a large excess of the (unlabelled) second antibody. In these conditions we expect staining of variant cells only, in particular of variants that have lost reactivity with the second antibody. Such cells can then be positively selected for in the cell sorter.

The wild-type cells used in our study were descendants of the LDHB cell line which originated from a spontaneous lymphoma of a (C3H × DBA/2)F$_1$ mouse and which is described in ref. 3. LDHB cells possess 41 chromosomes and carry on one of their two chromosomes no. 17 the structural gene for the H–2K^k molecule. Because H–2K^k is only poorly expressed on the surface of LDHB cells[1], a 'high-producer' subline was established by staining LDHB cells with fluorescent, monoclonal anti-H–2K^k antibodies[2], isolating the brightest cells in the FACS I, growing them up in culture and repeating the process. After eight cycles of sorting and subsequent growth *in vitro*, the cells were cloned by limiting dilution (cloning efficiency 70%). The cells then grew in culture for 5 months with a doubling time of 18 h, during which time they were selected for high H–2K^k expression by cell sorting five times. The resulting cell line, HK13, exhibited bright fluorescence on staining with fluorescent anti-H–2K^k antibodies, 10 times above that of spleen cells from (C3H × DBA/2)F$_1$ mice, and from this cell line we isolated a somatic variant with structurally altered H–2K^k.

For this purpose we used fluorescein-labelled antibody H100-5/28 for cell staining and antibody H100-27/55 as inhibitor (compare with Fig. 1). The properties of these monoclonal

---

* Present address: Biochemical Institute, Christian-Albrecht-University, D-2300 Kiel, FRG.

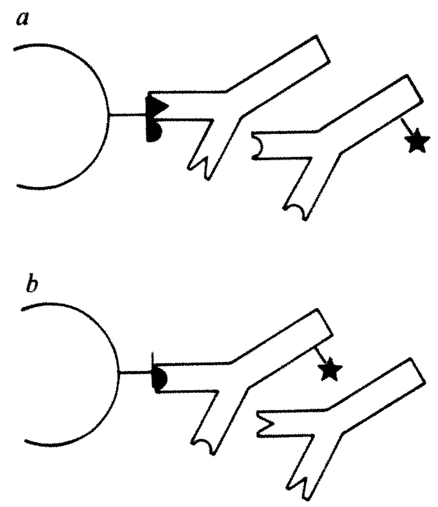

Fig. 1 Principle of variant selection. *a*, The labelling of cells carrying wild-type H-2K^k by a fluorescent (★) monoclonal antibody is inhibited by an unlabelled second antibody which binds to a neighbouring antigenic determinant. *b*, Cells expressing variant H-2K^k molecules that have lost the neighbouring determinant are successfully stained in the same experimental conditions. In reality, the unlabelled antibody is present in a 1,000-fold excess.

antibodies against H-2K^k are described in refs 1 and 2. The methods for attaching fluorescein groups to antibodies and for cell staining have been described previously[3]. Antibody H100-27/55 inhibited almost completely fluorescent staining of HK13 cells by antibody H100-5/28. Rare spontaneous variants whose staining could not be inhibited, and which were apparently present in a population of 2.4×10^7 HK13 cells (the total number of cells initially sorted; compare with Table 1), were isolated during three rounds of separation in the cell sorter and subsequent growth *in vitro*. The technical details of our cell-sorting procedure have been described previously[4]. Table 1 summarizes this particular series of cell sorting.

The proportion of variant (fluorescent) cells in the cell population increased dramatically after each sort (30–100-fold) and reached 78% after the third round of cell sorting and growth. These cells were again stained as before and variants were cloned directly by sorting single fluorescent cells into the wells of a 96-microwell tissue culture plate[5]. Fourteen clones were picked, recloned twice by limiting dilution (cloning efficiency ~70%) and subjected to fluorescence analysis. With one exception, all the clones behaved similarly in this analysis—almost 100% of the cells exhibited bright fluorescence when labelled with fluorescein-conjugated antibody H100-5/28, whereas the fluorescence on labelling with fluorescein-conjugated antibody H100-27/55 was close to background. (In fact the fluorescence was slightly above background. We attribute this to the slight cross-reaction of antibody H100-27/55 with the H-2D^k product[2] (also expressed in HK13 cells) because the staining could not be inhibited by unlabelled antibody H100-5/28.) The binding of antibody H100-5/28 to the variant cells was not significantly inhibited by even a 1,000-fold excess of antibody H100-27/55 in a radioinhibition assay[1] (data not shown).

To demonstrate that the variant cells indeed express structurally altered H-2K^k molecules, a clone exhibiting particularly strong fluorescence with antibody H100-5/28 was selected (HK13.S1) and grown up in tissue culture. 1×10^8 variant and wild type cells (HK13) were surface iodinated with ^{125}I by the lactoperoxidase technique[6] and lysed at 4 °C with 0.5% NP40 in the presence of 10^{-3} M phenylmethylsulphonyl fluoride. Nuclei were spun down and the lysate deaggregated by high-speed centrifugation. Details of the method are given in ref. 7. H-2K^k molecules were then precipitated from the lysates with monoclonal antibodies H100-27/55 and H100-5/28 and analysed on SDS-polyacrylamide gels (for experimental details see Fig. 2 legend). The results are shown in Fig. 2.

In the case of the HK13 cell lysate, the familiar 45,000- and 12,000-molecular weight bands of H-2K heavy and light chains appear on the gels on precipitation with either of the two monoclonal antibodies (tracks *a* and *b*). As staining of HK13 cells by either antibody can be completely inhibited by the other, we assume that the protein bands in tracks *a* and *b* represent the heavy and light chains of a single H-2K^k molecule that co-expresses the determinants recognized by the two antobodies. With the variant cell lysate, bands of similar size appear on the gel, but only on precipitation with antibody H100-5/28; anti-

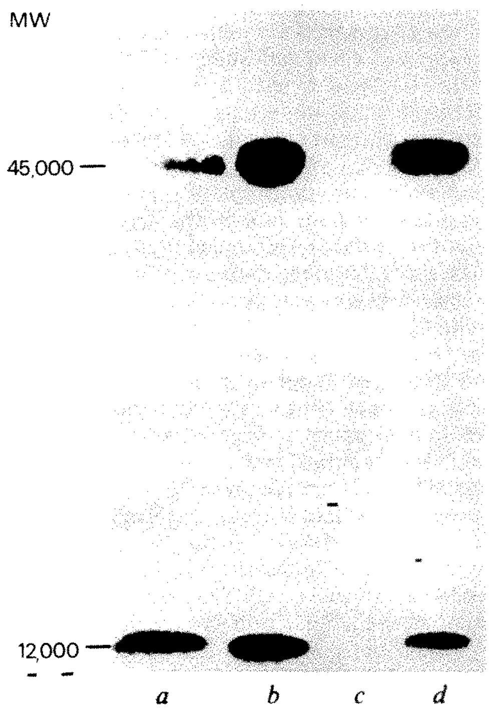

Fig. 2 Electrophoretic analysis of precipitations of wild-type and variant H-2K^k molecules with monoclonal antibodies H100-27/55 and H100-5/28. Detergent lysates (equivalent to 10^7 surface-iodinated cells) were incubated with 30 μg antibody (DEAE-cellulose purified) at 4 °C for 6 h and the immunoglobulin (IgG2a in both cases) was bound to 25 μl protein A-Sepharose (Pharmacia). After appropriate washings; sample buffer 4% SDS, 6 M urea, 10% 2-mercaptoethanol and bromophenol blue (tracking dye) was used to dissociate the antigen-antibody-protein A-Sepharose complexes. The figure shows the autoradiograph (8 days exposure) of a 10–15% gradient polyacrylamide slab gel run in 0.1% SDS in the discontinuous system of Laemmli[10]. One aliquot of HK13 (wild-type) lysate was precipitated with antibody H100-27/55 (track *a*) and another aliquot was precipitated with antibody H100-5/28 (track *b*). Similarly, HK13.S1 lysate (variant type) was precipitated with antibody H100-27/55 (track *c*) and with antibody H100-5/28 (track *d*). As identical amounts of antibodies H100-27/55 and H100-5/28 were used in our precipitating procedure, we consider the fainter bands in track *a* to be due to a lower precipitation capacity of antibody H100-27/55. MW, molecular weight.

body H100-27/55 does not bring down any detectable radioactivity (tracks *c* and *d*). Taken together, the data show that HK13.S1 cell membranes contain variant H-2K^k molecules, whose polypeptide chains are of similar size to those of the wild-type molecules but which lack one of the two antigenic determinants recognized by our two monoclonal antibodies and are co-expressed in wild-type H-2K^k. The different fluorescent-staining patterns of wild-type and variant cells are thus due to an alteration of H-2K^k itself and not, for example, to a change in its orientation in the cell membrane.

The selection method described here makes it possible to isolate efficiently and at will a somatic-cell variant that stably expresses structurally altered H-2K^k molecules on the surface. From the data in Table 1, we conclude that spontaneous variants of the selected phenotype were present in the population of HK13 cells at a frequency of 10^{-5}–10^{-6}. Taking into account the generation time of the cells and the number of generations after cloning, we estimated roughly a frequency of variation of 10^{-6}–10^{-7} per cell per generation. This low frequency and the stability of the variant suggest that the phenotypic change in HK13.S1 cells is due to mutation. Preliminary experiments indicate that both antibodies used in the variant selection also react with unglycosylated H-2K^k molecules. The mutation carried by HK13.S1 cells may therefore have occurred in the structural gene for H-2K^k. Structural analysis of the variant protein or of the corresponding genetic material is required to establish this point. We provisionally designate the mutation as H-2K^{ks1} (the prefix 's' standing for 'somatically derived'), assuming that the mutation is expressed exclusively in the H-2K^{kS1} molecule. We have meanwhile isolated a second H-2K^k structural variant using a different pair of monoclonal antibodies (unpublished data) and thus feel that our method of selection may have wide applicability.

The advantages of our approach are that many cells can be screened and that we exclude variants that have lost the expression of the entire surface component in question—an event which is often more frequent than structural variation[8]. The latter feature also applies to the classical identification of structural H-2 mutations carried in the germ line by tissue transplantation between inbred animals (see ref. 9) but which is severely limited in quantitative terms.

The present approach allows us to study not only types and frequencies of mutations occurring in mammalian genes, such as genes in the H-2 complex and V and C genes encoding immunoglobulin heavy chains, but also the functional properties of the variant-gene products. With H-2 this might elucidate the role of H-2-encoded molecules in the immune system. It is encouraging that we have found that the variant H-2K^k molecules expressed in HK13.S1 cells function very efficiently as targets for alloreactive killer T cells but are deficient as restricting elements in trinitrophenyl-specific, H-2-restricted cytotoxic reactions (J. Neuerburg and H.-W. Vohr, unpublished data).

This work was supported by the Deutsche Forschungsgemeinschaft through SFB 74 and the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen. We thank W. Santüns for help in the cell sorter experiments and Ms C. Schenkel for technical assistance, Dr K. Reske for technical advice and Dr A. Radbruch for analysing the LDHB cell karyotype.

Expression of cell-surface HLA-DR, HLA-ABC and glycophorin during erythroid differentiation

‡ Ludwig Institute for Cancer Research, Sutton, Surrey SM2 5PX, UK

The unexpected discovery that Ia-like (HLA-DR) antigens[1-3] in humans were present on blast cells from acute myeloblastic leukaemia[4,5] led to the finding that normal granulocytic progenitors, in contrast to their mature descendents, also expressed HLA-DR antigens. Thus, anti-Ia sera stain a proportion of myeloblasts in normal bone marrow[6,7], inhibit myeloid progenitor (CFU-GM) colony formation in the presence of complement[8] and can be used to label and separate CFU-GM on a fluorescence-activated cell sorter (FACS)[9]. Winchester *et al.* subsequently reported that erythroid progenitors (BFU-E and CFU-E) were also inhibited or killed by anti-Ia (p28,37) and complement[10]. These observations raised the possibility that HLA-DR (or presumptive I-region equivalent) products might have a regulatory role in early haematopoiesis. We have now analysed HLA-DR and HLA-ABC antigen expression on normal erythroid progenitors using monoclonal antibodies to non-polymorphic determinants and fluorescence-activated cell sorting. In parallel experiments, we tested a monoclonal antibody to glycophorin, a well defined erythroid-specific cell-surface membrane glycoprotein[11]. We report that HLA-DR, HLA-ABC and glycophorin are all expressed at various stages during erythroid differentiation.

Table 1 lists the results of assays for erythroid burst-forming units (BFU-E) and colony-forming units (CFU-E) in a series of experiments in which monoclonal anti-HLA-DR was used to stain blood or marrow cells followed by analysis and sorting on the FACS (Fig. 1).

The majority of recoverable BFU-E consistently seem to localize in the HLA-DR-positive population, whereas CFU-E are found mostly, but not exclusively, in the fraction which has either low density or no HLA-DR. When light scattering was used as an additional parameter for sorting, both the BFU-E and CFU-E seemed to be restricted to the population within the larger light-scattering (or presumed bigger) cell size range.

The total recovery of BFU-E in the separated fractions was, however, only approximately one-third (Table 1 legend). Much higher recovery of CFU-E in these experiments and of BFU-E in experiments with anti-HLA-ABC and anti-glycophorin indicate that this is probably not a technical artefact; neither is it attributable to an inhibiting effect of the monoclonal anti-HLA-DR because no diminution of BFU-E activity is seen in the stained but unsorted cells (see control 2 in Table 1). This result may therefore indicate that sorting on the basis of HLA-DR expression separates cells whose interaction may be required for optimal BFU-E activity.

When monoclonal anti-HLA-ABC (PA 2.6) was used to stain bone marrow cells, all BFU-E and CFU-E were sorted into the HLA-ABC$^+$ (positive) population (Table 1, experiments 6, 7). Bone marrow cells were sorted on the basis of intensity of fluorescence staining with monoclonal anti-glycophorin (Fig. 1). More than 99% of both BFU-E and CFU-E were found in the fraction giving minimal or negative staining (Table 1, experiments 8, 9).

Less than 5.0% of the morphologically recognizable erythroid cells were separated into the HLA-DR-positive fractions. By contrast, almost all the cells in the glycophorin-positive popu-

The unfractionated controls and the positive and negative cell fractions were washed three times in cold alpha medium (Flow) and 2% fetal calf serum (FCS). The cells were then cultured in a mixture containing 30% FCS (Gibco Bio-Cult), 1% bovine serum albumin (Sigma), 10^{-4} M mercaptoethanol, penicillin, streptomycin, 0.9% methylcellulose (Dow) and 2.5 units ml^{-1} erythropoietin (Connaught Step III)[24]. The final concentration of nucleated cells was 1 or 2×10^5 ml^{-1}, although occasionally $<1\times10^5$ cells were obtained for some of the fractions. Volumes of 1 ml of the mixture were plated in 35-mm tissue culture plates (Nunc) in duplicate, and incubated at 37 °C in a high humidity 5% CO_2/95% air tissue-culture incubator. Recognizable CFU-E, identified by the pink-red colour of the cells and comprising one or two clusters, were counted directly on day 7 using an inverted microscope at ×40 magnification. BFU-E, large, red colonies comprising three or more sub-colonies, were counted on day 14. In each experiment, controls 1 and 2 are unlabelled and labelled fractionated cells, respectively. Recovery per 10^5 unfractionated cells is determined by multiplying the number of colonies per 10^5 cells (column 2) by the proportion of cells in that fraction.

* Total colonies recovered, expressed (in parentheses) as a percentage of the mean of the two unfractionated controls. Note, however, that selection of cells on the FACS involves some loss of cells.

† Number of colonies recovered in different fractions expressed as a percentage of total colonies recovered.

lation were identifiable as erythroid precursors at different stages of maturation; almost no recognizable erythroid cells were found in the glycophorin-negative fraction.

It has been suggested that BFU-E activity is enhanced by T cells[12]. As most T cells have no detectable glycophorin and are largely though not entirely HLA-DR negative, potential T-cell–BFU-E interactions could be compromised by the cell-separation experiments described above. To investigate this possibility we labelled bone marrow T cells with a mixture of two pan-T monoclonal antibodies OKT1 (ref. 13) and OKT11 (ref. 14), separated stained and unstained cells on the FACS and assessed the effect of recombination of these fractions. The results (Table 2) indicate that effectively all BFU-E and CFU-E are unreactive with these particular monoclonal anti-T reagents and that bone marrow T cells have, if anything, an inhibitory effect on BFU-E at the cell concentrations used. Further experiments are required to investigate this possibility more thoroughly. Note, however, that the reported promoting effect of blood T cells on BFU-E may be restricted to circulating erythroid progenitors[12] and that this response has not been confirmed in another laboratory[15].

Fluorescence-activated cell sorting with monoclonal antibodies provides an incisive approach to the analysis of cell-surface antigen expression on numerically infrequent progenitor cells. Our data using this approach suggest that the earliest detectable, committed erythroid progenitors, BFU-E, express HLA-DR as well as HLA-ABC antigens and that the former are progressively lost during differentiation through CFU-E to morphologically recognizable erythroblasts. HLA-ABC antigens are lost more slowly, for the majority of CFU-E are positive, as are at least a proportion of morphologically recognizable precursors. Although mature red blood cells have no detectable HLA-ABC, previous studies have indicated that normoblasts and reticulocytes may express at least a low density of these antigens[16–18].

In contrast, the antigenic determinant of glycophorin detected by the monoclonal antibody we have used is not expressed until the post-CFU-E, HLA-DR-negative stage of erythroid maturation. More than 90% of all morphologically recognizable erythroblasts were sorted into the glycophorin$^+$, HLA-DR$^-$ fraction on the FACS. Gahmberg *et al.* similarly reported that basophilic normoblasts had a low density of cell-surface glycophorin but could not see binding of rabbit antibodies to glycophorin on less mature pronormoblasts[19].

We incidentally noted that CFU-GM (which grow in colony assays for erythroid cells) separate predominantly in the HLA-DR$^+$, HLA-ABC$^+$, glycophorin$^-$ fractions. This confirms previous cell-sorting experiments in which CFU-GM were present in the fraction stained with non-monoclonal anti-p28,33 (Ia-like or HLA-DR antigen)[9].

Table 2 Effect of bone marrow T cells on BFU-E and CFU-E

Bone marrow cells stained with optimal concentration of OKT1 plus OKT11, sorted on the FACS and plated *in vitro* for CFU-E and BFU-E assays (see Table 1 legend). Control = stained but unseparated. Expt 1.5: negative (non-T)/bright (T) ratio 1:1. Expt 1.6: negative (non-T)/dim (T) ratio 0.6:1 (insufficient cells available for 1:1 ratio). Expt 2.5: negative (non-T)/bright (T) ratio 1:0.8 (insufficient cells available for 1:1 ratio). Expt 2.6: negative (non-T)/dim (T) ratio 1:1.

* Calculated for the number of cells added to mixtures and the ratio of CFU-E to BFU-E per 10^5 cells in each separated population before mixing.

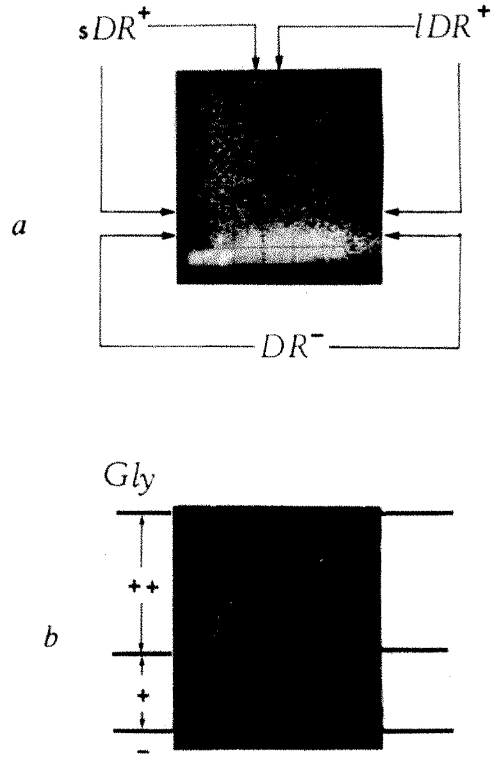

Fig. 1 Separation of erythroid precursors using monoclonal anti-HLA-DR and the FACS. Normal bone marrow was obtained by aspiration from the posterior iliac crest of adult human volunteers, or during femoral osteotomy of haematologically normal children. Approximately 5–10 ml of marrow from two to four aspirations were collected into 10 ml Hank's buffered salt solution containing 100 U of preservative-free heparin. Marrow suspensions were centrifuged (400*g* for 40 min at 20 °C), in Ficoll–Isopaque (1.077 g cm^{-3}), the interface mononuclear cells collected, washed twice and suspended in Eagle's medium plus 20% FCS. Murine monoclonal antibodies were produced using cell hybridization methods as described previously. Monoclonal anti-HLA-DR (DA2) identifies a non-polymorphic determinant associated with an Ia-like polypeptide (p28,34) complex on B lymphoblasts[22]. Monoclonal antibody to HLA-ABC (PA 2.6) similarly recognizes a non-polymorphic determinant shared by products of the A, B, C but not the D locus[22]. Monoclonal antibody LICR.LON/R10 was raised against erythrocytes and specifically precipitates glycophorin A[23]. 20–100 × 10^6 bone marrow cells in 50–100 μl were incubated for 30 min at 4 °C with previously determined optimal concentrations of the various monoclonal antibodies. After two washes, the cells were stained with an affinity-purified $F(ab')_2$ preparation of goat antibodies which had been cross-absorbed with insolubilized human immunoglobulin and labelled with fluorescein isothiocyanate. The stained cell suspension was analysed by FACS (modified FACS-I, Becton Dickinson)[9]. Cells were separated in sterile conditions using relative fluorescence intensity (vertical axis, *a*, *b*) and in some experiments relative light-scattering levels (horizontal axis) to separate cells according to size (*b*) (sDR$^+$ = small HLA-DR-positive cells; lDR$^+$ = large HLA-DR-positive cells; DR$^-$ = total HLA-DR-negative cells; Gly = glycophorin; ++, brightly stained with anti-glycophorin; +, dimly stained; −, unstained).

Winchester *et al.*[10] previously reported that both BFU-E and CFU-E could be inhibited by treatment with a rabbit anti-p28,37 (Ia-like) serum and rabbit complement before colony assay. This observation suggests that erythroid progenitors express Ia-like (HLA-DR) cell-surface antigens and/or that other cells essential for BFU-E and CFU-E activity are inhibited by the antisera used. The experiments reported above demonstrate unequivocally that some BFU-E express a monomorphic HLA-DR antigenic determinant but that CFU-E were predominantly HLA-DR negative. Anti-p28,33 (Ia-like) antisera may have exceedingly high cytotoxic titres which are in excess of binding titres as assessed by immunofluorescence[11]. It is therefore possible that CFU-E have a very low density of HLA-DR antigens which was below our 'selected' level of positivity on the FACS but sufficient to render the cells susceptible to antibody-dependent lysis (or functional inhibition) by complement.

Pluripotent haematopoietic stem cells seem to be Ia-antigen (HLA-DR equivalent) negative in mice[20], and possibly also in man[21]. The transient expression of HLA-DR on early erythroid and granulocytic lineage progenitors suggests that cell-surface molecules carrying these determinants might be important in cell interactions regulating committed progenitor cells. Note, finally, that as there is no evidence for biosynthesis of HLA-DR by these progenitor cells, we cannot exclude the possibility that these cell-surface-associated molecules are somehow 'acquired' from other cells in the bone marrow.

This work was supported in part by the Imperial Cancer Research Fund and Child Health Research Appeal Trust. We thank Dr W. Bodmer for supplying monoclonal antibodies to HLA-DR and HLA-ABC and Drs G. Goldstein and P. Kung (Ortho Pharmaceuticals) for monoclonal anti-T reagents (OKT1, OKT11).

Tetrapeptides of the eosinophil chemotactic factor of anaphylaxis (ECF-A) enhance eosinophil Fc receptor

M. Capron, A. Capron, E. J. Goetzl & K. F. Austen

Certain mast cell products, including the tetrapeptides Ala-Gly-Ser-Glu (Ala^4) and Val-Gly-Ser-Glu (Val^4) of the eosinophil chemotactic factor of anaphylaxis (ECF-A)[1] and histamine[2], are preferentially chemotactic for eosinophils *in vitro*. Amino acid substitutions or modifications of the ECF-A tetrapeptides may substantially alter the chemotactic activity of human eosinophils[3]. The cellular mechanism whereby ECF-A tetrapeptides enhance IgG-dependent killing of schistosomula by rat eosinophils[4] is, however, unclear. We now report that the parent tetrapeptides and the substituted analogue Val-Pro-Ser-Glu (Pro^3), but not histamine, increase the number of rat and human eosinophils that form rosettes with erythrocytes bearing IgG antibodies. Moreover, we find a correlation between the effect of these substances on the expression of rat eosinophil IgG Fc receptors and their capacity to increase the IgG-dependent cytotoxicity of rat eosinophils for *Schistosoma mansoni* schistosomula.

Rat eosinophil-rich populations were composed of non-adherent peritoneal cells from normal Fischer rats[4]. Rat peritoneal neutrophils were obtained 7 h after the intraperitoneal injection of 10% proteose-peptone in saline. Human eosinophils and neutrophils were obtained from venous blood of normal subjects or patients with hypereosinophilia not due to parasitic infections and prepared by centrifugation on metrizamide discontinuous gradients[5]. The different leukocyte populations were adjusted to 4×10^6 ml^{-1} in minimal essential medium. Various concentrations of the agonists or medium alone were added to the leukocyte populations and the mixtures were incubated under a CO_2 atmosphere at 37 °C with constant agitation. Immunoglobulin Fc receptors were estimated by the EA-rosette technique using sheep erythrocytes (E) sensitized with the IgG fraction of antisera to E prepared in rats (EA rat) or in rabbits (EA rabbit)[6] (Fig. 1).

The percentage of control rat eosinophils that formed EA rosettes was significantly higher with EA rabbit than with EA rat (Fig. 1), perhaps implying a higher affinity of the rat eosinophil Fc receptor for rabbit immunoglobulins. (Similar differences with immunoglobulins from different animal species have already been noticed with guinea pig eosinophils[7].) When rat eosinophils were pretreated with increasing concentrations of Val^4, Ala^4 and Pro^3 tetrapeptide, there was a dose-dependent increase in the percentage of eosinophils that formed EA rat rosettes. Neither Val-Gly-Ser-Glu-methyl ester nor the lower concentrations of histamine significantly altered the expression of rat IgG Fc receptors on eosinophils, but 10^{-4} M histamine depressed receptor expression (Fig. 1*a*). The lowest concentration of three of the peptides and all concentrations of the Val-Gly-Ser-Glu-methyl ester and histamine examined suppressed the expression of receptors for EA rabbit relative to

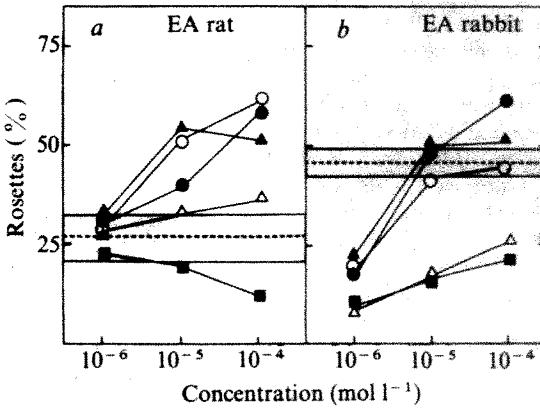

Fig. 1 Role of increasing concentrations of the ECF-A tetrapeptides Ala-Gly-Ser-Glu (●) (Serva) and Val-Gly-Ser-Glu (○), the analogues Val-Pro-Ser-Glu (▲) and Val-Gly-Ser-Glu-methyl ester (△) and histamine (■) (Sigma) on EA rat and EA rabbit rosette formation by rat eosinophils after 60 min incubation at 37 °C. A 60-min incubation was used for all subsequent experiments, as a preliminary study on the influence of incubation time has shown that the maximum effect occurs after 60 min incubation. Abscissa: final concentration of the products. The dotted line represents the mean percentage rosettes of rat eosinophils incubated for 60 min with minimal essential medium (±s.e.). The γ-globulin (IgG) fraction of rat or rabbit antisera to sheep erythrocytes (E) was prepared as described in ref. 6. Rat IgG-coated E (EA rat) or rabbit IgG-coated E (EA rabbit) were prepared by mixing equal volumes of rat or rabbit IgG anti-E with a 2% solution of fresh E as described[6]. Mixtures of 0.1 ml of the leukocyte suspensions and 0.1 ml of E, EA rat or EA rabbit at a concentration of 3×10^8 ml^{-1} were centrifuged at 100*g* for 10 min at 4 °C and incubated for 30 min at 0 °C. The pellet was gently resuspended and cytocentrifuge preparations were made. These were fixed in methanol and treated with Giemsa stain. All leukocytes with three or more adherent EA were considered to be rosettes. The percentage of 300 eosinophils that formed rosettes was counted for each slide. All results are expressed as the mean of the values for triplicate studies. Val-Gly-Ser-Glu, Val-Pro-Ser-Glu and Val-Gly-Ser-Glu-methyl ester were prepared according to ref. 3. Highly purified peptides were prepared by standard solid phase method and subsequently purified by sequential application of gel filtration on Sephadex G-25 in 0.05 M acetic acid and then reverse phase HPLC on a C18 column using sodium phosphate 0.02 M, *p*H 4.2. Thus, no active fragment of endotoxin could be present. Each point represents the mean of at least five experiments. Data were compared by one-way analysis of variance ($P < 0.05$) and Student's *t*-test. The increase in EA rat rosettes was significant for Ala-Gly-Ser-Glu (10^{-4} mol l^{-1}) and Val-Gly-Ser-Glu and Val-Pro-Ser-Glu (10^{-4} and 10^{-5} mol l^{-1}) ($P < 0.05$, *a*). Ala-Gly-Ser-Glu significantly increased the % of EA rabbit rosettes at the 10^{-4} mol l^{-1} concentration ($P < 0.05$, *b*).

0028-0836/81/020071—03$01.00

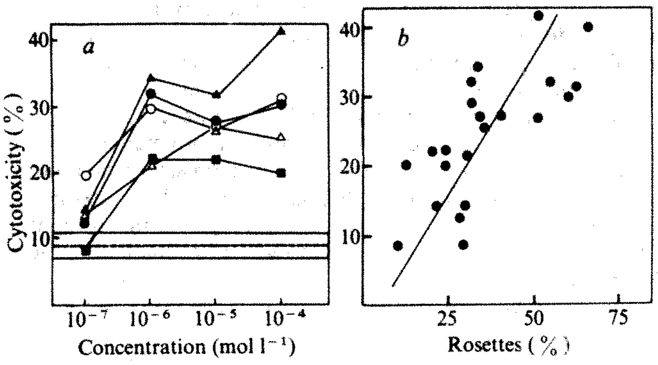

Fig. 2 *a*, Effect of increasing concentrations of Ala-Gly-Ser-Glu (●), Val-Gly-Ser-Glu (○), Val-Pro-Ser-Glu (▲), Val-Gly-Ser-Glu-methyl ester (△) and histamine (■) on rat IgG-dependent eosinophil cytotoxicity for schistosomula *in vitro*. Abscissa: final concentration of the products in the cytotoxicity assay. Ordinate: percentage dead schistosomula after 48 h contact with effector cells. *S. mansoni* schistosomula (prepared by penetration of cercariae through mice abdominal skin) were incubated overnight with heat-inactivated sera from *S. mansoni* infected rats[4]. Eosinophil-rich cell populations that were initially composed of 49% eosinophils and 10% mast cells were depleted of mast cells by centrifugation on 22.5% metrizamide[14] to yield a population of 53% eosinophils and 0.5% mast cells. The purified eosinophils were added to antibody-coated schistosomula at an effector to target ratio of 6,000 : 1, in a total volume of 200 μl. Aliquots (20 μl) of the various mediators were then added to each well of the cytotoxicity assay, giving final concentrations of 10^{-7}–10^{-4} mol l^{-1} (ref. 4). All values represent the mean of 3–13 experiments. Data were compared by one way analysis of variance ($P < 0.01$) and Student's *t*-test. The percentage of cytotoxicity was measured by direct visual examination of dead schistosomula in triplicate experiments[4]. The dotted line represents the mean percentage of cytotoxicity ± s.e. of antibody-coated schistosomula incubated with the mast cell-depleted eosinophils in medium alone. Ala-Gly-Ser-Glu, Val-Gly-Ser-Glu and Val-Pro-Ser-Glu significantly increased the levels of cytotoxicity for the three highest concentrations ($P < 0.05$). The increase with Val-Gly-Ser-Glu-methyl ester is only significant for the 10^{-5} mol l^{-1} concentration, and no significant effect was obtained with histamine. *b*, Correlation between the percentage of rat eosinophils that formed EA rat rosettes (abscissa) and the IgG-dependent cytotoxicity of rat eosinophils for schistosomula (ordinate), in the presence of the different mediators that had been tested (see Fig. 1*a* and *a* above). The effect of different concentrations of the mediators on the expression of rat IgG Fc receptors is significantly correlated with the increase in IgG-dependent rat eosinophil cytotoxicity for *S. mansoni* schistosomula ($r = 0.72$, $P < 0.001$; $n = 23$). A statistical analysis showed best fitting with a first-order regression line.

the levels detected on control eosinophils. Only 10^{-4} M Ala-Gly-Ser-Glu significantly increased the apparent number of EA rabbit rosettes (Fig. 1*b*).

The experimental model previously used to show that the ECF-A tetrapeptides could stimulate rat IgG-dependent eosinophil cytotoxicity for *S. mansoni* schistosomula *in vitro*[4] was applied in parallel with the EA-rosette assay. A population of normal rat peritoneal cells enriched in eosinophils and depleted of mast cells was incubated with various concentrations of the mast cell mediators and rat IgG antibody-coated schistosomula (Fig. 2*a*). A highly significant increase in the levels of cytotoxicity was obtained with the ECF-A tetrapeptides Ala-Gly-Ser-Glu and Val-Gly-Ser-Glu and with the analogue Val-Pro-Ser-Glu at the three highest concentrations. A smaller effect was detected with Val-Gly-Ser-Glu–methyl ester, and histamine showed no significant effect. Comparison of the EA rat rosette and the IgG-dependent cytotoxicity assay results as a function of the dose of the tetrapeptides or histamine revealed a highly significant correlation ($r = 0.72$, $P < 0.001$; Fig. 2*b*).

To determine whether the Fc receptor enhancement was restricted to rat eosinophils, similar experiments were performed with human eosinophils. When blood eosinophils from patients with parasite-unrelated hypereosinophilic syndromes were preincubated with various mediators, an increase in the percentage of rosettes was obtained both with EA rat and with EA rabbit, but the effect was significant only for Ala-Gly-Ser-Glu (Fig. 3*a*). When eosinophils were prepared from normal subjects, the increase in rosettes was very pronounced in the case of EA rat with Ala-Gly-Ser-Glu, Val-Gly-Ser-Glu and Val-Pro-Ser-Glu and was also significant with EA rabbit in the presence of Ala-Gly-Ser-Glu (Fig. 3*b*); however, neither Val-Gly-Ser-Glu-methyl ester nor histamine had a significant effect. The specificity of the effect for eosinophil IgG Fc receptors was investigated by examining the formation of EA rat and EA rabbit rosettes by rat and human neutrophils (Table 1). In both cases, the percentage of rosettes was higher with EA rabbit than with EA rat and none of the ECF-A tetrapeptide analogues significantly increased the extent of rosette formation. In contrast, 10^{-4} M histamine significantly suppressed the formation of EA rat rosettes with rat neutrophils without affecting the formation of other neutrophil rosettes.

Table 1 Effect of ECF-A tetrapeptides, analogues and histamine on neutrophil rosettes

	% Rat neutrophil rosettes		% Human neutrophil rosettes	
Incubation with	EA rat	EA rabbit	EA rat	EA rabbit
Medium	25.6 ± 3.2	94.0 ± 2.1	14.2 ± 6.5	99.6 ± 0.4
Ala-Gly-Ser-Glu	28.8 ± 5.4	93.3 ± 6.6	22.8 ± 3.9	100.0 ± 0
Val-Gly-Ser-Glu	34.0 ± 7.8	79.2 ± 3.9	12.5 ± 4.7	95.0 ± 5.0
Val-Pro-Ser-Glu	18.7 ± 5.3	90.2 ± 9.1	16.4 ± 6.2	98.8 ± 0.8
Val-Gly-Ser-Glu-methyl ester	23.7 ± 5.9	82.0 ± 9.4	15.2 ± 6.6	82.5 ± 12.7
Histamine	6.6 ± 1.7*	91.3 ± 3.7	10.3 ± 1.2	100.0 ± 0

Rat neutrophils were obtained from the peritoneal cavity of rats 7 h after the interaperitoneal injection of 10 ml of 10% proteose-peptone in saline. Human neutrophils were prepared from venous blood from hypereosinophilic or normal subjects according to ref. 5. Rat or human neutrophils were preincubated for 60 min at 37 °C with the various mediators at a final concentration of 10^{-4} mol l^{-1}. The values given represent the mean of five experiments ± s.e.

*The extent of suppression was significant at $P < 0.01$.

The data indicate that the human ECF-A tetrapeptides Ala[4] and Val[4], and the analogue Pro[3] markedly increase the number of Fc receptors for rat IgG on the rat eosinophil membrane. The enhancement of the expression of IgG Fc receptors on eosinophils and the augmentation of the cytotoxic capacity of rat eosinophils for IgG-coated schistosomula exhibit similar dose–response relationships, suggesting that the two phenomena are related on a fundamental cellular level. The incubation of human eosinophils with Ala-Gly-Ser-Glu and, in some cases, with Val-Pro-Ser-Glu and Val-Gly-Ser-Glu, also increased the expression of Fc receptors, whereas Val-Gly-Ser-Glu-methyl ester and histamine were inactive. Previous reports have shown no enhancement of the expression of human eosinophil IgG receptors by the ECF-A tetrapeptides, whereas complement receptors were increased by both the ECF-A tetrapeptides and histamine[8,9]. These earlier studies mainly used eosinophils from hypereosinophilic subjects and erythrocytes sensitized with rabbit antibodies. The present work clearly shows that when eosinophils from patients with hypereosinophilia were compared with normals for rosette formation with EA rabbit (Fig. 3), the patients had a higher proportion of eosinophils expressing Fc receptors, such that the increase by the tetrapeptides was only significant for one of the tetrapeptides studied. The major difference between the present report and previous studies limited to eosinophils from hypereosinophilic patients may therefore be explained by the fact that a significant increase could not be seen in the latter case because the starting percentage of Fc receptor expression was higher. It seems likely that the use of normal human eosinophils and EA-IgG rat unveiled the effects of the ECF-A tetrapeptides on the expression of eosinophil Fc receptors. Another possible explanation for the difference between the results of the two studies concerning EA-IgG rat and EA-IgG rabbit could be the preferential stimulatory role of ECF-A on surface receptors for anaphylactic antibodies which represent a more important part of rat IgG than rabbit IgG. This hypothesis is now being tested.

The large difference in the percentage of neutrophils that formed rosettes with EA rat compared with EA rabbit indicates that both the rat and human neutrophil Fc receptor seemed to possess a higher affinity for rabbit antibody than for rat anti-

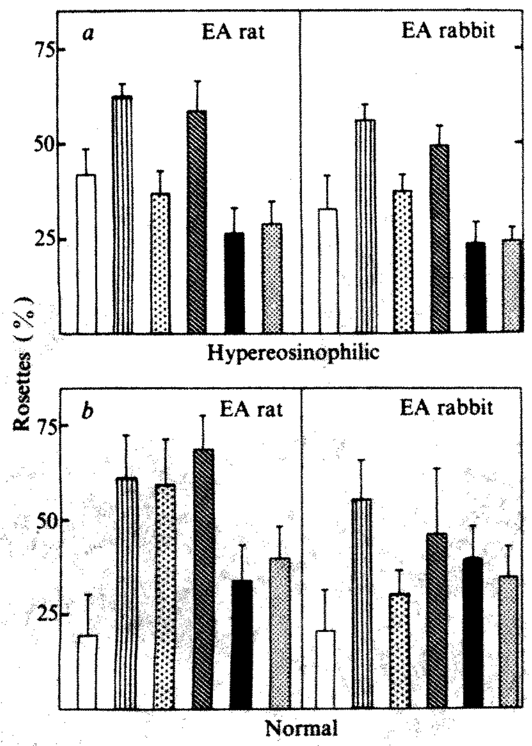

Fig. 3 The effect of the ECF-A tetrapeptides Ala-Gly-Ser-Glu and Val-Gly-Ser-Glu, the analogues Val-Pro-Ser-Glu and Val-Gly-Ser-Glu-methyl ester, and histamine on EA rat and EA rabbit rosette formation by human eosinophils. Eosinophils were prepared from venous blood of nine patients with eosinophilia of non-parasitic aetiology (*a*) and from that of four normal subjects (*b*) by centrifugation on metrizamide discontinuous gradients[5]. 80–100% pure eosinophils were obtained from both groups of individuals. EA rat and EA rabbit were prepared according to Fig. 1. □, medium; ▥, Ala-Gly-Ser-Glu; ░, Val-Gly-Ser-Glu; ▨, Val-Pro-Ser-Glu; ■, Val-Gly-Ser-Glu-methyl ester; ▩, histamine. The results are expressed as the mean of triplicate experiments (± s.e.) and were compared by a Student's *t*-test. *a*, The increase in EA rat and EA rabbit rosettes was significant with Ala-Gly-Ser-Glu ($P<0.05$). *b*, The increase in EA rat rosettes was significant with Ala-Gly-Ser-Glu, Val-Gly-Ser-Glu and Val-Pro-Ser-Glu ($P<0.05$) whereas only Ala-Gly-Ser-Glu significantly increased EA rabbit rosettes ($P<0.05$).

body. The mast cell mediators that increased the expression of eosinophil Fc receptors did not enhance either rat or human neutrophil Fc receptors, even when the percentage of Fc receptors expressed by normal neutrophils was very low (EA rat rosettes). These results therefore suggest that the effect of the tetrapeptides is specific for eosinophils.

The enhancement and inhibition of eosinophil IgG Fc receptors by mast cell-derived mediators may be a function of alterations in the rate of induction of new receptors or in the exposure of previously 'hidden' receptors, as has been suggested for complement receptors[9,10]. It has been observed that the number of erythrocytes per eosinophil is also increased, when the percentage of rosetting eosinophils is enhanced by the tetrapeptides. Further, a correlation exists between the eosinophil chemotactic activity of the tetrapeptides and their effects on the expression of IgG Fc receptors on the eosinophil membrane[11]. The parent tetrapeptides Ala^4 and Val^4 and the Pro^3 analogue exhibit the highest activity in the three assays that have been examined, namely chemotaxis, rosette formation and cytotoxicity, whereas histamine is less active or inhibitory at comparable concentrations. A relationship between surface binding sites for chemotactic factors and for the Fc fraction of IgG has been envisioned for lymphocytes[12]. Similarly, it is possible that the enhancement or inhibition of expression of eosinophil IgG Fc receptors by chemotactic factors involves an interaction between surface receptors common for chemotactic and IgG Fc binding functions, or with distinct receptors that are concurrently activated by the chemotactic factors. The capacity of the tetrapeptides of ECF-A to enhance the expression of eosinophil C3b (ref. 8) as well as IgG Fc receptors supports the latter possibility and suggests that modification of the properties of receptors may be a general membrane response of eosinophils to some chemotactic factors. The ability of defined chemotactic factors to modulate both the migration of the eosinophils and their expression of surface receptors for immunologically relevant principles indicates a more general role for chemotactic factors that should be explored for other classes of leukocytes.

A recent study reports the increased capacity of eosinophils to bind to IgG-coated particles *in vitro* when exposed to various stimuli such as soluble immune complexes or endotoxin[13]. Results of this and the present study therefore suggest possible mechanisms to account for the higher proportion of eosinophils with Fc receptors in hypereosinophilic syndromes.

The present work is thus the first demonstration that mast cell mediators like the ECF-A tetrapeptides can not only promote eosinophil recruitment but also increase IgG-mediated eosinophil cytotoxicity against *Schistosoma* targets, by enhancing the expression of eosinophil IgG Fc receptors. These results, combined with previous studies on the enhancement of complement receptors and complement-mediated eosinophil cytotoxicity[10], provide novel evidence for mast cell–eosinophil interaction in immunity against helminthic parasites.

We thank Professor M. Goudemand, Professor A. B. Tonnel and Dr L. Prin for providing human eosinophils, and J. E. Papin and S. Torres for technical assistance. This work was supported by INSERM U 167 and CNRS ERA 422.

Synaptic localization of kainic acid binding sites

A. C. Foster, E. E. Mena, D. T. Monaghan & C. W. Cotman

Department of Psychobiology, University of California, Irvine, Irvine, California 92717

The heterocyclic compound kainic acid (KA) is a potent excitant when applied to mammalian neurones[1]. Lesions caused by injections of KA into the rat striatum and hippocampus cause similar patterns of damage to those seen in Huntington's chorea and status epilepticus, respectively[2,3]. Although it was originally thought to be a glutamate agonist[4], it is now clear that KA does not act on the majority of the receptors for glutamate[5–7], and in fact seems to act on a class of receptors which are distinct from those which mediate responses to other excitatory amino acids[8,9]. The potent and selective neurotoxic effects of this compound[10] may be mediated by these same receptors. At present, the relative distribution of junctional and extrajunctional (non-synaptic) receptors is unknown and resolution of this issue would provide important insights into the action of KA on the central nervous system (CNS). We show here that KA binding sites are greatly enriched in isolated synaptic junctions from rat brain and, using an *in vitro* autoradiographic technique, we have found that these binding sites are concentrated specifically in terminal fields where KA acts as a potent neurotoxin.

Synaptic junctions (SJs) and other subcellular fractions were prepared by the method of Cotman and Taylor[11], and assayed for ^{3}H-KA binding[12,13]. Table 1 shows the relative values for specific binding (the ^{3}H-KA binding which can be displaced by 100 μM unlabelled KA) in the isolated fractions, which are expressed as a value relative to the whole particulate fraction (=1). Membranes from crude mitochondrial pellet (P_2) were not enriched in KA binding sites relative to the whole particulate fraction. However, on subfractionation of P_2, the highest specific binding values were found in the synaptic plasma membranes (SPMs), in agreement with previous results[13]. The P_1, P_3, myelin enriched and mitochondria enriched fractions also had specific KA binding sites. This may be due to the presence of synaptic plasma membranes in these fractions, and indeed both purified myelin and mitochondria have been found to contain lower levels of high-affinity binding sites for ^{3}H-KA[13].

Specific KA binding sites in SJs were enriched 22 times over those measured in the whole brain particulate fraction, and 10 times over those in SPMs. This enrichment in SJ fractions is greater than that shown previously for any other receptor or receptor-related function. The absolute amount of binding to SJs, averaged over four separate preparations and assayed at a concentration of 40 nM, was 1,819 ± 378 fmol per mg protein. The majority of specific KA binding sites in the SPMs could be recovered in SJs (73 ± 14% of binding sites; 9.4 ± 0.6% protein; $n = 4$); which suggests that most of the binding sites for KA in SPMs are located at the junctional area. Similarly, 80% of the binding sites in SPMs for L-glutamate and L-aspartate are recovered in SJs; quinuclidinyl benzoate binding sites are not detectable in SJs prepared by this method.

Two components of KA binding were apparent in SJs (assayed over a ^{3}H-KA concentration range of 1–100 nM). The mean values from two determinations measured for the high-affinity component were $K_D = 4.95$ nM and $B_{max} = 1{,}349$ fmol per mg protein, and for the low-affinity component 32.6 nM and 3,257 fmol per mg protein, respectively. These values for the K_Ds agree with those previously reported in crude membrane preparations[14], and indicate that the increase of KA binding seen in SJs is a true enrichment of sites and is not due to an increase in affinity caused, for example, by removal of an endogenous inhibitor.

If KA binding sites are predominantly synaptic, they might be localized to discrete terminal fields. KA binding sites can be viewed directly in rat brain slices by an *in vitro* autoradiographic technique[15]. Using this method, KA binding sites were seen to be particularly enriched in discrete parts of the hippocampus, pyriform cortex, cerebellum and striatum. In the hippocampus a small band of silver grains was associated with the inner part of the molecular layer of the dentate gyrus, corresponding to the terminal field of the commissural/associational fibres. However, the greatest density of grains was seen over the stratum incidium in the CA3 region corresponding to the terminal zone of the mossy fibre input to the CA3 pyramidal cells (Fig. 1). The KA binding sites labelled by this technique were apparently identical to those revealed in membrane binding assays, as this pattern of binding could be completely displaced with an excess of unlabelled KA, and binding to these slices was saturable with a K_D value in the range found for SJs. The pattern of KA binding sites we have observed in the hippocampus is particularly interesting in view of the previous reports that the CA3 pyramidal cells of the hippocampus are extremely sensitive to the neurotoxic action of KA[16], particularly at the mossy fibre terminal zone[17]. Other brain areas also showed KA sites but in general these were of lower concentration than the CA3 field (manuscript in preparation).

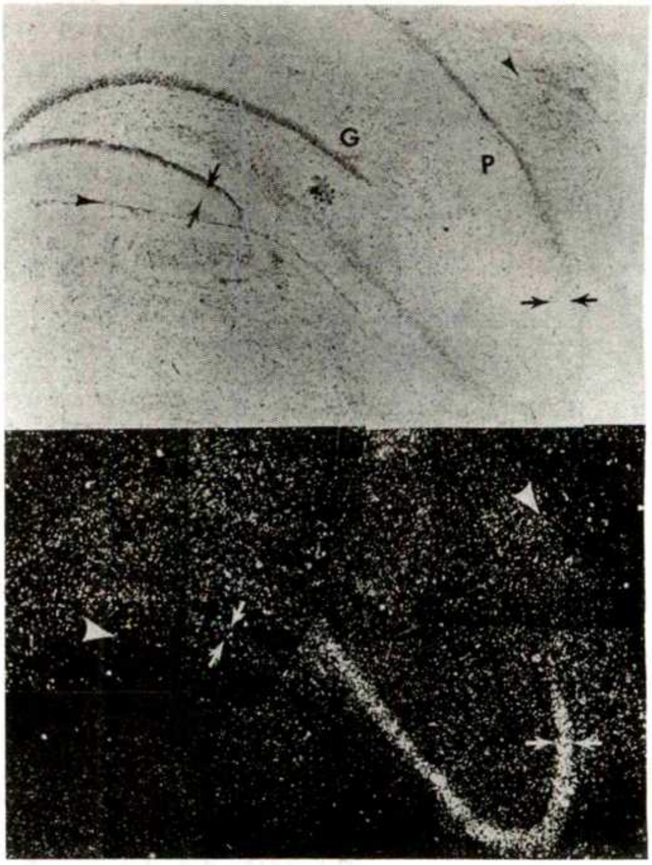

Fig. 1 Distribution of KA binding sites in the rat hippocampus. Brain slices (15 μm) from adult Sprague–Dawley rats were sliced on a cryostat, mounted unfixed on glass microscope slides and processed for the localization of binding sites using a modification of the method of Young and Kuhar[15]. ^{3}H-KA was used at a final concentration of 100 nM, and incubated at 0 °C for 30 min. Bottom: dark field illumination, small arrows indicate the areas of high silver grain density. Top: cresyl violet-stained tissue section; small arrows indicate identical area in dark field possessing high silver grain density. G, granule cells; P, pyramidal cells.

Table 1 Specific binding of ^{3}H-KA to subcellular fractions of rat brain

Fraction	Specific ^{3}H-KA binding relative to OH (=1)	n
Whole particulate (OH)	1	4
Crude mitochondrial pellet (P_2)	0.73 ± 0.34	4
Microsomes (P_3)	0.56, 0.25	2
Crude myelin	0.05, 0.13	2
Synaptic plasma membrane (SPM)	2.08 ± 0.41	4
Mitochondria	0.95 ± 0.21	3
Synaptic junction (SJ)	22.37 ± 5.79	4

Subcellular fractions were prepared from whole rat forebrain as described by Cotman and Taylor[11]. All fractions were washed in 0.2 mM HEPES, 0.05 mM $CaCl_2$ buffer (pH 7.4) and pelleted at 80,000g for 20 min. Binding assays were done in triplicate essentially as previously described[13]. Crude myelin was taken as the fraction floating on the 0.8 M sucrose layer. The mitochondria fraction was the 1.2 M pellet.

The results presented here, therefore, suggest a discrete localization of KA binding sites in the mammalian CNS. At a subcellular level, SJs contribute the majority of the 'synaptic population' of KA binding sites, and in the hippocampus these sites are present in high density in close apposition to the mossy fibre–CA3 pyramidal cell synapse. Neither glutamate nor aspartate seem to be transmitters at this synapse[18]. Specific and localized synaptic receptors imply that appropriate natural ligands exist. Our data, together with evidence that KA does not act on glutamate sites and that KA receptors are a discrete population[8,9], suggest that endogenous ligands for KA receptors exist. Such a compound would be a mediator or modulator of synaptic transmission at sites where we have shown KA receptors to exist. Furthermore, the identification of such compounds may provide new insights into the aetiology of Huntington's disease and epilepsy.

Corticotropin regulates trans-synaptically the activity of septo-hippocampal cholinergic neurones

Lawrence J. Botticelli* & Richard J. Wurtman

Laboratory of Neuroendocrine Regulation, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The activity of septo-hippocampal neurones is affected by the action on cholinergic perikarya in the septum of a variety of putative neurotransmitters[1–4], including substance P[5,6] and β-endorphin[7,8]. (The latter is released in the septal region from neurones which originate in the medial basal hypothalamus.) It has also been reported that two other neuropeptides, corticotropin ($ACTH_{1-24}$) and α-melanotropin (α-MSH), affect acetylcholine turnover in septo-hippocampal neurones in a manner that is not blocked by transection of the afferents to the hippocampus, from which it has been inferred that the neurotransmitters act directly on the hippocampus[9]. We now describe experiments with corticotropin which show that the effect is rather the influence on septo-hippocampal cholinergic neurones of peptidergic neurones within the septum.

Male Sprague–Dawley rats (150–200 g, Charles River Breeding Laboratories) were housed in groups of three to five at an ambient temperature of 23–24 °C for 5–7 days before experimentation. Animals had free access to food (Purina Rat chow; Ralston-Purina) and water, and were exposed to light (Vita-Lite, 300 μW cm^{-2}; Duro Test Corporation) daily between 0700 and 1900 h.

A polyethylene tube was implanted in the lateral ventricle (2 mm lateral, 1 mm posterior to bregma and 3 mm ventral to the dural surface) of each rat 3 days before experimentation. Cannulae were kept in position with dental cement. For intraseptal injections, guide cannulae were implanted stereotaxically into the septum (coordinates AP 8.5, ML 0.0, DV 0.0, 5.0 mm ventral to the dural surface) 5 days before experimentation. For intrahippocampal injections, cannulae were placed in the dorsal hippocampus (coordinates AP 4.0, ML 2.0, DV 2.0) 3 days before experimentation. Cannulae placements were verified histologically by staining a 1 : 3 or 1 : 5 series of 40-μm frozen frontal cryostat sections with thionin. For peptide co-administration studies, rats were equipped with both intraventricular and intraseptal cannulae.

Table 1 Effects of peptides on hippocampal acetylcholine (ACh) content

Treatment	Hippocampal ACh (pmol per mg)
Vehicle	40.0 ± 2.3 (n = 6)
β-lipotropin	37.5 ± 1.7 (n = 5)
β-endorphin	51.4 ± 2.7* (n = 5)
Corticotropin	25.5 ± 1.5* (n = 5)
$ACTH_{4-10}$	38.7 ± 2.9 (n = 5)
α-MSH	39.9 ± 2.2 (n = 5)

Rats were killed 30 min after intraventricular administration of each peptide. Values are expressed as means ± s.e.m. Data were analysed by analysis of variance (corrected for unequal sample size), followed by *a posteriori* multiple comparisons of within-group means using Scheffe's method[11].

* $P < 0.001$ differs from vehicle-treated animals (*a posteriori*).

Peptides dissolved in pyrogen-free water were microinjected into the lateral ventricle (10 μg, into the septum (1.0 μg in 1.0 μl given over 5 min), or the dorsal hippocampus (1.0 μg in 1.0 μl given over 3 min). At 30 min after peptide micro-administration the animals were killed by a beam of microwave irradiation directed at the skull. After decapitation, brains were removed from the skull and specimens of cerebral cortex, striatum and hippocampus (dorsal) dissected by hand; their acetylcholine and choline content was determined radioenzymatically using [γ-^{32}P]ATP (specific activity 10–30 Ci nmol^{-1}; Amersham) as labelled substrate[10]. Significance of treatment-induced differences in regional brain acetylcholine or choline content was determined by analysis of variance (Wang 2200 series software; Wang Laboratories), followed by *a posteriori* multiple comparisons of within-group means using Scheffe's method[11].

Acetylcholine content in cortex, striatum and hippocampus was unchanged after intraventricular administration of β-LPH (Table 1). As described previously[8], intraventricular β-endorphin significantly increased acetylcholine content in the hippocampus (38%; $P < 0.001$) (Table 1) but not elsewhere. Corticotropin had an opposite effect on hippocampal acetylcholine concentrations, causing them to fall by about 30% ($P < 0.001$) (Table 1), but like β-endorphin, failed to affect acetylcholine levels in the two other brain regions examined. Neither $ACTH_{4-10}$ nor α-MSH affected acetylcholine concentrations in any brain region examined (Table 1). None of the peptides affected choline levels in any region (data not shown).

When smaller doses (1 μg) of β-endorphin or corticotropin were microinjected directly into the septum, hippocampal acetylcholine levels changed in the same direction as after its

Table 2 Effects of β-endorphin and/or corticotropin on hippocampal acetylcholine

Treatment	Hippocampal ACh (pmol per mg)
Vehicle	37.7 ± 1.2 (n = 4)
β-endorphin (i.s.t.)	58.4 ± 3.0* (n = 5)
Corticotropin (i.s.t.)	21.6 ± 2.4* (n = 5)
β-endorphin + corticotropin (i.s.t.)	42.0 ± 3.1† (n = 6)
β-endorphin (i.v.t.) + corticotropin (i.s.t.)	39.9 ± 1.3† (n = 6)
β-endorphin (i.s.t.) + corticotropin (i.v.t)	37.9 ± 2.6† (n = 6)

Rats were killed 30 min after injection of β-endorphin and corticotropin [either both intraseptally (i.s.t.) (0.5 μg each) or one intraseptally (1.0 μg) and the other intraventricularly (i.v.t.) (10 μg)]. Values are expressed as means ± s.e.m. Data were analysed by analysis of variance (corrected for unequal sample size) followed by *a posteriori* multiple comparisons of within-group means using Scheffe's method[11].

* $P < 0.001$ differs from vehicle-treated animals (*a posteriori*).

† $P < 0.001$ differs from peptide-treated animals (*a posteriori*).

* Present address: Addiction Research Foundation, 701 Welch Road, Palo Alto, California 94304.

0028-0836/81/020075—02$01.00

intraventricular injection but to a greater extent: β-endorphin administration increased acetylcholine concentrations by 56% ($P < 0.001$), whereas corticotropin decreased hippocampal acetylcholine by 44% ($P < 0.001$) (Table 2). Co-administration of the neuropeptides, either both intraseptally (0.5 μg each), or one intraseptally (1.0 μg) and the other intraventricularly (10 μg), did not significantly change hippocampal acetylcholine levels (Table 2). Direct administration of β-endorphin or corticotropin into the dorsal hippocampus (1.0 μg) also failed to affect hippocampal acetylcholine (Table 3).

Corticotropin and β-endorphin, which may share a common precursor[12], have similar brain distributions; they are concentrated within a major cell group in the periarcuate hypothalamus, projecting to the anterior hypothalamus, pons, the periaqueductal grey and the septal region[13-15]. Nerve fibres immunoreactive for both corticotropin and β-endorphin surround the third ventricle, extend throughout the diencephalon and portions of the limbic brain, and descend into the central grey. No corticotropin or endorphin immunoreactivity has been detected in the hippocampus, cerebrum or cerebellar cortices. Corticotropin and β-endorphin can sometimes block each other's effects, or produce effects opposite to one another[16-18], which suggests that these peptidergic neurones may participate reciprocally in common neuronal systems.

Table 3 Effects of intrahippocampal β-endorphin or corticotropin on hippocampal acetylcholine

Treatment	Hippocampal ACh (pmol per mg)
Vehicle	39.6 ± 2.1 ($n = 5$)
β-endorphin	43.6 ± 1.5 ($n = 5$)
Corticotropin	41.9 ± 2.8 ($n = 5$)

Rats were killed 30 min after injection of peptides into the dorsal hippocampus (1.0 μg per 1.0 μl for 3.0 min). Values are expressed as means ± s.e.m.

The activity of septo-hippocampal neurones is controlled partly by axosomatic and axodendritic synapses in the septum itself, and partly by hippocampal axoaxonic synapses. Intraseptally injected β-endorphin produces a naltrexone-reversible decrease in the turnover of hippocampal acetylcholine[7], suggesting that endorphin interacts with opiate receptors in the septal region. In contrast, corticotropin has been reported to increase the turnover of this neurotransmitter in Ammon's horn, even after transection of the cingulum, entorhinal area and fimbria[9]. Such observations have been interpreted as suggesting a direct action of these neuropeptides on receptors in the hippocampal formation. Our observations that intraseptal corticotropin decreases hippocampal acetylcholine, that intrahippocampal corticotropin fails to change the content of hippocampal acetylcholine and that co-administered β-endorphin and corticotropin block each other's effects on hippocampal acetylcholine, imply that corticotropin-containing peptidergic neurones do act within the septum, and thereby influence the physiological activity of septo-hippocampal cholinergic neurones.

These studies were supported in part by research grants awarded to R.J.W. from the National Institute of Mental Health (MH 28783), the Ford Foundation and the Wallace Genetic Foundation. L.J.B. was a predoctoral fellow of the National Institute on Drug Abuse (DA 05089). β-Lipotropin was supplied by Dr C. H. Li, β-endorphin by the Psychopharmacology Research Branch, National Institute of Mental Health, corticotropin, $ACTH_{4-10}$ and α-MSH were gifts of Organon Pharmaceuticals, and all other chemicals used were purchased from either Eastman Organic or Aldrich.

Serotonin stimulates phosphorylation of Protein I in the facial motor nucleus of rat brain

Annette C. Dolphin* & Paul Greengard†

Department of Pharmacology, Yale University School of Medicine,
New Haven, Connecticut 06510

Protein I is one of the best candidates for a neuronal protein whose phosphorylation may have a functional role in synaptic activity[1]. It is a substrate for both cyclic AMP-dependent[2] and Ca^{2+}-dependent[3] protein kinases, and these kinases show differential specificity for its multiple phosphorylation sites[4]. Protein I is found exclusively in the central[5] and peripheral[6] nervous systems, and immunohistochemical[5] and subcellular fractionation[7] studies suggest an association primarily with synaptic vesicles. Using slices of rat cerebral cortex incubated *in vitro*, Protein I was phosphorylated both by agents which increase intracellular cyclic AMP and by agents causing Ca^{2+} influx, although not by any putative neurotransmitters or neuromodulators[8]. We have now examined the facial motor nucleus and report here that serotonin produces a phosphorylation of Protein I when incubated with facial nucleus slices. Demonstration of a neurotransmitter-dependent alteration in the state of phosphorylation of a synapse-specific protein may be due to the relatively simple neuronal circuitry within the facial motor nucleus.

The facial motor nucleus contains a single class of neuronal cell bodies and no interneurones[9,10]. Most of the afferent fibres are excitatory onto the facial motoneurones[10] and stimulation of motoneurone firing is mimicked by the iontophoresis of glutamate[10]. The facial nucleus also receives a facilitatory serotonergic input from the raphe magnus[10-12], which represents about 2% of the terminals in the nucleus[13].

Slices prepared from excised rat facial nuclei were preincubated for 1 h in Krebs–Ringer bicarbonate buffer (KRB). The slices were then incubated for 1–20 min in the presence of serotonin or other agents. The reaction was terminated by homogenizing the tissue in zinc acetate (5 mM), which inhibits phosphatase activity[8]. Protein I was quantitatively extracted and subjected to 'back-phosphorylation' by the catalytic subunit of cyclic AMP-dependent protein kinase, using [γ-^{32}P]ATP as substrate. This method of back-phosphorylation gives a measure of the amount of dephospho-Protein I remaining in the slice at the end of the incubation period, from which one can calculate the amount of Protein I that was converted to the phosphorylated form during incubation with the various agents[8] (see Figs 1 and 2 legends).

In resting conditions, after preincubation of the slices for 1 h, Protein I seemed to be almost entirely in the dephosphorylated

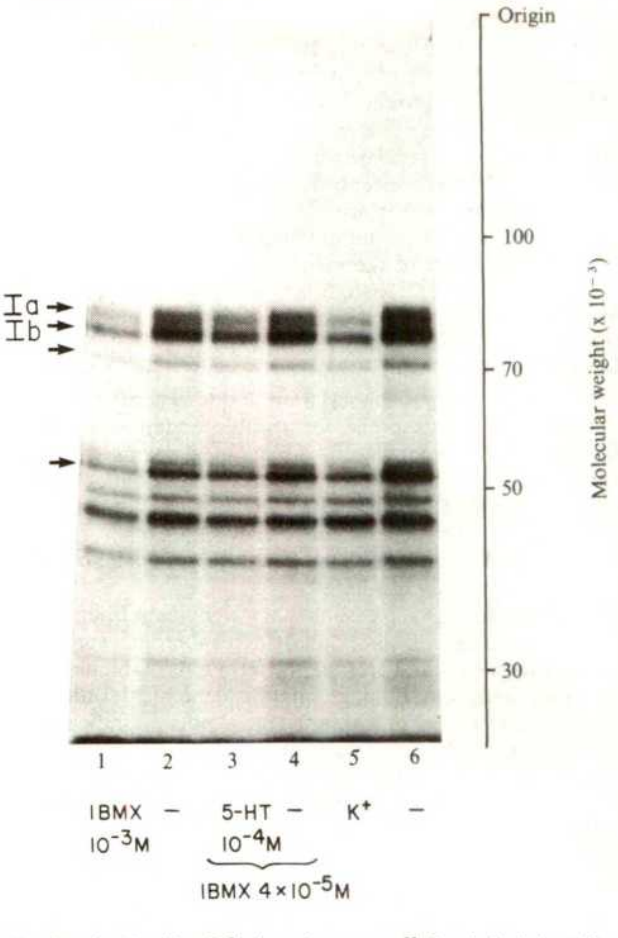

Fig. 1 Autoradiogram of an SDS-polyacrylamide gel showing the effect of IBMX, of serotonin (5-HT) and of high K^+ on protein phosphorylation in slices of rat facial nucleus. Male Sprague–Dawley rats (150–250 g) were killed by decapitation. The brain was removed and a transverse slice, 1.2 mm thick, was taken through the brain stem immediately posterior to the trapezoid body. The regions containing the facial nuclei were then dissected manually as cubes taken from the ventral edge of the slice with the pyramidal tracts as the medial borders. Each excised nucleus was quartered using a sagittal and a horizontal cut. The four slices from a single facial nucleus were transferred together to a glass homogenizer containing 10 ml of KRB, *p*H 7.4, at 35 °C (composition in mM: Na^+, 158; K^+, 3; Ca^{2+}, 1.5; Mg^{2+}, 1.3; PO_4^{3-}, 1.3; HCO_3^-, 26; Cl^-, 136; ascorbate, 1; D-glucose, 20). The medium was continuously gassed with H_2O-saturated 95% O_2–5% CO_2 throughout the preincubation and incubation periods. Slices were preincubated for 1 h with one change of medium. In all cases, the effect of the agent to be tested was determined by incubating it for 1 or 10 min with one of a pair of facial nuclei, the other of which was used as a control. Substances to be tested were added in KRB such that the final incubation volume was 10 ml. The incubations were terminated by aspirating the KRB, adding 5 ml of ice-cold Zn-acetate (5 mM) and homogenizing with a Teflon pestle. The amount of Protein I present in the dephospho-form at the termination of the incubation was determined by back-phosphorylation as follows: the homogenate was centrifuged at 4,000*g* for 15 min and the pellet resuspended in 1 ml of 10 mM Na-citrate-phosphate buffer, *p*H 2.8, at 4 °C. Triplicate 100-μl aliquots of this suspension were taken for protein assay using a method with which monoamines did not interfere[31]. The suspension was centrifuged at 23,000*g* for 15 min and 500 μl of the supernatant was adjusted to *p*H 6 with 0.5 M Na_2HPO_4 and centrifuged at 15,000*g* for 15 min. All *p*H 6 supernatants from one experiment were then diluted to equal protein concentration with 10 mM Na-citrate-phosphate buffer (*p*H 6). Duplicate or triplicate 60-μl aliquots were used in the back-phosphorylation assay containing (in 100-μl final volume): 50 mM HEPES (*p*H 7.4), 10 mM Mg^{2+}, 1 mM EGTA, 1 mM EDTA, 3 μM [γ-^{32}P]ATP (specific activity 50–100 c.p.m. $fmol^{-1}$) and a low concentration (7.5 nM) of the purified catalytic subunit (C) of cyclic AMP-dependent protein kinase, prepared according to Beavo *et al.*[32]. The back-phosphorylation assay was carried out for 30 min at 30 °C and samples were subjected to SDS-polyacrylamide gel electrophoresis and autoradiography as previously described[8]. In control experiments, it was established that the back-phosphorylation assay conditions used resulted in a maximal incorporation of ^{32}P into phospho-peptide 1 of Protein I, with negligible phosphorylation of other phosphorylation sites on Protein I (ref. 33, and A.C.D., unpublished observations). Phospho-peptide 1 is the only tryptic phosphopeptide derived from Protein I which shows a high affinity for phosphorylation by cyclic AMP-dependent protein kinase, although it is also phosphorylated in a Ca^{2+}-dependent manner[33]. Protein I is indicated by two arrows. It consists of two subspecies Ia and Ib of M_r 86,000 and 80,000. Lanes 1 and 2 incubations were with or without 10^{-3} M IBMX for 10 min; lanes 3 and 4 incubations were with or without 10^{-4} M serotonin for 10 min, in the presence of a low concentration of IBMX (4×10^{-5} M) added to both incubation tubes 2 min before the start of incubation; lanes 5 and 6 incubations were in the presence or absence of 60 mM K^+ (K^+ being substituted isotonically for Na^+) for 1 min.

form. A 10-min incubation with serotonin (10^{-4} M) increased the phosphorylation of Protein I in facial nucleus slices (Fig. 1, lane 3 compared with 4), as did the phosphodiesterase (PDE) inhibitor isobutyl methylxanthine (IBMX) (10^{-3} M; Fig. 1, lane 1 compared with 2). Each of these agents raises cyclic AMP levels in facial nucleus slices[14]. Several other proteins also showed increases in their state of phosphorylation in response to incubation of slices with serotonin and IBMX, indicating that they are also endogenous substrates for cyclic AMP-dependent protein kinase. The latter demonstrations are reasonable in view of the methodology used for the back-phosphorylation assay, in which the low concentration of catalytic subunit used selectively phosphorylated only those substrate proteins with a high affinity for this enzyme. As neurotransmitters thought to act through cyclic AMP can cause numerous biological responses in their target cells (for example, alterations in membrane excitability, in intermediary metabolism and in protein synthesis), many different phosphoproteins are probably involved in these responses[15,16]. Indeed, several endogenous substrates for cyclic AMP-dependent protein kinase have already been detected in isolated neuronal membrane preparations[2,17–20].

Incubation of facial nucleus slices with a high concentration of K^+ (60 mM) also increased the phosphorylation of Protein I and several other phosphoproteins (Fig. 1, lane 5 compared with 6). That high K^+ altered the state of phosphorylation of several of the substrate proteins affected by serotonin suggests that regulation of phosphorylation sites on proteins by both cyclic AMP-and Ca^{2+}-dependent protein kinases may not be unusual. In this regard, note that two of the affected proteins, indicated by arrows in Fig. 1, seem to be the same as the 74,000 and 55,000 molecular weight (M_r) proteins whose phosphorylation was affected by 8-bromo-cyclic AMP, high K^+ and veratridine in slices of rat cerebral cortex[8].

The formation of phospho-Protein I from dephospho-Protein I, as a function of serotonin concentration, is shown in Fig. 2. The stimulation of phosphorylation caused by serotonin was potentiated by IBMX (Fig. 2) at a concentration (4×10^{-5} M) which alone caused little alteration in the state of Protein I phosphorylation. In the presence of this concentration of IBMX, the maximal effect of a 10-min incubation with serotonin (10^{-3} M) was to convert $30.1\pm3.7\%$ ($n=9$) of Protein I from the dephospho- to the phospho-form, and the EC_{50} of serotonin was 4×10^{-6} M. The time course of Protein I phosphorylation by serotonin (10^{-3} M) in the presence of IBMX (4×10^{-5} M) was investigated and found to be similar to that observed for 10^{-3} M IBMX in cortical slices[8]. The conversion of dephospho-Protein I to phospho-Protein I was half-maximal after about 2 min, maximal after 5 min and remained constant for at least another 15 min.

That the maximal phosphorylation of Protein I in response to serotonin was not greater than 30% may be because, to excise the facial nucleus intact, it was necessary to take some tissue from adjacent regions which are not innervated by serotonergic terminals. Moreover, in all tissue-slice systems studied so far (for review, see ref. 15), 30–50% of Protein I has been observed to be refractory to phosphorylation in steady-state conditions by 8-bromo-cyclic AMP, IBMX, K^+ or veratridine, either alone or in combination. In the present study, incubation with 10^{-3} M IBMX for 10 min produced a $50.2\pm3.4\%$ ($n=8$) phosphorylation of Protein I, and incubation of facial nucleus slices for 1 min with 60 mM K^+-KRB produced a $48.5\pm3.6\%$ ($n=7$) phosphorylation of Protein I. The nature and subcellular localization of the refractory Protein I is being investigated.

That serotonin affected Protein I phosphorylation by interaction with specific receptors was indicated by the ability of mianserin, an antagonist at central serotonin receptors[21–23], to block the phosphorylation of Protein I induced by 10^{-4} M serotonin (Fig. 3). However, 10^{-5} M mianserin also caused a slight phosphorylation of Protein I when incubated with slices in the absence of serotonin. This and other classical serotonin antagonists have been found to be partial agonists of serotonin sensitive adenylate cyclase in brain, in that they stimulate adenylate cyclase at concentrations of 10^{-5} M and above[23].

In addition to the serotonergic input to the facial nucleus, there is a noradrenergic input which has been estimated to be about one-fifth that of the serotonin innervation of the facial nucleus in the rat[10,24]. Also, functional α-adrenergic receptors have been demonstrated on the facial motor neurones[10]. However, (−)noradrenaline (10^{-3} or 10^{-4} M) with or without 4×10^{-5} M IBMX, and (−)phenylephrine (10^{-3} M), had no affect on Protein I phosphorylation in this system.

In view of the widespread occurrence of adenosine receptors associated with adenylate cyclase in nervous tissue, we examined the effect of the adenosine analogue 2-chloroadenosine (10^{-3} M) on the phosphorylation of Protein I in facial nucleus slices. This agent converted 33.3±6.5% ($n=4$) of Protein I to the phospho-form. The effects of adenosine analogues are reported elsewhere[25].

We conclude for two reasons that a significant fraction of the Protein I that is phosphorylated in response to serotonin is probably located in the presynaptic terminals that innervate the facial motoneurones. First, immunohistochemical studies of the distribution of Protein I within the facial nucleus indicate that it is present in most and possibly all nerve terminals, whereas it was not detectable in the motoneurone somata (P. De Camilli and A. C. D., unpublished results). Second, serotonin has been found to stimulate selectively the phosphorylation of phosphopeptide 1 of Protein I in synaptosomes prepared from the rat facial nucleus: these results were obtained by preincubating synaptosomes with ^{32}P-inorganic phosphate to prelabel the presynaptic ATP pool, and then measuring the incorporation of ^{32}P into Protein I in response to incubation of the synaptosomes with serotonin[26].

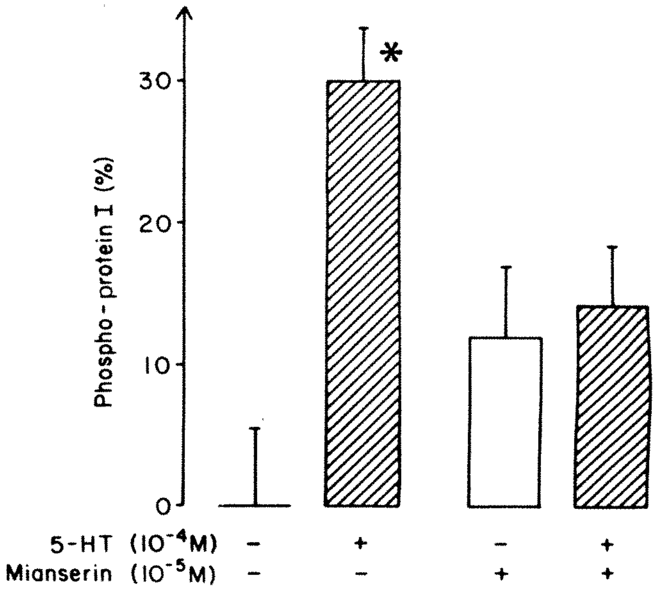

Fig. 3 The effect of the serotonin antagonist mianserin on the phosphorylation of Protein I in rat facial nucleus slices. One of each pair of facial nucleus slices was incubated with, and one without, serotonin (5-HT, 10^{-4} M) for 10 min. Mianserin (10^{-5} M), where included, was added to each pair 15 min before the end of the incubation. IBMX (4×10^{-5} M) was present in all incubation tubes and was added 12 min before the end of the incubation. The amount of dephospho- and phospho-Protein I was determined as described in Fig. 2 legend and was calculated with reference to slices incubated in the absence of both serotonin and mianserin. The basal level of phosphate incorporation into Protein I in the absence of serotonin and mianserin was 6.7±0.4 pmol per mg Zn acetate-precipitable protein. Data represent the mean±s.e.m. for five samples, each assayed in duplicate.*, $P<0.01$ when the effect of serotonin is compared with basal level (Student's t-test).

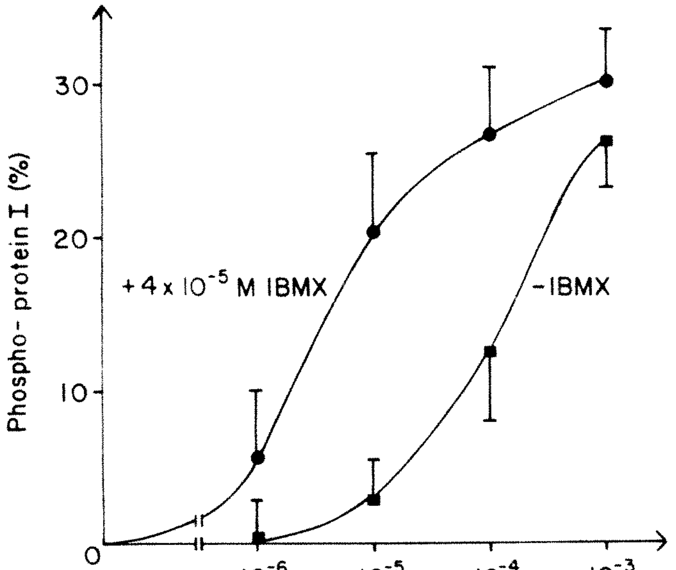

Fig. 2 Formation of phospho-Protein I from dephospho-Protein I in slices of rat facial nucleus incubated in the presence of various concentrations of serotonin. Experimental slices were incubated in the presence of the indicated concentration of serotonin, in the presence (●) or absence (■) of 4×10^{-5} M IBMX. Paired control slices were incubated in the absence of serotonin, in the presence or absence of 4×10^{-5} M IBMX, respectively. After termination of the incubation and extraction of Protein I from the slices, the amount of Protein I present in the dephospho-form in the extract was assayed by back-phosphorylation of dephospho-peptide 1, as described in Fig. 1 legend. The amount of phosphate incorporated into Protein I was determined as previously described[8], and the per cent conversion of dephospho- to phospho-Protein I due to serotonin was then calculated for each pair of incubations. Each data point represents the mean ± s.e.m. of 5–10 pairs of samples, each assayed in duplicate. The basal level of phosphate incorporation into Protein I was 7.9±0.8 pmol per mg Zn acetate-precipitable protein ($n=25$) in the absence of IBMX, and 7.4±0.7 pmol per mg Zn acetate-precipitable protein ($n=25$) in the presence of IBMX (4×10^{-5} M).

In a previous study of the facial nucleus, using electron microscope autoradiography with ^{3}H-serotonin, no specialized axo-axonic synapses involving serotonergic terminals were seen[13]. All the serotonergic terminals observed to form synapses innervated motoneurone somata or dendrites[13]. Electrophysiological studies suggest that a major effect of the serotonin input to the facial nucleus is to facilitate motoneurone excitation by a direct action on the motoneurone cell bodies[10,13,27]. The present studies on Protein I phosphorylation indicate that serotonin may also serve a paracrine function[28], diffusing to neighbouring presynaptic elements and possibly modifying neurotransmitter release. Thus, in the facial motor nucleus, serotonin may modulate function in both pre- and postsynaptic elements. Support for this interpretation is provided by studies of the crustacean neuromuscular junction, where serotonin acts both on excitatory nerve endings to facilitate transmitter release[29] and directly on muscle fibres to stimulate contracture[30].

We thank Dr G. K. Aghajanian for many helpful discussions and for provision of unpublished data. This work was supported by USPHS grants AA-04183, DA-01627, MH-17387 and NS-08440 and a grant from the McKnight Foundation.

Defect in cyclic AMP phosphodiesterase due to the *dunce* mutation of learning in *Drosophila melanogaster*

Duncan Byers*

Division of Biology, California Institute of Technology, Pasadena, California 91125

Ronald L. Davis* & John A. Kiger Jr

Department of Genetics, University of California at Davis, Davis, California 95616

Cyclic AMP is an intracellular mediator ('second messenger') in the nervous and endocrine control of cellular function, regulating different processes in different cell types. Although evidence is incomplete, it seems that cyclic AMP enhances the calcium-mediated release of neurotransmitter in some neurones[1–3]. A simple form of memory in the mollusc *Aplysia* is probably encoded as a cyclic AMP-induced enhancement of neurotransmission at certain synapses of the central nervous system[4]. The possibility that cyclic AMP participates in learning mechanisms may be explored using genetic mutants. For this purpose the fruitfly *Drosophila* is suitable as it is genetically well characterized and can learn through olfaction[5], vision[6] or taste[7]. We show here that independent searches for mutations of olfactory learning[8] and of cyclic AMP metabolism[9], and for mutations causing female infertility[10] have each led to the same gene—the *dunce* gene. Our evidence indicates that the normal *dunce* gene may specify a cyclic AMP phosphodiesterase.

Two different mutant alleles of the *dunce* gene, *dunce*^{1} and *dunce*^{2}, were isolated in a search for mutations of olfactory learning[8]. The *dunce* mutants do not learn to avoid an odorant associated with electric shock or quinine powder, although both of these are effective reinforcers for normal flies. The mutants can sense odorants, however, as they show normal inherent olfactory preferences in other situations[8,11]. The learning performance of *dunce* in other sorts of learning test can be normal (visual learning[12]), intermediate (leg-position learning; R. Booker and W. G. Quinn, personal communication) or poor (larval olfactory learning[13]). In morphology and general vigour, *dunce*^{1} and *dunce*^{2} seem normal. Both mutations reduce the fecundity of females, *dunce*^{1} to about half the normal number of offspring and *dunce*^{2} to 2% of the normal[14].

Table 1 Learning in the *dunce* mutants

Genotype	Olfactory learning index (Λ)
+ (normal Canton-S)	0.33 ±0.01 ($n = 463$)
dunce^1	0.04 ±0.01 ($n = 88$)
dunce^2	0.05 ±0.01 ($n = 47$)
Df(1)N$^{71h24\text{-}5}$/*Df(1)dm*^{75e19}	0.03 ±0.03 ($n = 6$)
dunce^1/*dunce*^{2}	0.07 ±0.02 ($n = 6$)
dunce^1/*Df(1)N*$^{71h24\text{-}5}$	0.05 ±0.01 ($n = 4$)
dunce^2/*Df(1)N*$^{71h24\text{-}5}$	0.02 ±0.02 ($n = 6$)
dunce^2/*Df(1)dm*^{75e19}	0.02 ±0.02 ($n = 5$)
+/*dunce*^{1}	0.26 ±0.02 ($n = 9$)
+/*dunce*^{2}	0.25 ±0.05 ($n = 9$)
+/*Df(1)N*$^{71h24\text{-}5}$	0.18 ±0.03 ($n = 5$)
+/*Df(1)dm*^{75e19}	0.26 ±0.03 ($n = 5$)

Scores are mean ± s.e.m. of n independent determinations of the learning index, Λ. The mutants *dunce*^{1} and *dunce*^{2} were previously referred to as *dunce*^{DB38} and *dunce*^{DB276} respectively[11–13]. The learning tests of normal (+), *dunce*^{1} and *dunce*^{2} were made with males alone, females alone and mixed groups; there were no significant sexual differences in learning. The other genetic combinations were tested as females heterozygous for two different X chromosomes, listed one before and one after a solidus. Before learning was tested, the two deficiency strains were backcrossed for two generations with strains derived from Canton-S to reduce possible genetic variation due to chromosomes other than the X. For learning measurements, flies were trained and tested in groups as previously described[5,8], with 3-octanol and 4-methylcyclohexanol as odorants and electric shock as punishment (see text). The learning index, Λ, is defined as the fraction of flies avoiding the odorant previously associated with shock minus the fraction avoiding the control odorant[5]. A positive score indicates learning (theoretical maximum = 1.0) and zero indicates no learning.

Other mutations of the *dunce* gene and some genetic deletions of *dunce* were identified through study of the genetics of cyclic AMP metabolism in *Drosophila*. As in other animals, cyclic AMP is synthesized from ATP by adenyl cyclase and hydrolysed to 5′-AMP by cyclic AMP phosphodiesterase. Animals typically have several forms (isozymes) of cyclic AMP phosphodiesterase[15–17]. In *Drosophila*, two forms, here designated I and II, have been described and partially purified; these differ in molecular weight, substrate specificity and other properties[18,19]. A search for genes with major control over the cyclic AMP phosphodiesterase activity revealed that the 'genetic dosage' of region 3D3–3D4 of the X chromosome affects the activity of the smaller form (form II) in a manner suggesting that this region may include the structural gene of form II[9,18]. Using two genetic deletions, *Df(1)N*$^{71h24\text{-}5}$ and *Df(1)dm*^{75e19} (see Fig. 1), one can generate (female) flies not carrying this region on either X chromosome[20]. These females are morphologically

Table 2 Cyclic AMP phosphodiesterase activity in unfractionated homogenates of the *dunce* mutants

Genotype	Cyclic AMP phosphodiesterase activity (pmol cyclic AMP hydrolysed per min per mg live weight) Male	Female
Normal (Canton-S)	226±7 ($n = 10$)	174±8 ($n = 11$)
dunce^1	135±13 ($n = 6$)	113±10 ($n = 6$)
dunce^2	94±13 ($n = 6$)	101±5 ($n = 6$)

Activities are mean ± s.e.m. of n assays using the procedure of Kiger and Golanty[9]. For each assay two flies were homogenized at 0 °C in 0.4–1.0 ml of buffer. Duplicate 0.05-ml portions of each homogenate were mixed with 0.05 ml of tritium-labelled cyclic AMP in water, yielding reaction mixtures containing 10^{-4} M cyclic AMP, 10 mM $MgCl_2$, 2 mM 2-mercaptoethanol and 40 mM Tris-HCl, *p*H 8.0. The mixtures were incubated at 30 °C for 20 min and then heated at 90 °C to stop the reactions. Substrate and products were separated by chromatography on paper, eluted from the paper and measured in a scintillation counter.

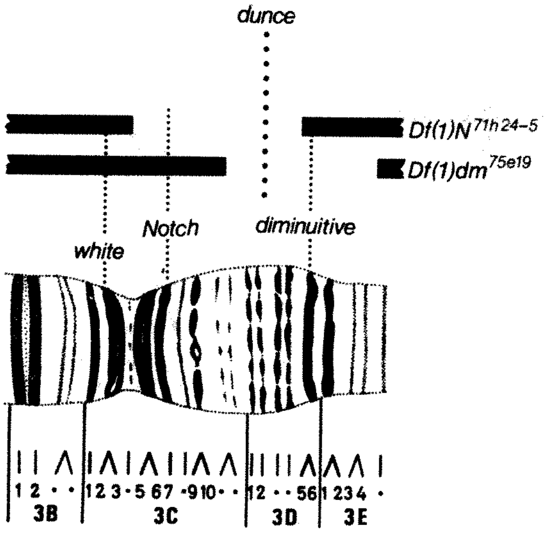

Fig. 1 Cytogenetic location of the *dunce* gene and two deletions of the *dunce* gene. At the top are illustrated the breakpoints found by Lefevre of *Deficiency (first chromosome) Notch*$^{71h24\text{-}5}$ *(Df(1)N*$^{71h24\text{-}5}$*)*, a deletion of chromosomal bands 3C4 to 3D4 inclusive, and *Df(1) diminuitive*^{75e19} *(Df(1)dm*^{75e19}*)*, a deletion of bands 3C12 to 3E4 inclusive[27]. The horizontal solid bars indicate regions of intact chromosome and the gaps indicate deleted regions. In alignment below is part (3%) of Bridges' drawing[28] of the *Drosophila* X chromosome of the larval salivary cells. Locations of the genes *white*, *Notch* and *diminuitive* are also shown.

normal and appear to be vigorous and healthy, even though they lack five adjacent chromosomal bands, including the *dunce* locus. They are sterile, and they lack the form II of cyclic AMP phosphodiesterase activity.

Still two other mutant alleles of the *dunce* gene have been found among 225 female-sterile mutants isolated by Mohler[10] on the *Drosophila* X chromosome. We show no data for them here but introduce them briefly. Both are located within chromosomal region 3C12–3D4 and are deficient in the form II of cyclic AMP phosphodiesterase; this was the first evidence that female infertility and defective cyclic AMP metabolism are associated with one gene in this region rather than two neighbouring genes[21]. In addition, the two mutants of Mohler are unsuccessful in olfactory learning and fail to complement *dunce*^{2} in learning or fertility[14]. Therefore they are alleles of the dunce gene, and we, with Mohler, rename them *dunce* ^{M11} and *dunce* ^{M14}.

Measurements of olfactory learning ability were made using the olfactory learning paradigm of Quinn, Harris and Benzer[5]. For training, groups of approximately 50 flies were attracted with a light to run alternately on to two printed circuit grids spread with different odorants, with one of the grids electrified. To test later whether learning had occurred, similar grids were used without shock, and the number of flies avoiding each odorant grid recorded. Normal and *dunce* flies tend to avoid the charged grid during training. Afterwards, however, normal flies selectively avoid the odorant previously paired with shock, whereas *dunce* flies do not[8]. Normal flies can learn to avoid the odorant on either of the two training grids, depending only on which grid is electrified: therefore the selective avoidance is not due to pseudoconditioning or inherent odour bias, but is an example of associative learning[5]. The learning index, Λ, defined in Table 1 legend, is a measure of the selective avoidance[5].

For normal flies of the Canton-S strain, Λ is 0.33 (Table 1). The mutants *dunce*^{1}, *dunce*^{2} and *Df(1)N*$^{71h24\text{-}5}$*/Df(1)dm*^{75e19} learn poorly ($\Lambda = 0.04$, 0.05 and 0.03, respectively). Heterozygous *dunce*/ + flies do not seem to learn as well as +/+ normal flies, suggesting that one normal gene may not be sufficient for normal learning. Flies heterozygous for pairs of different *dunce* deletions or mutations learn poorly (Table 1), showing that the different mutations do not complement each other in the combinations tested. Therefore, the *dunce* gene is located within the region of overlap of the two deletions.

The cyclic AMP phosphodiesterase activity of *dunce* was measured in two ways. First, adult flies were homogenized, radio-labelled cyclic AMP was added and the rate of hydrolysis of cyclic AMP measured. The rate of hydrolysis of cyclic AMP is reduced in *dunce*^{1} and *dunce*^{2} to approximately half of normal (Table 2). Second, groups of normal or *dunce* flies were homogenized, then centrifuged briefly to remove particulates, the supernatants were fractionated on sucrose density gradients and the distribution of cyclic AMP phosphodiesterase activity on the gradients measured. Normal *Drosophila* display two prominent forms (I and II) of soluble cyclic AMP phosphodiesterase[18], as shown in Fig. 2. The mutants *dunce*^{1} and *dunce*^{2} seem to have

Table 3 Cyclic AMP in the *dunce* mutants

Genotype	Cyclic AMP in adult whole fly (pmol per mg live weight) Male	 Female
Normal (Canton-S)	1.5±0.1 ($n=4$)	1.6±0.1 ($n=6$)
dunce^{1}	2.7±0.1 ($n=6$)	2.3±0.2 ($n=6$)
dunce^{2}	2.8±0.1 ($n=6$)	2.6±0.1 ($n=5$)

Cyclic AMP was measured by radioimmunoassay (NEN) in which *Drosophila* cyclic AMP competed with a standard amount of ^{125}I-labelled cyclic AMP for antibody binding sites. Values are mean ±s.e.m. of n extracts assayed. For each extract, four to six flies were homogenized together in 0.1 M HCl at room temperature. The extracts were heated for 2 min in a boiling water bath, cleared by centrifugation, neutralized to pH 6.2, cleared again by centrifugation, diluted and assayed as described previously[22]. The recovery of cyclic AMP was estimated with a small quantity of tritium-labelled cyclic AMP added to the initial homogenates and averaged 96%. If the cyclic AMP of normal flies (1.5 pmol per mg) were distributed uniformly through the fly, its concentration would be ~1.5 μM.

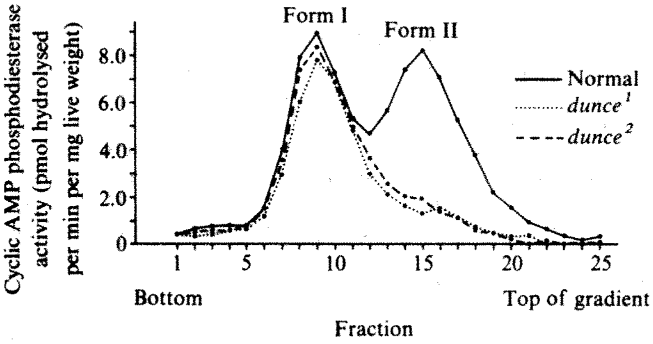

Fig. 2 Sucrose density gradient sedimentation of the soluble cyclic AMP phosphodiesterase activity of normal (Canton-S) and *dunce Drosophila*. Enzyme activity is expressed in pmol of cyclic AMP hydrolysed per min per mg live weight. Groups of 40 adult females were homogenized at 0 °C in 1.0 ml of buffer (10 mM $MgCl_2$, 1 mM $CaCl_2$, 2 mM 2-mercaptoethanol, and 40 mM Tris-HCl, pH 8.0). The same buffer was used for all subsequent steps. The homogenates were centrifuged at 105,000g for 60 min. 0.2-ml portions of the supernatants were layered on 5–20% sucrose density gradients (4.6 ml) and centrifuged at 165,000g (r_{av}) for 18 h. The gradients were divided into 0.18-ml fractions and duplicate 0.08-ml portions of each fraction were mixed with 0.02 ml of 5×10^{-4} M tritium-labelled cyclic AMP (NEN), incubated at 30 °C for 30 min, and then heated at 90 °C to stop the reactions. The product, 5'-AMP, was converted to adenosine with unpurified *Crotalus atrox* venom (Sigma) and measured with the resin assay of Thompson and Appleman[15]. Blank controls were treated identically except that buffer was added instead of homogenate; the radioactivity of the blanks (4,100 c.p.m.) was subtracted from each fraction. Before correction, the most active fractions contained about 15,000 c.p.m., representing hydrolysis of 12% of the radioactive cyclic AMP. The recovery of applied cyclic AMP phosphodiesterase activity from each gradient was ~50%.

normal amounts of form I and their activity at the position of form II is small, though not zero (Fig. 2). On similar gradients of $dunce^{M11}$, $dunce^{M14}$ and $Df(1)N^{71h24-5}/Df(1)dm^{75e19}$ (not shown), form I is approximately normal and form II is undetectable (less than 5% of normal).

If the activity of a cyclic AMP phosphodiesterase were reduced, then the concentration of cyclic AMP in the fly might be expected to rise. To test this, the amount of cyclic AMP in normal and *dunce* flies was measured using a radioimmunoassay. Normal adults yielded 1.5 pmol of cyclic AMP per mg live weight (Table 3 and ref. 22). The mutants $dunce^1$ and $dunce^2$ yielded about 160% of the normal quantity of cyclic AMP (Table 3). Cyclic AMP in similar extracts of $dunce^{M11}$, $dunce^{M14}$ and $Df(1)N^{71h24-5}/Df(1)dm^{75e19}$ is 300–600% of the normal[21,22].

We conclude that the normal *dunce* gene product has roles in behaviour, reproduction and cyclic AMP metabolism. The results show that the *dunce* gene and one isozyme of cyclic AMP phosphodiesterase are closely related in some way, but further experiments are required to test whether *dunce* is the structural gene of this enzyme. If elimination of cyclic AMP phosphodiesterase is in fact the cause of poor learning in *dunce*, then pharmacological inhibition of cyclic AMP phosphodiesterase activity should interfere with learning in normal flies. This expectation is confirmed by an experiment of Dudai and Jan[23], recently reconfirmed by Dudai[24]. They found that the olfactory learning performance of *dunce* mutants is mimicked by normal flies fed caffeine, an inhibitor of cyclic nucleotide phosphodiesterases[25,26]. One question still unanswered is whether the normal product of the *dunce* gene forms an integral part of a molecular apparatus of learning.

We thank J. D. Mohler and G. Lefevre Jr for mutant strains. Altered substrate specificity of herpes simplex virus thymidine kinase confers acyclovir-resistance

G. Darby & H. J. Field

Division of Virology, Department of Pathology, University of Cambridge, Cambridge CB2 2QQ, UK

Acyclovir (9-[2-hydroxyethoxymethyl]guanine or ACV) is a nucleoside analogue with considerable potential for the treatment of herpes simplex virus (HSV) infections in man[1,2]. Two virus-coded enzymes are important in the mechanism of action of this drug: thymidine kinase (TK) which initiates its activation by converting it to the monophosphate[3] and DNA polymerase whose action is inhibited by ACV triphosphate[4]. Changes in either gene may confer resistance[5–7], but all reported mutations in the TK gene have resulted in failure of the resistant virus to induce appreciable levels of the enzyme. Such TK$^-$ mutants arise readily in tissue culture systems[8,9] where the enzyme is non-essential for virus replication[10], but in animals they show considerably reduced pathogenicity and neurovirulence[7,11–14]. We now describe the isolation of a resistant mutant which induces a TK of altered substrate specificity and we show that this virus retains pathogenicity for mice with only a slight attenuation of neurovirulence.

To obtain conditions *in vitro* which would be selective against the readily occurring TK$^-$ variants, serum-starved BHK cells were used. It is known that TK$^-$ virus is at a disadvantage in resting cells[11,15] and it was therefore hoped that selecting for resistance in these cells would increase the probability of isolating TK$^+$ resistant virus. In fact both TK$^+$ and TK$^-$ resistant clones were obtained using this method.

Table 1 Resistance of TK$^+$ and TK$^-$ variants of SC16

Virus	TK (% SC16)	Resistance to ACV (ED_{50}, μg ml^{-1}) BHK cells	$D2_1$ cells*	Resistance to PAA (ED_{50}, μg ml^{-1}) BHK cells
SC16	100	0.02	0.01	11
SC16 S1	30–40	2.7	0.01	12
SC16 S6	<0.1	3.0	ND	ND

The parental strain of HSV1 (SC16) was originally isolated from an oral lesion. It has been well characterized in mice[21] and has previously been used to derive ACV-resistant variants[7]. 2×10^6 BHK cells were seeded into 25-cm^2 plastic tissue-culture flasks and incubated overnight in Glasgow-modified Eagle's medium supplemented with 10% tryptose phosphate broth and 10% calf serum. After 24 h the medium was removed, the cells washed and the flasks replenished with Eagle's medium without tryptose phosphate broth and with calf serum reduced to 0.5%. The cells were then maintained for 5 d before being inoculated with SC16 at a multiplicity of 0.1 plaque-forming unit (PFU) per cell in the presence of 0.1 μg ml^{-1} ACV. After 3 d of incubation, the cells were collected, subjected to ultrasonic disruption, then the released virus was titrated and used to inoculate further bottles of serum-starved cells. The second and third passage were in 1.0 and 10 μg ml^{-1} ACV respectively. Clones were isolated from the virus yield from the third passage. TK activity was measured on extracts of BUdR-resistant BHK (BU-BHK) cells obtained 18 h after inoculation with virus at 5 PFU per cell. The cells were resuspended at 3×10^7 per ml in 0.01M Tris and disrupted by ultrasonic vibration. Reactions were performed at 37 °C in 0.125-ml aliquots containing 0.02M phosphate buffer pH 6, 5mM $MgCl_2$, 5mM ATP and 40 μM 14C-thymidine (1.6 μCi ml^{-1}). Reactions were carried out using the method described by Klemperer *et al.*[22]. The results are expressed as % phosphorylation compared with the SC16 extract. Plaque reduction assays for both ACV and PAA were performed by inoculating monolayers of BHK cells with 200 PFU virus. After adsorption for 1 h, overlay medium was added containing increasing concentrations of the test drug. Graphs were plotted of % plaque reduction against $\log_{10}$ drug concentration and the ED_{50} values were assessed directly from the graphs.

* $D2_1$ cells are LTK$^-$ cells transformed to TK$^+$ phenotype using sheared *HSV-2 DNA*[23].

0028-0836/81/020081—03$01.00

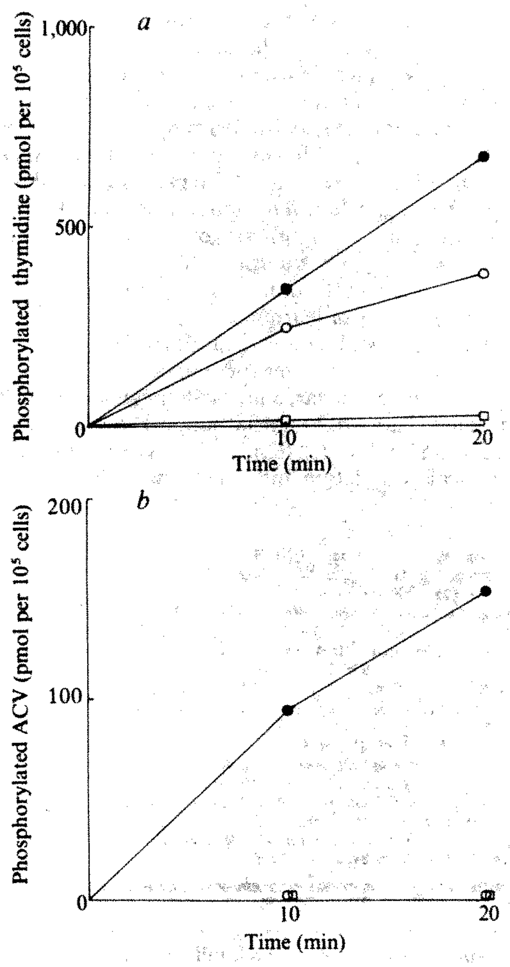

Fig. 1 The phosphorylation of thymidine and acyclovir by extracts of BU BHK cells infected with wild-type or ACV-resistant HSV. *a*, Phosphorylation of thymidine; *b*, phosphorylation of acyclovir. ●, SC16; ○, SC16 S1; □: SC16 S6. The preparation of infected cell extracts and assay for thymidine kinase are described in Table 1 legend. The assay for ACV was similar except that ^{14}C-thymidine was replaced by 0.8 mM ^{3}H-ACV (40 μCi ml^{-1}). The reactions were allowed to proceed for 0, 10 and 20 min and the 0-min values were subtracted. ^{3}H-ACV was prepared by a modification of the procedure described by Shelton and Clark[24].

HSV-1 strain SC16 was passaged in the presence of increasing concentrations of ACV in serum-starved BHK cells and the yield from the third passage was cloned in the absence of drug in actively growing BHK cells. Two of these clones (SC16 S1 and SC16 S6) were examined in detail. Both were shown to be approximately 100-fold more resistant to ACV (ED$_{50}$ 2–3 μg ml^{-1}) than the parental strain (Table 1). Thymidine kinase assays on infected cell extracts taken 18 h after high multiplicity infection showed that SC16 S1 induced TK whereas no activity was detected in the case of S6. However, the level of TK induced by SC16 S1 was rather less (30–40%) than that induced by the parental virus. One possible explanation for this difference would be a mutation in the TK gene.

Three lines of evidence were subsequently obtained which also suggested that the resistance of SC16 S1 resides in an altered TK and not at the level of DNA polymerase. First, SC16 S1 was sensitive to ACV when tested in D2$_1$ cells which carry and express the HSV TK gene (Table 1). These cells 'activate' the drug and only viruses which have acquired resistance at loci other than TK are resistant in them[8,16]. Secondly, viruses which are resistant at the DNA polymerase locus are also frequently resistant to phosphonoacetic acid (PAA)[5,6,8]. However, SC16 S1 was as sensitive as the parent to this drug (Table 1).

The third line of evidence concerns the direct measurement of the ability of the induced TK to phosphorylate ACV *in vitro*. The ability of extracts from cells infected with SC16 or ACV-resistant strains to phosphorylate thymidine and ACV were compared. The results of this experiment are shown in Fig. 1. Clearly the parent virus is able to phosphorylate both thymidine

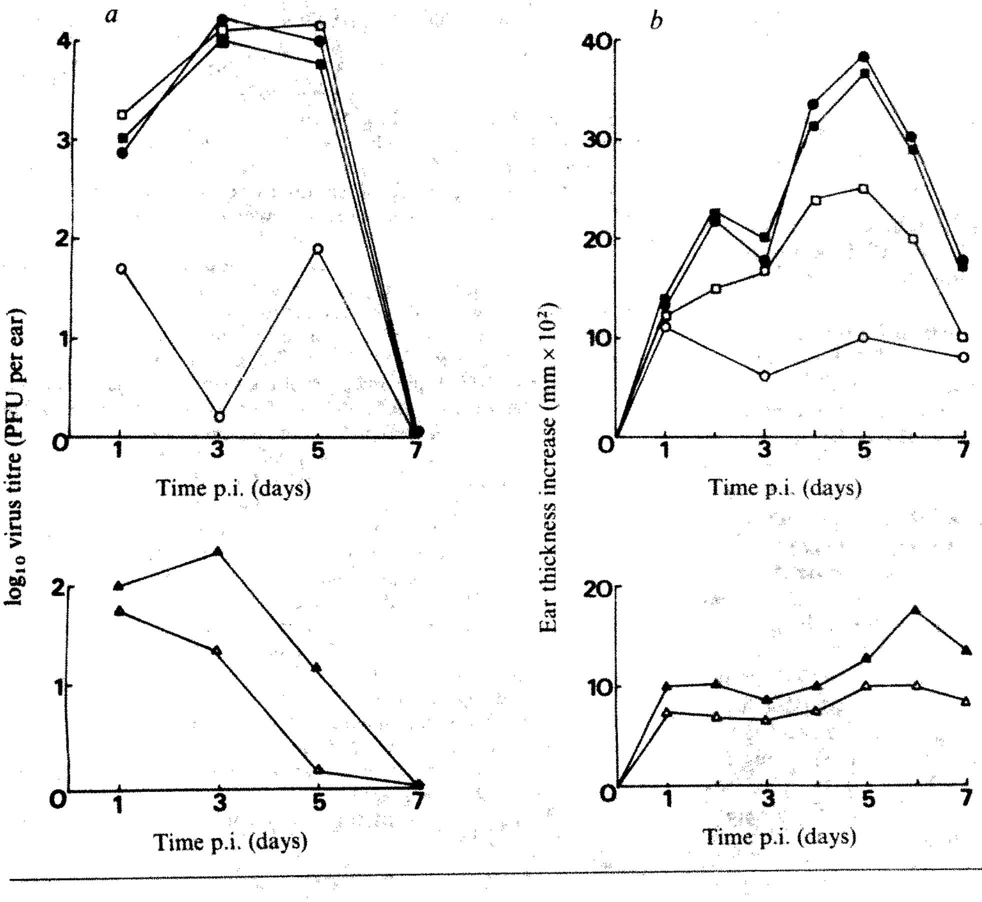

Fig. 2 Pathogenicity for mice of wild-type and TK^{+}- and TK^{-}-resistant strains of HSV, with and without ACV-treatment. *a*, Virus growth; *b*, cell-mediated inflammation. SC16: ●, untreated; ○, ACV-treated. SC16 S1: ■, untreated; □, ACV-treated. SC16 S6: ▲, untreated; △, ACV-treated. 10^{4} PFU test virus were inoculated into the left ear pinna of anaesthetized, 4-week-old female BALB/c mice. Virus growth in the ear was measured by homogenizing the pinnae from groups of three mice, and virus titres were determined by plaque titration in BHK cells. Ear thickness was measured using an engineer's micrometer—the thickness increase has been found to be a reliable indicator of cell-mediated inflammation[18]. The drug was suspended in water and given in twice daily intraperitoneal injections totalling 50 mg per kg per day. The effects of ACV on sensitive and resistant strains of HSV in this model have been described previously[7,17]. p.i., Post-infection.

Table 2 Virulence of TK^+ and TK^- variants of SC16 in BALB/c mice

Virus	TK induction	Ear inoculation latency in cervical ganglia*	i.c. Inoculation PFU/LD_{50}†
SC16	+	7/10 (0/10)	6
SC16 S1	+	5/12	60
SC16 S6	–	0/12	$>10^6$

* These mice are the survivors from the experiment illustrated in Fig. 2. The second, third and fourth cervical ganglia were explanted into Eagle's medium and incubated at 37 °C for 6 d. The tissue was then homogenized and tested for the presence of infectious virus by plaque titration in BHK cells as described previously[11]. Ratios are the number of mice from which latent virus was reactivated over the number of animals tested, the number in parentheses being the proportion positive following twice daily treatment with 50 mg per kg per day ACV injected intraperitoneally from the time of virus inoculation until 10 d thereafter.

† Dilutions of virus were inoculated into the left cerebral hemisphere in 0.02 ml Eagle's medium. The ED_{50} value was obtained using the Spearman–Karber method from the numbers of mice dying between days 2 and 14 after inoculation.

and ACV, though the actual amount of ACV phosphorylated is very much less. In contrast, the mutant-infected cell extracts failed to phosphorylate ACV although the S1 extract contained significant TK activity. Another isolate of HSV [C1(101)] which induces similar levels of TK to SC16 S1 was also tested; in this case ACV-phosphorylating activity was readily measured[20]. All the evidence is therefore consistent with the resistance of SC16 S1 residing in its failure to activate the drug in infected cells and this in turn is presumably due to a mutation in the TK gene which generates an enzyme with an altered substrate specificity.

As the resistant virus SC16 S1 was TK^+, it was obviously of interest to investigate its virulence in an animal model system. We have previously used the mouse ear model to investigate the pathogenicity of mutant viruses[7,11]. It can be seen from the data (Fig. 2) that SC16 S1 grows as well in the mouse ear as does the parent strain. In contrast, the growth in the ear of the TK^- mutant SC16 S6 was greatly impaired. Furthermore, a normally effective treatment routine[7,17] had little inhibitory effect on this virus because there was no marked reduction in virus titres in ear tissue or inflammation as determined by measurement of ear thickness[18]. The cervical dorsal root ganglia were later explanted from surviving mice to test for the presence of a latent infection (Table 2). Latent infections were detected in ganglion explants from both SC16 and SC16 S1 but not from S6. This was to be expected because of the reduced replication of the latter virus in the skin during the acute phase of the infection.

A further measure of the neurovirulence of the viruses was obtained by measuring the ED_{50} dose following intracerebral inoculation[11,19]. SC16 S1 seemed to be slightly attenuated relative to its parent showing a 10-fold increase in the ratio of plaque-forming units per LD_{50} (Table 2). However, the TK^- strain, SC16 S6, was highly attenuated showing >1,000-fold increase. The pathogenicity data reported here are very similar to those obtained with another TK^+ ACV-resistant strain of HSV [C1(101)P_2C_5][7], though recent evidence regarding this virus strongly suggests that, unlike SC16 S1, its resistance resides at the level of DNA polymerase and not TK[20].

The results described here suggest that HSV may acquire resistance to ACV by a mutation in the TK gene which alters the substrate specificity of the induced enzyme. Both this kind of mutant and the TK^+ DNA-polymerase mutants which have already been reported would seem likely to arise *in vivo* as there is little reduction in their growth potential. It remains to be seen, however, whether such viruses will be isolated from or constitute a problem in patients undergoing treatment with nucleoside analogues such as ACV.

This work was supported by a MRC programme grant. We thank Mrs Elizabeth Lay for her technical assistance and Mrs M. Wright for preparing the manuscript. Acyclovir was a gift from Dr G. B. Elion.

Terminal direct repeats in a retrovirus-like repeated mouse gene family

Eli Keshet & Yosef Shaul

Department of Virology, Weizmann Institute of Science, Rehovot, Israel

The mouse genome contains multiple copies of a dispersed gene family known individually as VL30 genes[1] which are thought to be associated with retroviruses. The copies consist of closely related 5.2-kilobase DNA sequences flanked by unrelated cellular DNA, and although no sequence homology has been found between the genes and the exogenous or endogenous retroviruses so far tested, the 30S RNA transcripts expressed by the genes are efficiently packaged into virions, recovered from infected cells[2–4] and transmitted to other cells by pseudo-type infection[5]. Stimulated by recent reports[6–10] of the similarity between retroviruses and transposons (from which retroviruses may have evolved[6]), and in particular by the recognition that both types of genetic elements are characterized by a large terminal repeat (LTR), we set out to determine whether the VL30 genes are also distinguished by this property. Using cloned DNAs from a mouse gene library and heteroduplex analysis, we have now found that the VL30 genes do indeed carry terminal direct repeats 400 base pairs long.

Individual copies of these 'retrovirus-like' genes (referred to as VL30 genes) were cloned from a gene library of the inbred mouse strain BALB/c in bacteriophage λ (ref. 1). The construction of the gene library from mouse genomic fragments obtained by a partial *Eco*RI digestion enabled us to select clones which, despite having *Eco*RI cleavages sites within VL30 DNA, encompass the entire 5.2 kilobases of the element and also contain some flanking DNA sequences. Such a clone with an *Eco*RI site, roughly in the middle of VL30 DNA, was used in the experiment designed to visualize LTRs (Fig. 1). As illustrated in Fig. 1, the presumptive LTRs are readily dissociated from each other by *Eco*RI digestion and subcloning of each fragment into the *Eco*RI site of plasmid pBR322. The subcloning procedure results in recombinant plasmids harbouring the eukaryotic insert in each of the two possible orientations. The orientation of insertion of several recombinant plasmids was determined by restriction enzyme digestions and blot hybridization analyses of the vector–insert junction fragments (data not shown). Two recombinant plasmids, whose VL30 DNA is inserted in the orientation depicted in Fig. 1, were linearized by *Sal*I digestion and analysed by heteroduplexing. This procedure visualizes large repeats in VL30 DNA that are in a direct orientation. A

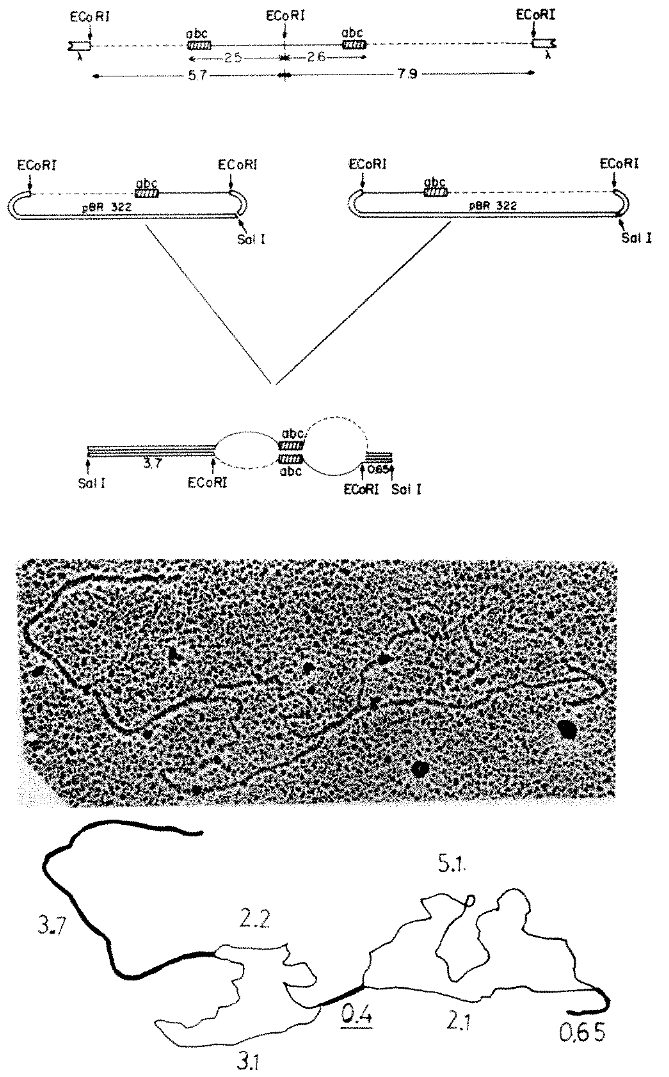

Fig. 1 Visualization of a direct repeat by heteroduplex analysis. Top: diagrammatic representation of cloned DNAs used and their expected heteroduplex. Upper drawing is of clone 3 of VL30 DNA in bacteriophage λ. Sizes (in kilobases) of the retrovirus-like DNA sequences (solid line) and their flanking DNA sequences (dashed line) were determined previously[1]. Hatched boxes indicate presumptive direct repeats in DNA. The middle drawing is of subclones of the 5.7- and 7.9-kilobase *Eco*RI fragments of clone 3 in plasmid pBR322. The lower drawing is an expected heteroduplex structure between the two *Sal*I-linearized plasmids (drawing is out of scale). Bottom: electron micrograph of a typical heteroduplex. The indicated sizes (kilobases) are average values obtained from measurements of 10 heteroduplexes. The size of the duplexed region was standardized with respect to the duplexed regions of the vector (3.7 and 0.65 kilobases). The sizes of the single-stranded regions were standardized with respect to a single-stranded ϕX174 included in the same field.

duplexed region, representing a direct repeat of ~400 base pairs, was observed (Fig. 1). A control heteroduplex, where the 5.7-kilobase *Eco*RI fragment is inserted into the plasmid in the opposite orientation (and is expected, therefore, to visualize inverted repeats) failed to reveal such a structure (data not shown). Several heteroduplexes were measured. On the basis of the known map location of the *Eco*RI site and the known sizes of the DNA sequences flanking this particular VL30 DNA[1], we could identify the direct repeat with the 400 base pairs residing at each terminus of VL30 DNA (Fig. 1).

As the inherent limitations in the accuracy of heteroduplex measurements prevent exact localization of the repeated DNA sequences within the cloned DNAs, we used another approach that exploits the availability of the poly(A)-containing 30S RNA transcripts of VL30 DNA. A hybridization probe corresponding to the 3′ end of the 30S RNA was prepared (Fig. 2). Although this probe contains sequences confined to the 3′ end—one-fifth of the RNA—it efficiently hybridized to both *Eco*RI fragments (Fig. 2), thus confirming the existence of repeated DNA sequences, and ruling out the possibility that the repeats are contained within DNA sequences adjacent to VL30 DNA. Assuming a gross co-linearity between VL30 DNA and its 30S RNA transcript, this result also places the repeated sequences at both termini of VL30 DNA.

During the propagation of recombinant phages in bacteria, some of the cloned DNAs accumulated a significant fraction of phages with a shorter eukaryotic insert. Heteroduplex analysis revealed that all these phages suffered a unique deletion of 4.7 kilobases in VL30 DNA (data not shown) and suggested to us that the deletion mutants might have arisen as a result of intramolecular recombination involving the direct terminal repeats. Such an event would lead to the loss of all VL30 DNA sequences except for one copy of the LTR. To test this possibility, a deleted form of one of the cloned phages was heteroduplexed with non-deleted phage of another VL30 clone. The rationale for this experiment is given in Fig. 3. Two types of heteroduplex are anticipated which differ with respect to the choice of the LTR copy of the non-deleted phage that anneals with the sole LTR copy retained by the deleted phage. In each case, the two heteroduplexed DNAs shared only their λ 'arms' and an additional 0.4-kilobase segment (Fig. 3). The observed heteroduplexes were consistent with structures predicted on the basis of the known size of each flanking DNA sequence and thus verified the structure suggested for the deletion. It is likely that deletions, similar to those described above, that occur during

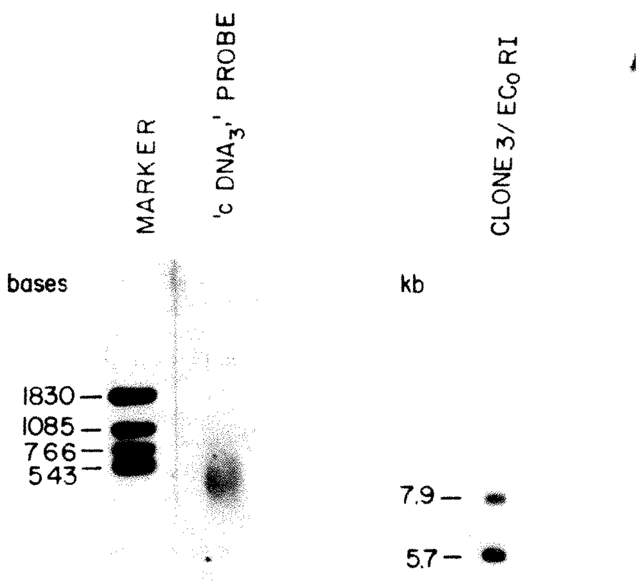

Fig. 2 Evidence for LTR in VL30 DNA with the aid of a 3′ end-specific probe. 30S RNA was extracted from purified virions of Ra-MuLV produced by JLS-V9 cells. RNA was randomly sheared and poly(A)-containing RNA was purified by two cycles of oligo(dT)-cellulose chromatography. RNA was size fractionated by centrifugation through a sucrose gradient and molecules smaller than 800 bases were pooled. ^{32}P-labelled cDNA was synthesized with oligo(dT)$_{12-18}$ as a primer. This cDNA was designated cDNA$_{3'}$. Left: size determination of the cDNA$_{3'}$ probe. A sample of cDNA$_{3'}$ was electrophoresed through a 1.2% agarose gel and autoradiographed. Size markers are ^{32}P-labelled *Hin*fI fragments of SV40 DNA. Right: 0.5 µg DNA of clone 3 DNA was digested with *Eco*RI, electrophoresed through a 0.7% agarose gel, blotted on to a nitrocellulose filter, hybridized with cDNA$_{3'}$ and autoradiographed.

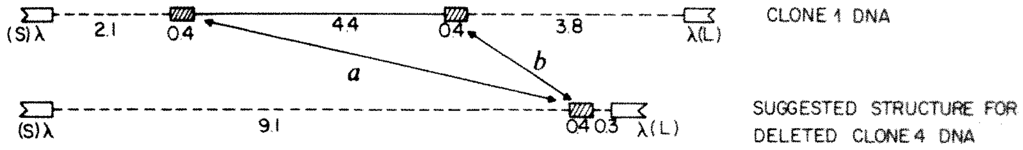

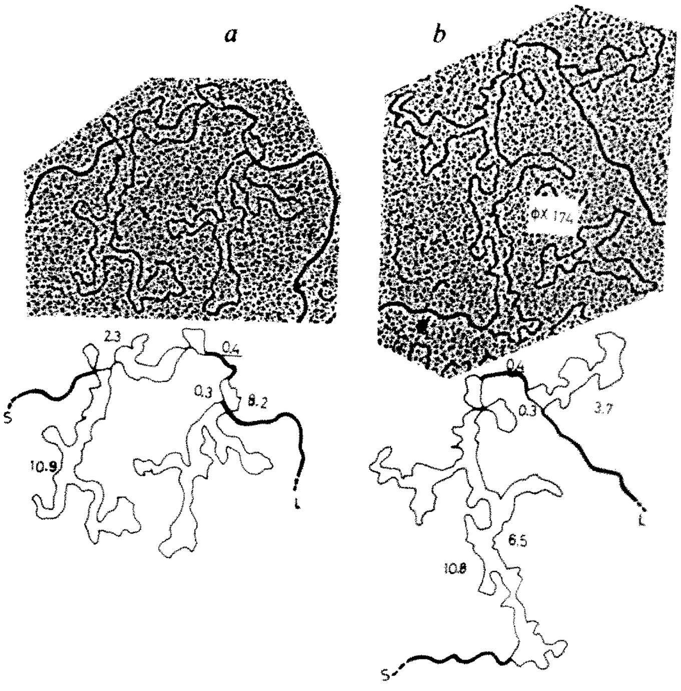

Fig. 3 Characterization of the specific deletion in cloned VL30 DNA. Top: clones 1 and 4 were previously characterized with respect to the size of VL30 DNA (solid line) and flanking DNA sequences (dotted line)[1]. Boxes indicate direct terminal repeats. S and L indicate short and long arms of the λ vector, respectively. *a* And *b* indicate the two possible forms of heteroduplexes. Bottom: electron micrographs of heteroduplexes between clone 1 DNA and deleted clone 4 DNA. A representative heteroduplex of each type is shown.

propagation of cloned VL30 DNA in bacteria, also occur in the mouse genome. Lauer *et al.* have recently described deletions in human α-globin genes that are indistinguishable from deletions that occur in bacteria with respect to the location of the breakpoints of deletion[11]. The availability of cloned LTR DNA sequences, devoid of other VL30 DNA sequences, provides a probe for such genomic deletions.

The biological significance of VL30 DNAs is unknown. They may represent degenerative endogenous viral genomes or may be cellular genetic elements of a protoviral nature. Structurally, these genetic elements strongly resemble eukaryotic transposons[12,13]. Shared features include similar size and reiteration frequencies, a dispersed genomic distribution, efficient transcription of a poly(A)-containing RNA and the presence of large direct repeats at the termini of these elements. Whether these DNA sequences actually transpose remains to be determined.

This work was carried out in the laboratory of Dr H. Aviv whom we thank for his help. We also thank Ms Y. Bernstein for technical assistance.

A general method for site-directed mutagenesis in prokaryotes

Gary B. Ruvkun & Frederick M. Ausubel

Cellular and Developmental Biology Group, Department of Biology, Harvard University, Cambridge, Massachusetts 02138

The genetic analysis of genes from prokaryotic species for which experimental genetic systems have not yet been developed is often limited by the difficulty of producing mutations in those genes. We report here a general technique applicable to Gram-negative prokaryotes for site-directed mutagenesis of cloned DNA fragments which we have applied to the study of the symbiotic nitrogen fixation genes of *Rhizobium meliloti*. In particular, we mutagenized cloned *R. meliloti* restriction fragments in *Escherichia coli* with transposon Tn*5* and then replaced the wild-type parental DNA sequences with the mutant DNA sequences in the *R. meliloti* genome. Using this method we show that an *R. meliloti* DNA restriction fragment, cloned previously on the basis of homology to *Klebsiella pneumoniae nif* genes[1], contains gene(s) essential for symbiotic nitrogen fixation. In addition, we use this method to construct a physical genetic map of a subset of the *R. meliloti nif* genes.

The bacterial species *R. meliloti* fixes nitrogen in symbiotic association with alfalfa (*Medicago sativa* L.). Establishment of symbiosis begins with the bacterial invasion of roots and culminates in the development of the root nodule, a specialized structure within which the *Rhizobium* differentiate into nitrogen-fixing bacteroids[2]. *R. meliloti* can be grown in culture apart from its host plant, but does not normally fix nitrogen in this free-living state. Therefore, the isolation and characterization of nitrogen fixation (*nif*) mutants using standard bacterial genetic techniques would require the screening of thousands of potential bacterial mutants on individual plants. Fig. 1 Physical genetic map of *R. meliloti nif* genes *D* and *H*. Restriction maps of plasmid pRmR2 and each pRmR2::Tn*5* plasmid were constructed using a combination of digestions in 1 × universal restriction enzyne buffer (1 × UREB = 60 mM NaCl, 10 mM Tris *p*H 7.4, 6 mM $MgCl_2$, 6 mM *β*-mercaptoethanol) with restriction endonucleases *Eco*RI, *Hin*dIII, *Xho*I and *Bam*HI followed by gel electrophoresis in 1–1.5% agarose gels. These digested DNAs were transferred to nitrocellulose by the method of Southern[7] and hybridized with probes derived from the *K. pneumoniae* 6.3-kilobase *Eco*RI fragment cloned in pSA30 (ref. 22). As shown in *b*, the 1.4-kilobase *Hin*dIII–*Bam*HI fragment of pSA30 contains the C-terminal coding region of *nifD* and the 0.7-kilobase *Bgl*II–*Eco*RI fragment contains the N-terminal coding region of *nifH* (ref. 23). These fragments were eluted from preparative agarose gels as described previously[1], and labelled with [α-^{32}P]TTP (350 Ci $mmol^{-1}$, Amersham) using the nick translation method to a specific activity of 5×10^7 c.p.m. per μg of DNA. Approximately 10^6 c.p.m. were hybridized to the nitrocellulose sheet as described previously[1]. Regions of homology in the *R. meliloti nif* region to *K. pneumoniae nifD* and *nifH* genes (shown in heavy lines) were localized by a combination of restriction endonuclease sites present in the 3.9-kilobase *Eco*RI fragment and new restriction sites generated by various Tn*5* insertions. The region of homology to *K. pneumoniae nifD* was localized to a 1.5-kilobase region between Tn*5* insertions 2 and 10. The region of homology to *K. pneumoniae nifH* was localized to a 1.0-kilobase region to the right of Tn*5* insertion 10 and to the left of *Xho*I site B on pRmR2. R, *Eco*RI restriction site; H, *Hin*dIII restriction site; X, *Xho*I restriction site; B, *Bam*HI restriction site; Bg, *Bgl*III restriction site.

circumvent the tedium of this approach, we have developed new physical and genetic methods to identify and manipulate *R. meliloti nif* genes.

We previously showed that the *K. pneumoniae* DNA sequences coding for one subunit of nitrogenase (*nifD*) and nitrogenase reductase (*nifH*) share DNA homology with 13 widely divergent nitrogen-fixing species, including *R. meliloti*[1]. We used this homology to clone a 3.9-kilobase *R. meliloti Eco*RI fragment in the plasmid cloning vector pACYC184 (ref. 3) (pRmR2; see Fig. 1). To obtain genetic verification that pRmR2 contains essential *nif* genes and to initiate a detailed genetic analysis of *R. meliloti nif* genes, we developed a method to replace the *R. meliloti* wild-type genomic *nif* genes with homologous sequences altered by transposon Tn*5* mutagenesis. We chose transposon Tn*5* for this mutagenesis because it confers resistance to kanamycin (Km) and neomycin (Nm) in *E. coli* and *R. meliloti*, exhibits little insertion site specificity and in general causes polar insertion mutations[4,5]. The experimental strategy we adopted involved the series of steps summarized below and in Fig. 2.

Step I: Plasmid pRmR2 was mutagenized with Tn*5* by infecting an *E. coli* strain containing pRmR2 with λ::Tn*5* (ref. 6). Plasmids carrying Tn*5* insertions were isolated and the locations of the Tn*5* insertions determined by restriction enzyme analysis (see Fig. 2 legend). Six plasmids carrying Tn*5* insertions at different locations along the entire length of the 3.9-kilobase fragment were selected for further study (see Fig. 1). We will refer to these as '*nif* region::Tn*5*' insertions.

Step II: A DNA transformation system has not been developed for *R. meliloti*. Therefore, to introduce the *nif* region::Tn*5* insertions into *R. meliloti*, each *nif* region::Tn*5* *Eco*RI fragment was recloned into the conjugative cloning vector pRK290. (Plasmid pRK290, constructed by Ditta *et al.*[6], is a 20-kilobase derivative of the P-group conjugative plasmid RK2, confers tetracycline (Tc) resistance and contains a single *Eco*RI site suitable for cloning.) The resulting pRK290-*nif* region::Tn*5* hybrid plasmids were conjugated into *R. meliloti*. Total DNA was isolated from the *R. meliloti* exconjugants and analysed by the Southern gel transfer and hybridization procedure[7]. The pRK290-*nif* region::Tn*5* hybrid plasmids had the expected restriction map and replicated stably in *R. meliloti* (see Fig. 3).

Step III: Our strategy for isolating *R. meliloti* strains in which the plasmid-borne *nif* region::Tn*5* fragment had replaced the genomic wild-type *nif* region was based on the assumption that homologous recombination between pRK290-*nif* region::Tn*5* and the *R. meliloti* genome would occur in a small subpopulation of cells and result in the 'transfer' of the Tn*5* insertion mutation from the plasmid to the genome. Cells in which this recombination event had occurred were detected by conjugation of a second P-group plasmid, pR751 (ref. 8), which is incompatible with pRK290, into the *R. meliloti* strains containing the pRK290-*nif* region::Tn*5* plasmid, and simultaneous selection for neomycin resistance (retention of Tn*5*) and trimethoprim (Tp) resistance (conferred by pR751). All the Tp^rNm^r exconjugants were Tc^s, indicating loss of pRK290. These *R. meliloti* $Tp^rNm^rTc^s$ exconjugants could have resulted from Tn*5* transpositions to pR751 or to the *R. meliloti* genome as well as from homologous recombination between pRK290-*nif* region::Tn*5* and the *R. meliloti* genome. To demonstrate that Tn*5* had recombined into the *R. meliloti* genome by means of flanking *nif* DNA sequence homology, DNA was isolated from the $Tp^rNm^rTc^s$ exconjugants, cleaved with *Bgl*II and analysed by the Southern gel transfer and hybridization technique using

Alfalfa seeds (variety Iroquois) were sterilized for 30 min in 70% ethanol followed by 30 min in 50% commercial bleach, and then germinated in the dark in distilled water for 3 days. Individual seedlings were planted on 6-ml slants of nitrogen-free agar (0.1% $CaHPO_4$, 0.02% K_2HPO_4, 0.02% $MgSO_4 \cdot 7H_2O$, 0.02% NaCl, 0.01% $FeCl_3$, 1.0% agar)[13] in 18 × 150 mm test tubes and grown at 27 °C with overhead illumination of 200 foot-candles on 16-h days for 7 days before bacterial inoculation. A freshly grown colony of *R. meliloti* grown on LB agar plus appropriate drugs was picked with a flat toothpick, suspended in 5 ml distilled water and used to inoculate five alfalfa seedlings. After 4 weeks of growth in the conditions described above, the tubes were sealed with serum stoppers, injected with 1 ml acetylene gas per tube, and incubated at room temperature in the dark for 24 h. Ethylene gas production was monitored by gas chromatography as described previously[14]. Control plants not inoculated with bacteria did not form nodules and no acetylene reduction was detected. All plants inoculated with *R. meliloti* formed nodules but those inoculated with strains containing nif^-::Tn*5* insertions did not exhibit detectable levels of nitrogenase activity and had approximately 5–10 times the normal number of nodules per plant. Both the control plants and the plants inoculated with Nif^- bacterial strains were stunted and yellow after 4 weeks of growth compared with plants inoculated with Nif^+ bacterial strains, which were green and visibly larger. NT, not tested.

^{32}P-labelled pRmR2 DNA as a hybridization probe. Homologous recombination of each *nif* region :: Tn*5* insertion from the plasmid into the *R. meliloti* genome *nif* region would result in a different predictable change in the restriction map of that region whereas transposition of Tn*5* would not be expected to change the restriction map of the genomic *nif* region. Figure 3*a*, *b*, *c* illustrates the expected *Bgl*II restriction fragments homologous to pRmR2 for various strains intermediate in the transfer of Tn*5* from pRK290-*nif* region :: Tn*5* to the *R. meliloti* genome. Figure 3*d* is an autoradiogram of an actual hybridization and shows that in the Tp^{r}Nm^{r}Tc^s strains examined, each *nif* region :: Tn*5* had replaced the normal 3.9-kilobase *nif* region in the *R. meliloti* genome through a homologous recombination event. Among 24 Tp^{r}Nm^{r}Tc^s colonies analysed, none contained Tn*5* transpositions to new locations in the genome or to pR751, and none contained replicon fusions between pR751 and pRK290-*nif* region :: Tn*5* (ref. 9).

Step IV: Each *R. meliloti* strain containing a verified Tn*5* insertion in the *nif* region of the genome was inoculated onto a sterile alfalfa seedling and nitrogenase activity was determined 3–4 weeks later using the acetylene reduction technique as described in Table 1 legend. Among five strains containing Tn*5* insertions in the *nif* region, three had undetectable levels of nitrogenase activity (Nif$^-$) on establishment of symbiosis, whereas two had normal nitrogenase activity (Nif$^+$) (Fig. 1, Table 1). The construction of two Nif$^+$ strains with genomic Tn*5* insertions in the 3.9-kilobase *Eco*RI fragment demonstrates that the construction of the three Nif$^-$ :: Tn*5* mutations in unlikely to be an artefact of the cloning and recombinational techniques used in our gene replacement strategy. All the strains with a normal genomic *nif* region, and also plasmid pRK290-*nif* region :: Tn*5*, were Nif$^+$, indicating that none of the *nif* region :: Tn*5* insertions was a dominant *nif*$^-$ mutation. All five strains containing Tn*5* recombined into the genome were prototrophic, indicating that the Nif$^-$ phenotype of three of the strains was not an indirect effect of auxotrophy.

In conjunction with the data presented in Table 1 and Fig. 3, which correlate Tn*5* map position with Nif phenotype, we have used pRmR2 :: Tn*5* plasmids to map the approximate positions of *R. meliloti nif* genes on the 3.9-kilobase *Eco*RI fragment. In these experiments we used specific *K. pneumoniae* restriction fragments carrying regions of genes *nifD* (nitrogenase) and *nifH* (nitrogenase reductase) as hybridization probes to various restriction digests of pRmR2 and pRmR2 :: Tn*5* plasmids (Fig. 1). We found that sequences within both *K. pneumoniae nifD* and *nifH* are conserved in *R. meliloti*. The conserved *R. meliloti* '*nifD*' sequences are localized to 1.5 kilobases between Tn*5* insertions 2 and 10, and the conserved *R. meliloti* '*nifH*' sequences are localized to 1.0 kilobase between Tn*5* insertion 10 and *Xho*I site B indicated in Fig. 1.

As expected on the basis of the interspecies DNA homology with *K. pneumoniae nif* genes, those Tn*5* insertions which cause a Nif$^-$ phenotype in *R. meliloti* are localized near or in these regions of homology, whereas the two Tn*5* insertions which have no effect on *nif* gene expression are located at the other end of the 3.9-kilobase *R. meliloti Eco*RI fragment and not in the region of interspecies *nif* gene homology. Because Tn*5* insertion 22 does not cause a Nif$^-$ phenotype, the *nif* gene *H* equivalent in *R. meliloti* probably starts to the left of this Tn*5* insertion (Fig. 1). The protein subunits for nitrogenase and nitrogenase reductase have average molecular weights of 55,000 and 28,000, respectively, in other *Rhizobium* species[10,11]; therefore, the minimum length of DNA necessary to code for these proteins should be 2.2 kilobases. Thus, it is likely that the 2.6 kilobases between Tn*5* insertion 22 and Tn*5* insertion 2 contains all of *nifH* and at least part of *nifD*.

An important conclusion to be drawn from the present data is that cloned *R. meliloti* DNA sequences homologous to *K. pneumoniae nifD* and *nifH* are essential for symbiotic nitrogen fixation. The data rule out the possibility that the DNA homology between *K. pneumoniae nif* genes and *R. meliloti* DNA is due to cryptic *nif* genes not functional in symbiotic

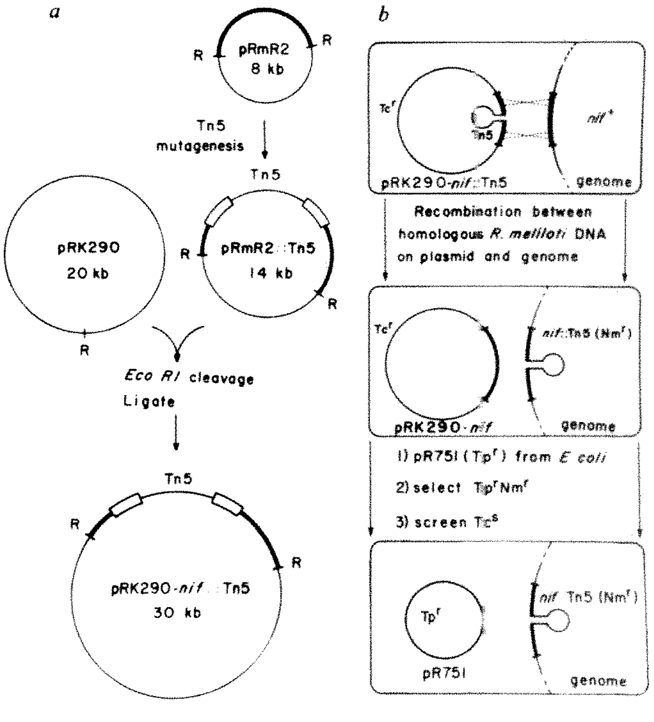

Fig. 2 Outline of experimental strategy used to introduce specific Tn*5* mutations into the *R. meliloti* genome. *a*, Mutagenesis of pRmR2 with Tn*5* and recloning of *nif* region :: Tn*5* fragments into pRK290. *E. coli* strain HB101/pRmR2 (*thr leu thi recA hsdR hsdM pro Str^r* Tc^r) was grown at 37 °C in LB medium containing 0.2% maltose and 10 μg ml^{-1} Tc to a density of 5×10^8 cells per ml and infected with λ*b*221 *rex* :: Tn*5 cI*857 O_{am8} P_{am29} (ref. 5) at a multiplicity of 0.1 particles per cell. Approximately 5×10^3 kanamycin-resistant survivors were obtained per plate when 0.2 ml of infected cells were plated on LB agar containing 20 μg ml^{-1} Km at 32 °C. Colonies from three plates were resuspended in 10 ml of 10 mM $MgSO_4$, plasmid DNA was isolated[15] and used to transform $CaCl_2$-treated strain HB101 (ref. 16), and Tc^r and Tc^{r}Km^r transformants were selected on LB agar containing 10 μg ml^{-1} Tc and 20 μg ml^{-1} Km. Approximately 20 Tc^{r}Km^r transformants were obtained per 10^4 Tc^r transformants. Plasmid DNA was prepared from 26 Tc^{r}Km^r colonies using a small-scale purification procedure[17], and the plasmid DNA was digested in UREB with *Eco*RI. Because Tn*5* is 5.7 kilobases and does not contain an *Eco*RI site, insertions of Tn*5* into the 3.9-kilobase *nif* homologous *R. meliloti Eco*RI restriction fragment were monitored (using agarose-gel electrophoresis) by the appearance of a 9.6-kilobase *Eco*RI restriction fragment and disappearance of the 3.9-kilobase *Eco*RI restriction fragment. Among the 26 plasmids, 11 contained Tn*5* insertions in the 3.9-kilobase *Eco*RI fragment and the sites of these Tn*5* insertions along the 3.9-kilobase *Eco*RI restriction fragment were determined by double restriction endonuclease digestions of each pRmR2 :: Tn*5* plasmid in 1X UREB with *Xho*I and *Eco*RI or *Hin*dIII and *Eco*RI. Six pRmR2 :: Tn*5* plasmids with Tn*5* insertions distributed along the entire length of the 3.9-kilobase *Eco*RI fragment were chosen for further analysis. A 0.5-μg aliquot of each of the six pRmR2 :: Tn*5* plasmids was digested with *Eco*RI as described above and mixed with a 0.5-μg aliquot of pRK290 DNA which had also been digested with *Eco*RI. The mixed DNAs were ligated with 1 unit of T4 DNA ligase, as described elsewhere[14], and the ligated DNA was used to transform *E. coli* strain MM294 (*endo*I *hsd*R *pro*). Following a nonselective growth in 1 ml LB for 2 h at 32 °C, a 0.1-ml aliquot was diluted into 5 ml LB containing 10 μg ml^{-1} Tc and 20 μg ml^{-1} Km and grown to saturation at 32 °C. 0.1 ml of this culture was mated simultaneously with 0.1 ml *R. meliloti* strain Rm1021 (nif$^+$Str^r) and 0.1 ml MM294/pRK2013, and incubated on an LB agar plate overnight at 32 °C. (Plasmid pRK2013 (ref. 18) contains the *tra* genes of RK2 cloned in plasmid ColE1 and complements pRK290 *in trans* for conjugation of pRK290.) Str^{r}Tc^{r}Nm^r *R. meliloti* exconjugants were selected on LB agar containing 250 μg ml^{-1} streptomycin (Str), 5 μg ml^{-1} Tc and 20 μg ml^{-1} Nm. Because pRK2013 (which confers Nm^r) cannot replicate in *R. meliloti*[6], this selection yielded *R. meliloti* exconjugants containing pRK290-*nif* region :: Tn*5* plasmids which arose at a frequency of 10^{-3}. *b*, Selection of *R. meliloti* strains in which the *nif* region :: Tn*5* mutations had recombined in the genome. *E. coli* strain J53/pR751 (ref. 8) was conjugated with each of the *R. meliloti* M1021/pRK290-*nif* region :: Tn*5* strains as described above and Str^{r}Tp^{r}Nm^r exconjugants were selected on LB agar containing 250 μg ml^{-1} Str, 700 μg ml^{-1} Tp and 30 μg ml^{-1} Nm. Exconjugants arose at a frequency of 10^{-6} and 24 of these (four from each of the six pRK290-*nif* region :: Tn*5* strains) were analysed as described in Fig. 3 legend. *R. meliloti nif* region DNA is shown in heavy lines; Tn*5* inverted repeat DNA shown as open boxes (R = *Eco*RI restriction site).

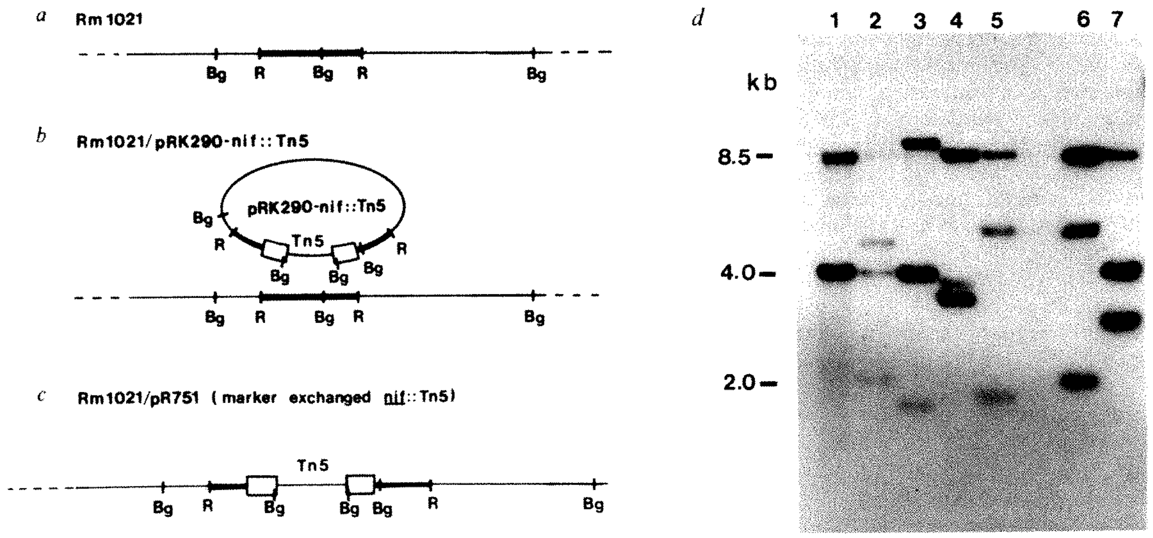

Fig. 3 Change in the *Rhizobium meliloti nif* region restriction map due to homologous recombination of *nif* region :: Tn*5* from pRK290 to the *R. meliloti* genome. A restriction map of the *nif* region in the *R. meliloti* genome was constructed as follows. Total DNA was isolated from *R. meliloti* strain Rm1021, using the Marmur technique[19]; approximately 1 μg of DNA was digested with restriction endonuclease *Bgl*II or *Eco*RI (5 U Bethesda Research Laboratories) or both, and restriction fragments were separated on 0.7% agarose gels and transferred to nitrocellulose by the method of Southern[7] as described elsewhere[2]. Plasmid pRmR2 was isolated by the cleared lysate technique[15] and labelled by nick translation[20,21] with [α-^{32}P]TTP (350 Ci mmol^{-1}, Amersham) and DNA polymerase I (Boehringer Mannheim) to a specific activity of 5×10^7 c.p.m. per μg of DNA, and 10^6 c.p.m. of labelled DNA probe was hybridized to each 10 × 15-cm nitrocellulose filter and exposed to Kodak XR-5 film as described elsewhere[2]. *a*, Restriction map of the normal *nif* region of *R. meliloti*. Hybridization of pRmR2 probe to *Bgl*II-digested Rm1021 DNA as described above should yield hybridization bands at 8.5 and 4.0 kilobases which overlap the 3.9-kilobase *Eco*RI fragment (shown in heavy lines) cloned in pRmR2. (The cloning vector pACYC184 does not hybridize to *R. meliloti* DNA; unpublished results.) *b*, Restriction map of the two regions of homology to pRmR2 in Rm1021 strains containing plasmid pRK290-*nif* region :: Tn*5*. Tn*5* insertion into any *Bgl*II restriction fragment adds two *Bgl*II sites each located 1.5 kilobases from the Tn*5* insertion site. Hybridization of pRmR2 probe to *Bgl*II-digested DNA from a Rm1021/pRK290-*nif* region :: Tn*5* strain as described above should yield the normal genomic 8.5- and 4.0-kilobases hybridization bands plus three additional hybridization bands due to the four *Bgl*II sites in each pRK290-*nif* region :: Tn*5* plasmid. *c*, Restriction map of the *nif* region of *R. meliloti* following homologous recombination of Tn*5* into the parent 3.9-kilobase *Eco*RI restriction fragment. Hybridization of ^{32}P-labelled pRmR2 DNA to *Bgl*II-digested DNA from a strain containing a genomic Tn*5* insertion into the parental *Eco*RI fragment cloned in pRmR2 should yield three bands, one of which should be either 4.0 or 8.5 kilobases (same as wild type) and two which should vary in size. The sum of the lengths of these latter two bands should be either 8.5 kilobases or 4.0 plus 3.0 kilobases (2 × 1.5 kilobases of Tn*5* DNA). Because each Tn*5* insertion which was used in the marker-exchange procedure was previously mapped on the parent pRmR2 :: Tn*5* plasmid, a unique *Bgl*II restriction hybridization map for the *nif* region could be predicted for each genomic Tn*5* insertion. For example, Tn*5* insertion 12 is located to the 'left' of the *Bgl*II site on pRmR2 as drawn here. As predicted, hybridization of ^{32}P-labelled pRmR2 DNA to *Bgl*II-digested DNA from a strain containing Tn*5* insertion 12 recombined into the *R. meliloti* genome yielded hybridization bands of 8.5, 3.8 and 3.4 kilobases (*d*, lane 4). Each of the other insertion mutations also gave the predicted hybridization patterns (*d*). *d*, Autoradiogram of ^{32}P-labelled pRmR2 hybridized to DNA from various *R. meliloti* strains (1 μg), digested with *Bgl*II (5 U, in 1X UREB), separated by 1.0% agarose-gel electrophoresis and transferred to nitrocellulose as described above from the following strains: lane 1: Rm1021/pR751 (hybridization bands at 8.5 and 4.0 kilobases); lane 2: Rm1021/pRK290-*nif* region :: Tn*5* no. 10 (hybridization bands at 20, 8.5, 4.8, 4.0 and 2.0 kilobases); lane 3: Rm1021 *nif* region :: Tn*5* no. 22/pR751 (hybridization bands at 9.8, 4.0 and 1.7 kilobases); lane 4: Rm1021 *nif* region :: Tn*5* no. 12/pR751 (hybridization bands at 8.5, 3.7 and 3.3 kilobases); lane 5: Rm1021 *nif* region :: Tn*5* no. 7/pR751 (hybridization bands at 8.5, 5.2 and 1.8 kilobases); lane 6: Rm1021 *nif* region :: Tn*5* no. 10/pR751 (hybridization bands at 8.5, 5.1 and 1.9 kilobases); lane 7: Rm1021 *nif* region :: Tn*5* no. 20/pR751 (hybridization bands at 8.5, 4.0 and 2.9 kilobases). *Bgl*II-digested DNA from strains M1021/pRK290, M1021/pR751 and M1021 all hybridized equivalently to pRmR2 probe (data not shown). The lower portion of the autoradiograph was photographically enhanced to show the faint smaller hybridization bands. Bg, *Bgl*II restriction site; R, *Eco*RI restriction site; kb, kilobases.

nitrogen fixation or due to homology with genes evolutionarily (or fortuitously) related to *K. pneumoniae nif* genes. Based on the interspecies homology with *K. pneumoniae nifD* and *nifH* and on the mutational analysis described here, we conclude that *R. meliloti* contains genes equivalent to *K. pneumoniae nifD* and *nifH*, although we cannot yet assign these homologous *R. meliloti nif* genes to separate complementation groups. Because we expect other nitrogen-fixing species to have similar genes, we propose the following nomenclature for nitrogenase genes from various organisms. Using the letters already assigned to *nif* genes in *K. pneumoniae*, we suggest adding the first letters of the genus and species names. Thus *K. pneumoniae nifH* would be written Kp *nifH* and the corresponding gene in *R. meliloti* would be written Rm *nifH*. This nomenclature is analogous to that already in use for distinguishing nitrogenase proteins isolated from different species[12].

Because the techniques described use a wide host-range conjugative cloning vector and do not necessarily require previous identification of genetic function of the cloned DNA, they should be applicable to fine-structure genetic analysis of a wide variety of Gram-negative prokaryotes. These techniques should also be useful in the initiation of genetic studies of DNA fragments cloned from Gram-negative prokaryotes by non-genetic criteria, for example, homology to inducible RNA or homology to specific DNA sequences. Finally, DNA fragments identified and cloned on the basis of transposon insertional inactivation can be further mutagenized using these techniques.

We thank G. Ditta for providing plasmids pRK290 and pRK2013 before publication, G. Jacoby for providing plasmid pR751, F. Lang for advice on decreasing background in Tp selections, and R. Hyde for preparation of this manuscript. This work was supported by USDA/SEA/CRGO grant 7900481 and NSF grant PCM7806834 awarded to F. M. A.

Escherichia coli ribosomal protein S8 feedback regulates part of *spc* operon

Dennis Dean, John L. Yates & Masayasu Nomura*

Institute for Enzyme Research, Departments of Genetics and Biochemistry, University of Wisconsin-Madison, Madison, Wisconsin 53706

In *Escherichia coli* the genes coding for the 52 ribosomal proteins (r-proteins) are organized into a number of transcription units located at various regions on the bacterial genome. The expression of r-protein genes is balanced so that individual r-protein synthesis rates change coordinately in response to changing environmental conditions, and significant amounts of free r-proteins do not exist in the cellular pool. We have suggested a model for the balanced regulation of r-protein gene expression, namely that r-protein synthesis and ribosome assembly are coupled so that r-proteins not incorporated into ribosomes prevent the further translation of r-protein mRNA by a feedback regulatory mechanism[1]. The model was tested *in vitro* by examining the effect of purified r-proteins on DNA directed r-protein synthesis[2,3], and *in vivo* by examining the effect of overproduction of certain r-proteins on the synthesis rates of other r-proteins[4,5]. *In vitro* experiments have revealed that some r-proteins (L1, L4, L10, S4 and S8) can selectively inhibit the synthesis of r-proteins whose genes are in the same operon as their own, and that this specific feedback regulation occurs at the level of translation rather than at the level of transcription of mRNA[2,3,6,7]. Regulatory roles for L1, S4 and L4 have also been established by *in vivo* experiments[4,5]. We have studied further the feedback regulatory properties of S8 *in vivo* and *in vitro*, and report here that the protein regulates a part of the *spc* operon.

Figure 1 shows the *in vitro* effects of purified S8 addition on synthesis of r-proteins encoded in the *spc* operon. Protein synthesis was directed by a DNA fragment containing most genes of the *spc* operon (L14, L24, L5, S14, S8, L6 and L18) or by λ*spc*1 DNA. λ*spc*1 transducing phage carries the genes in the *spc* and α operons (see Fig. 2). Radioactive proteins were precipitated from reaction mixtures with specific antisera and analysed by SDS-gel electrophoresis followed by autoradiography. Addition of S8 (2.9 μM) results in specific inhibition of L5 and S14 synthesis (Fig. 1*a*, 5–8), but only slight or no inhibition of other proteins from the *spc* operon. Densitometric tracings of films from several such experiments showed that S8 inhibits the synthesis of L5 and S14 by 75–90% but inhibits the synthesis of L14, L24, S8, L6, L18 and S5 by less than 30%. The effect of S8 addition on the synthesis of L30 and L15 was not examined.

We have previously reported that L24 synthesis was also inhibited by S8 (ref. 2). However, we have now established that S8 has no significant inhibitory effect on L24 synthesis in the DNA-directed system using immunoprecipitation methods and consider that the inhibition originally observed was inhibition of synthesis of S14, which co-migrates with L24 in the SDS gels used. As we have previously shown[2], addition of other r-proteins such as L1 or S4 has no inhibitory effects on synthesis of r-proteins contained within the *spc* operon. It is significant that expression from the promoter proximal genes (L14 and L24) is not inhibited by S8. These results support our previous conclusion that regulatory r-proteins act at the level of translation and not at the level of transcription originating from the promoter.

To test whether the regulatory effects of S8 observed *in vitro* also reflect *in vivo* regulatory properties of S8, we examined the effect of S8 over-production on synthesis rates of other r-proteins *in vivo*. A DNA fragment containing three genes from the *spc* operon (S8, L6 and L18) was cloned into a plasmid vector containing the *lac* operator and promoter so that the synthesis of S8, L6 and L18 were then controlled by the *lac* regulatory elements (pNO1017; see Fig. 2). Another plasmid (pNO1018) that contains only the S8 gene fused to the *lac* operator–promoter was derived from pNO1017 (see Fig. 2).

Effects of over-production of S8, L6 and L18, or S8 alone on the synthesis rates of other individual r-proteins were examined by stimulating transcription from *lacZp* in strains which harbour the recombinant plasmids carrying r-protein genes fused to *lacZp*. Exponentially growing cells were treated with an inducer of the *lac* operon, 1 mM isopropyl thiogalactoside (IPTG), to stimulate synthesis of the various cloned r-protein genes. Synthesis rates of individual r-proteins were then analysed by labelling cells with [^{3}H]lysine for 1 min followed by a 1-min chase with nonradioactive lysine. Relative synthesis rates were obtained by comparing the synthesis rates of individual r-proteins determined after IPTG induction with the synthesis rates of individual r-proteins before IPTG addition.

Table 1 Relative synthesis rates of ribosomal proteins after induction by IPTG

	Strains	
r-protein	NO2320 (carries pNO1017)	NO2321 (carries pNO1018)
S4	1.21	1.14

L30	0.26*	0.30*

For labelling experiments cells were grown in a synthetic minimal medium[12] supplemented with 0.4% glycerol, all amino acids (except methionine and lysine) at 50 μg ml^{-1}, and thiamine at 2 μg ml^{-1}. Cells were grown at 37 °C to 2×10^8 ml^{-1}. Samples of cells were pulse-labelled with ^{3}H-lysine (646 pmol ml^{-1}; 80.5 Ci mmol^{-1}) for 1 min followed by a 1 min 'chase' with excess nonradioactive lysine. Cells were labelled before (control cells), and 10 min after addition of IPTG to 1 mM (experimental cells). Cells were rapidly chilled and then mixed with a suitable amount of ^{14}C-lysine-labelled carrier cells. ^{14}C-labelled cells were prepared by growing cells in the presence of ^{14}C-lysine for several generations. r-Proteins were extracted and separated by two-dimensional gel electrophoresis[13]. After the gels had been stained, the spots corresponding to the indicated r-proteins were extracted, the gels were oxidized with a Packard sample oxidizer, and ^{3}H and ^{14}C measured separately. The ^{3}H/^{14}C ratio in each protein in the experimental cells was then compared with that in control cells using the expression:

$$\frac{[^3\mathrm{H}/^{14}\mathrm{C}]\text{ in protein } i \text{ in experimental cells}}{[^3\mathrm{H}/^{14}\mathrm{C}]\text{ in protein } i \text{ in control cells}}$$

The ratios obtained were then normalized to the ratio obtained for L1 (indicated by a box). Values given in the table are the average of two independent experiments. *Values significantly different from 1.0.

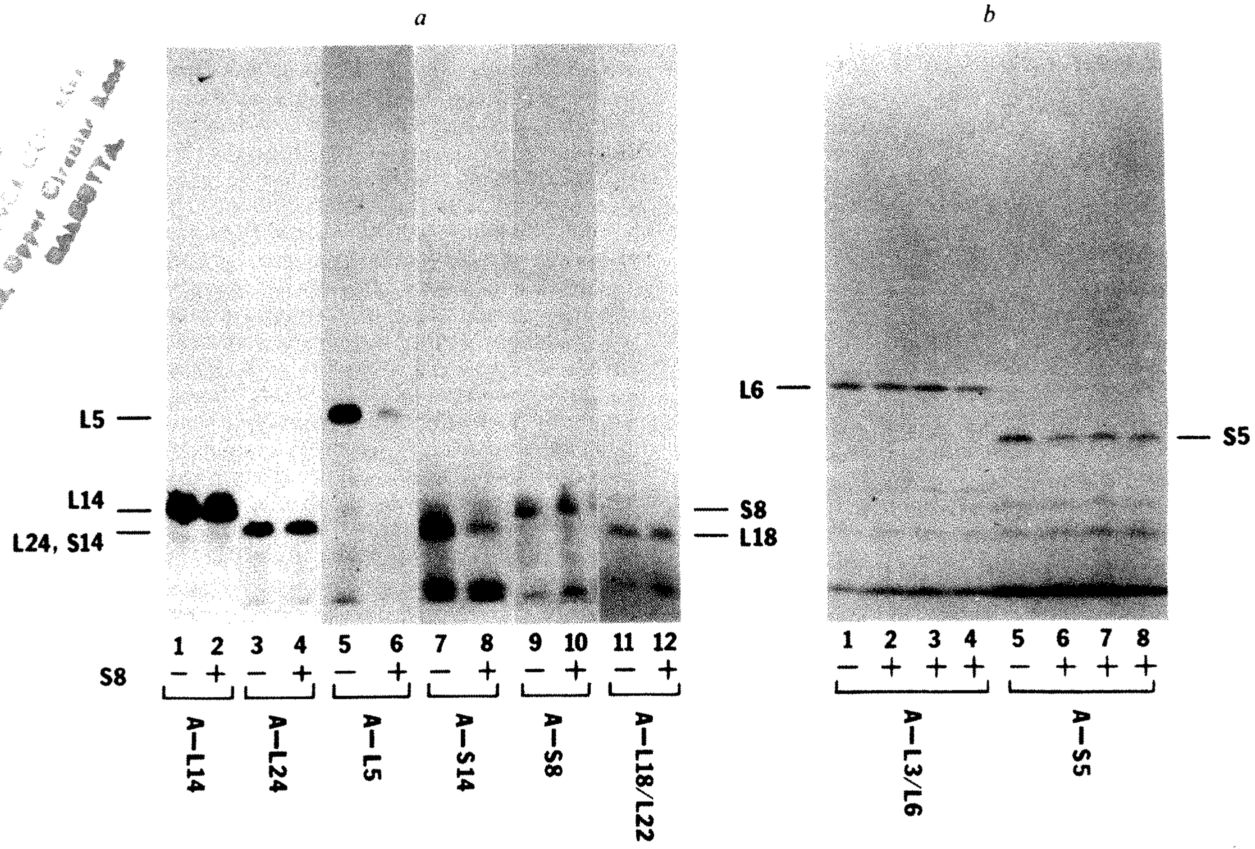

Fig. 1 Effects of S8 on protein synthesis from the *spc* operon *in vitro*. *a*, *In vitro* protein synthesis was carried out as described elsewhere[2] using the 10% *Eco*RI DNA fragment of λ*spc*2 transducing phage as template. This fragment carries genes between an *Eco*RI site in the S3 gene from the S10 operon and the *Eco*RI site in the S5 gene from the *spc* operon (see Fig. 2). Protein was labelled using ^{35}S-methionine (160 mCi per μmol, 15 μM). Two reaction mixtures (80 μl) received either no S8 (control sample) or 3 μg S8. The reactions were terminated after 60 min at 37 °C, then 3 μg S8 was added to the control sample. 10-μl aliquots (5 μl for 1 and 2) were taken from reaction mixtures which had been incubated in the absence or presence of S8, as indicated, and radioactive proteins synthesized were precipitated as described previously[2] by treating with antisera to specific r-proteins. The antiserum used for a particular experiment is shown at the bottom of the figure (A followed by the r-proteins used to raise that antiserum). A-L18/L22 is an antiserum raised against a mixture of r-proteins L18 and L22. Polyacrylamide gel electrophoresis was carried out according to the procedure of Laemmli[8] in 13.5% acrylamide-SDS gels. Gels were impregnated with diphenyloxazole (PPO)[9] and exposed to pre-flashed X-ray film[10]. In the autoradiograms shown the direction of migration is from the top to the bottom. The origin of radioactive protein bands migrating to the bottom of the gel is not known. No consistent pattern in the amounts of this material was observed in relation to the presence or absence of S8 in the reaction mixture. *b*, Proteins were synthesized using λ*spc*1 DNA as template and labelled with ^{3}H-lysine (80 mCi per μmol, 15 μM). Analysis was done as described above using 80 μl reaction mixtures with no S8 added during incubation (lanes 1, 5), 1.8 μg S8 added (lanes 2, 6), 2.7 μg S8 (lanes 3, 7) and 3.6 μg S8 (lanes 4, 8). To analyse L6, an antiserum against a mixture of L3 and L6 (A-L3/L6) was used.

Fig. 2 Construction of hybrid plasmids pNO1017 and pNO1018. The plasmid vector was pBGP120 (ref. 11), which is a derivative of RSF2124 and contains a region of the λ*plac* genome including the *lac* promoter and the main part of the *lacZ* gene. The approximate position of the *lacZp* ('Plac' in the figure) and the direction of transcription from *lacZp* (the thick horizontal arrow) are indicated. The vector region is hatched and the bacterial region is open. Plasmid pNO1017 was constructed by ligating *Eco*RI-digested pBGP120 and the *Eco*RI-*Sma*I fragment indicated in the figure purified from λ*spc*-DNA[2]: the fusion of the *Sma*I-*Eco*RI ends resulted in loss of the *Eco*RI and *Sma*I sites (indicated by a cross through an *Eco*RI site in pNO1017). pNO1018 was constructed by digesting pNO1017 with *Kpn*I and ligation to delete the region indicated by the cross-hatched region. The positions of the *Kpn*I sites are approximate.

Over-production of r-proteins S8, L6 and L18 resulted in an inhibition of synthesis of certain other r-proteins (L5, S14, S5, L30 and L15) contained within the *spc* operon (Table 1). Synthesis rates for the promoter proximal r-proteins (L14 and L24), however, were not affected. Similarly over-production of S8 alone inhibited the synthesis of L5, S14, L6, L18, S5, L30 and L15, but not the synthesis of L14 or L24. No significant changes in the synthesis rates of other r-proteins not contained in the *spc* operon were observed as a consequence of S8, L6 or L18 over-production. The *in vivo* results, therefore, confirm our *in vitro* results—S8 is capable of inhibiting synthesis of certain r-proteins encoded in the *spc* operon. Similar to previous results obtained with the S10 and α operons, synthesis of proteins from promoter distal genes were inhibited *in vivo* but not *in vitro*. As discussed previously[3,5], we believe that the observed regulatory effects on promoter distal genes observed *in vivo* are the consequence of a polar effect caused by direct inhibition of translation of upstream mRNA. The *in vivo* polar effect could be due to premature transcription termination, increased degradation of distal mRNA, or translation of distal cistrons requiring ribosomes that initiated in an earlier cistron. The important observation in the present study is that, unlike the previously studied r-protein operons, inhibition occurs at the third gene in the operon rather than the first. This result clearly indicates that inhibition of synthesis of specific r-proteins contained in the *spc* operon by S8 cannot occur at the level of initiation of transcription from the *spc* promoter. This conclusion is consistent with our previous *in vitro* observations that autogenous feedback regulation by repressor r-proteins occurs at the translation step rather than the transcription step[2,3]. It is particularly intriguing that synthesis of r-proteins that are coordinately regulated and whose genes are contained within a single transcription unit are apparently regulated independently at the translational level. The method of regulation of synthesis of r-proteins L14 and L24 is unknown.

Fibrinogen is a soluble plasma protein which, after cleavage by the specific proteolytic enzyme thrombin, polymerizes to form the filamentous fibrin network during blood clotting (see refs 1 and 2 for reviews). Fibrinogen has a molecular weight of 340,000 and is composed of two identical halves, each containing three peptide chains designated Aα, Bβ and γ. Fibrin monomers are produced by thrombin which releases the small negatively charged fibrinopeptides A and B. The overall shape of the fibrinogen molecule has not been unequivocally established[1,2]. The trinodular, elongated ($\sim$450 Å long) structure proposed by Hall and Slayter[3] is the most widely accepted model and it has obtained additional support from recent work[4–6]. Fibrin monomers are also about 450 Å long[7] and in fibres they probably have a half-staggered arrangement along the axis[7,8]. The fibres are an assembly of protofibrils whose structure and packing are not reliably known. We report here that highly oriented fibrin gels are formed when polymerization takes place slowly in a strong magnetic field. It is shown that the protofibrils pack into a three-dimensional crystalline lattice. We introduce magnetically induced birefringence as a potential tool for studying polymerization and briefly speculate on the applications of strong magnetic fields.

The sigmoidal variation of the birefringence (Fig. 1), observed when a fibrin gel is formed in a strong magnetic field, can bequalitatively explained as follows. Near the beginning there is little induced birefringence because the fibrinogen molecules and fibrin monomers present have only a small diamagnetic anisotropy[9]. The magnetic orienting energy is much less than the thermal energy kT and consequently they orient poorly. The upsurge in the birefringence commences with polymerization. Now many monomers come together in an ordered way, the diamagnetic anisotropy of the aggregates is many times that of a monomer and the magnetic orienting energy is sufficiently large to allow a high degree of orientation. The value of $\Delta n/C$, where n is the refractive index and C the concentration, at the end of the reaction increases as the rate of polymerization is reduced until a limiting value is reachd which corresponds to the maximum alignment of the fibres in the field used. Thus, when polymerization proceeds too rapidly, the interlinked network develops before the nascent fibres have had time to orient themselves fully.

Scanning micrographs of unoriented and magnetically oriented gels are compared in Fig. 2. The samples suffered distortion while being dried in preparation for electron microscopy. Nevertheless, the orientation of the gel can be easily seen to parallel the field direction.

Figure 3 shows the low-angle neutron diffraction pattern obtained from magnetically oriented fibrin gels. In addition to the familiar[10–12] 223 Å (±5 Å)-spaced meridional reflections, there are equatorial and other Bragg reflections which indicate that the fibrin monomers are arranged in a regular three-dimensional lattice. The sharpness of the meridional reflections, which is due to a fibre axial periodicity, shows that there is a high degree of crystallinity along the fibre axis[10]. These reflections exhibit little arcing and when the gel is tilted slightly from the vertical, the intensity of the higher orders is markedly reduced. Hence, the fibres are highly oriented along the magnetic-field direction. Rotating the gel about the vertical axis does not alter the non-meridional reflections, showing that the samples are rotationally symmetrical and therefore there can be little long-range rotational order between fibres.

The equatorial diffraction arises from the regular, lateral arrangement of the fibrin molecules. In the pattern there is a discrete peak at 184 ± 5 Å and an extended band with a maximum at about $184/5^{1/2}$ Å (Figs 3, 4). The diffraction is not detailed enough to deduce directly the parameters of the unit cell perpendicular to the fibre axis. However, from simple

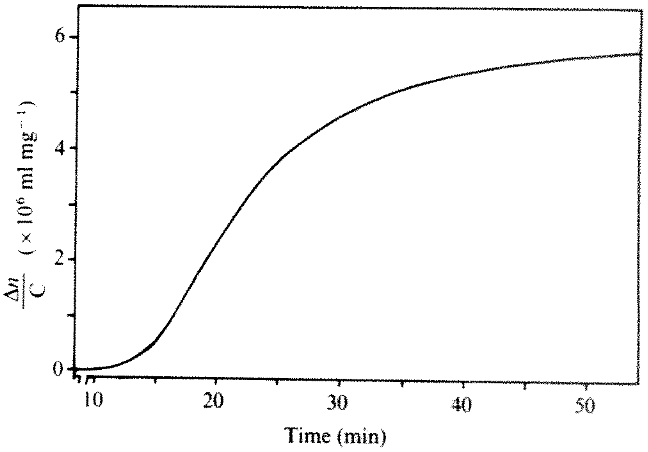

Fig. 1 The change with time of the birefringence per unit concentration of protein $\Delta n/C$ (C in mg ml^{-1}) when polymerization is performed in a constant magnetic field of 11 T (1 T = 10^4 G). The birefringence was measured at 6,328 Å by means of a mechanically driven Babinet Soleil compensator. A small volume of thrombin (0.10 NIH units) was used to induce polymerization at 22 °C of a 1-ml solution of fibrinogen (4.8 mg ml^{-1} in 0.05 M Tris-HCl buffer, pH 7.5, containing 0.10 M NaCl and 0.5 mM EDTA).

028-0836/81/020091—03$01.00

packing considerations one expects the basal unit cell, perpendicular to the fibre axis, to be nearly square or hexagonal. The position of the maximum at $184/5^{1/2}$ Å (Fig. 4) favours a unit cell with a square base of side about 184 Å. As there are few unit cells (23 in a fibre of 1,000 Å diameter) in a fibre cross-section, the relative breadth of the equatorial intensities does not necessarily mean that crystallinity in the lateral plane is less than along the axis. Additionally, fibres of unlike diameters could have slightly different basal unit-cell dimensions which would also give rise to broadening.

Within each quadrant (Fig. 3), between the equator and meridian, there are two maxima. The stronger of these is situated at the intersection of the first layer and row lines, while the second, at a higher angle, has a meridional position between the second and third layer lines, thus the true axial repeat is $n \times 223$ Å where n is an integer. Its smallest possible value is 2, in which case the second off-meridional reflection, if well resolved (its position could be influenced by intensities on adjacent layer lines), should lie halfway between layer lines 2 and 3. Figure 3 shows that this is approximately so but the maximum is broad and weak and consequently its position cannot be determined unequivocally. The value of $n = 2$ is supported by micrographs[7] and agrees with the prevalent view that the approximately 450 Å long molecules form a half-staggered arrangement along the fibre axis[8,10]. Therefore this analysis, which is partly qualified as described above, shows that the diffraction pattern can be indexed on a tetragonal unit cell (with $a = 2 \times 185$ Å and $c = 446$ Å) that contains eight molecules (using 6 $Å^3$ per dalton for the specific volume[13]) and has a space group which restricts reflections to l even when $h = k = 0$. There are no evident restrictions on the general (h, k, l) reflections. None of the four space groups proposed in a recent model building study[13] is supported by the diffraction pattern. However, one of these (space group I4) does have a tetragonal lattice with the unit-cell dimensions we find. Only the space groups $P4_2$ and $P4_222$ satisfy the above conditions.

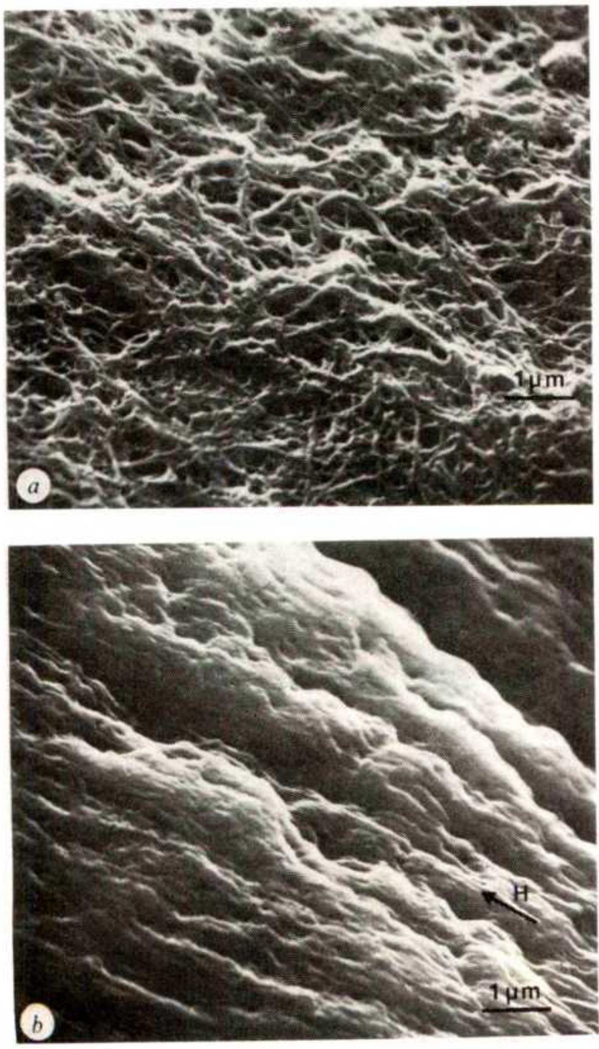

Fig. 2 Scanning electron micrographs of fibrin prepared as described in Fig. 1 legend. *a*, Without field; *b*, with field H in direction of arrow. The diameter of the fibres in *a* is ~1,000 Å. Drying has induced distortion and coalescence of the oriented *b* sample.

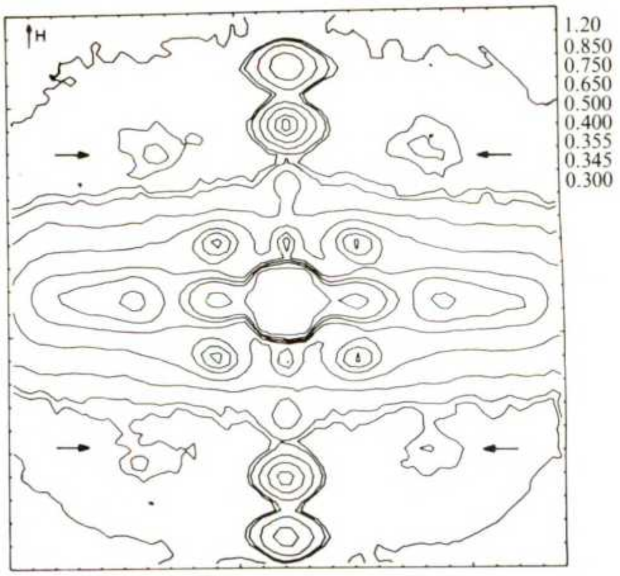

Fig. 3 Neutron diffraction pattern from fibrin (14 mg ml^{-1}) oriented in a magnetic field H of up to 18 T (arrow indicates field direction). The contour lines connect points of equal diffraction intensity. The conditions of the reaction are analogous to those described in Fig. 1 legend. The orientation was carried out in H_2O buffer which was replaced with D_2O buffer by diffusion, thereby greatly reducing the background level. The meridional reflections have a 223 ± 5 Å periodicity and the sharp equatorial peaks on either side of the centre are at 184 ± 5 Å. The arrows are drawn midway between the second and third layer lines. The central, rectangular region is due to the beam catcher. A sample in H_2O buffer gave a similar but less detailed diffraction pattern. Much slower polymerization in a field of 7 T also produced substantial orientation. The data were obtained with the two-dimensional (64 × 64-cm) detector of the low-angle scattering instrument D11[26] at the Institut Laue-Langevin, Grenoble. The specimen-to-detector distance was 2.55 m, the wavelength 5.8 Å and the spread $\Delta\lambda/\lambda$ 8% (full width, half maximum). So far, X-ray patterns from gels formed as above have only shown the meridional reflections.

The magnetic orientation demonstrated above is due to the diamagnetic anisotropy of the particles[9]. This depends strongly on the orientational order of the constituent diamagnetically anisotropic groups, which are chiefly α-helical peptide bonds and aromatic amino acid residues. Fibrin fibres orient parallel to the magnetic field and they contain a substantial proportion of α-helix[14] (~30% (refs 15, 16) by analogy with fibrinogen), which is also known to orient in the field direction[9,17]. A preliminary conclusion, which will be justified more completely elsewhere, is therefore that the α-helical regions in fibrin are aligned relatively parallel to the fibre long axis.

Clearly magnetic field orientation is a valuable technique. This is demonstrated by the success in orienting cell membranes[18,20] and two cylindrical viruses[21,22]. The experiments reported here confirm that magnetic orientation of biological samples is increasingly viable[21]. The technique could be extended to other biopolymers and to living cells. Oriented polymers have previously been produced by the application of magnetic fields[23–25], but in these the monomers formed a liquid-crystalline phase which oriented before polymerization advanced. In the formation of fibrin, the fibrinogen molecules (the precursors of monomers) interact very little, do not show

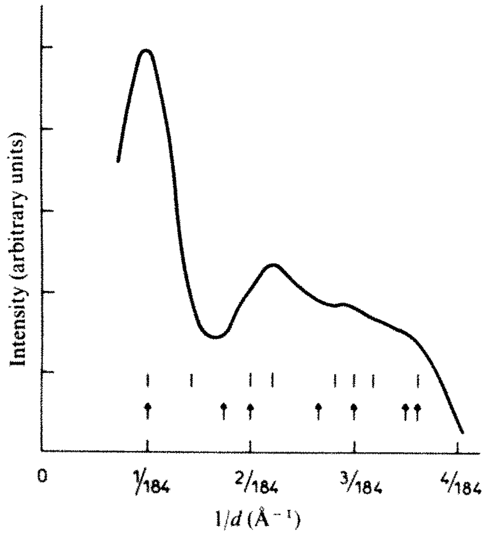

Fig. 4 The distribution of neutron-scattered intensity along the equator of Fig. 3; $1/d$ is the reciprocal of the Bragg spacing. The possible equatorial reflections from unit cells with a square (side 184 Å) and hexagonal (side $184 \times 2/3^{1/2}$ Å) base are shown by vertical lines and arrows respectively.

liquid–crystalline properties and orient poorly even in the strongest fields. These are important differences—they demonstrate that a liquid–crystalline phase or preformed orientation is not a prerequisite for the production of oriented polymers.

We thank G. Maret and C. Wilkinson for help and C. Berthet-Colominas for help with X-ray diffraction experiments. J.T. thanks the Deutsche Forschungsgemeinschaft for support. The work was partly supported by INSERM, FRA21. We are indebted to the Service National des Champs Intenses and to the Institut Laue-Langevin, both in Grenoble.

Orientation of oxygen in oxyhaemoproteins and its implications for haem catabolism

Stanley B. Brown*, Anthony A. Chabot†, Elizabeth A. Enderby* & Anthony C. T. North†

* Department of Biochemistry and † Astbury Department of Biophysics, University of Leeds, Leeds LS2 9JT, UK

Haem is degraded to bile pigments in the catabolism of haemoproteins in mammals[1] and in the formation of photosynthetic pigments in algae[2]. The first stage of this reaction involves oxygen attack at one of the four methene-bridge carbon atoms, which is ultimately eliminated as CO(ref. 1). The four bridges are not sterically equivalent (Fig. 1) and the bilirubin in mammalian bile and algal bile pigments consists almost exclusively of the α-isomers. Little is known about the structures of the ring-cleaving enzymes responsible, although microsomal haem oxygenase, which catalyses the breakdown of haem to biliverdin in mammals[1], has very similar spectroscopic properties to myoglobin[3]. The degradation process has been simulated *in vitro* by a 'coupled oxidation' method in which the proportions of the four possible isomeric products depend on the nature of the globin moiety to which the haem is bound[4]. We report here the use of an interactive computer display system[5] to explore the relative accessibilities of the four methene bridges to a haem-bound oxygen molecule in myoglobin and in the α and β chains of haemoglobin. Our calculated interaction energies agree well with the proportions of the four isomers that are observed experimentally.

The coupled oxidation method, in which the haem compound is reacted with a reducing agent (for example, ascorbate or hydrazine) and molecular oxygen[4], seems to be a good model for biological haem cleavage as the products (biliverdin, carbon monoxide and free iron) are the same and a reducing agent (NADPH) and molecular oxygen are required *in vivo* also. Labelling experiments using ^{18}O have confirmed the similarity of the mechanisms of oxygen incorporation into bile pigment in living rats[6], algae[7], in an *in vitro* haem oxygenase system[8] and in various coupled oxidation systems[8,9].

Whereas coupled oxidation of free haem in aqueous pyridine produces an almost random mixture of the four isomers[4], coupled oxidation of haemoproteins results in selective reactions; myoglobin, like haem oxygenase, yields α isomer almost exclusively, whereas human haemoglobin yields 65% α isomer and 35% β isomer with little or no γ or δ isomer[4]. After examination of molecular models of haemoglobin[10] and myoglobin[11], Brown[12] suggested an intramolecular mechanism for the activation of molecular oxygen for haem degradation and for the determination of bridge selectivity, an essential feature of which is attack of a methene bridge carbon atom by an iron-bound oxygen molecule, considered to be liganded as in oxyhaemoglobin or oxymyoglobin. In protein-free haem, each methene bridge would be equally accessible—this would account for the random formation of biliverdin isomers. In haemoproteins, access might be restricted by the limited space in the haem pocket, and the molecular models suggested that variations in accessibility were broadly consistent with the ratios of products observed.

We attempted to evaluate this intramolecular degradation hypothesis in a more quantitative way by calculating the energies of interaction between a haem-bound oxygen molecule and the surrounding protein residues as the oxygen molecule is rotated about the Fe-O axis (Fig. 1). We used an interactive computer display system[5] in which the present molecular conformation was depicted on a cathode ray tube as it was adjusted, and which could also evaluate functions that depend on conformation, such as the potential energy due to dispersion forces between pairs of atoms: this we modelled by the expression $E = -a_{ij}r_{ij}^{-6} + b_{ij}r_{ij}^{-12}$, where r_{ij} is the distance between atoms i and j and a_{ij}, b_{ij} are constants characteristic of the types of atoms concerned[13]. We evaluated E at 5° steps of the torsion angle τ

028-0836/81/020093—03$01.00

which defines rotation of O_AO_B about the FeO_A bond, including contributions for all significant pairwise interactions that involve O_B, apart from those with Fe and with O_A, which are independent of τ. Energies for the two kinds of haemoglobin chain were evaluated in isolation because interactions between O_B and atoms in neighbouring subunits are insignificant. Hydrogen atoms were not included in our calculations as experience suggests that they have relatively little effect due to the 'softness' of their potential function and the ability of methyl groups to rotate so as to minimize steric hindrance.

For haemoglobin, the X-ray coordinates of the oxy derivative are not known; therefore we used those published for horse aquo-methaemoglobin, apart from those of the Fe atom. Horse and human haemoglobins have identical amino acid sequences in the haem pocket region except for the substitution of β-E14 Ser (horse) by Ala (human); we allowed for this substitution by omitting the hydroxyl group, although this residue is too remote for it to contribute significantly to the interaction with O_B. Similarly, for myoglobin we used the published coordinates of sperm whale metmyoglobin apart from those of the Fe atom. These globin coordinates were obtained from the Protein Data Bank[14], files 2MHB and 1MBN respectively. The coordinates of each of these structures had been refined with constraints that forced the atoms of the haem groups (apart from the pendant side chains) to be coplanar and 4-fold symmetrical. We placed the Fe atoms on the axis of 4-fold symmetry but displaced from the plane of the haem group towards the proximal histidine residue by the distances given by Phillips[15]: 0.033 nm for myoglobin, 0.007 nm for the haemoglobin α chain and 0.021 nm for the β chain. For each chain, we used Phillips' values of 0.19 nm for FeO_A, 0.14 nm for O_AO_B and 121° for the angle FeO_AO_B.

The energy values thus calculated (Fig. 2 *a–c*) indicate the relative probability of finding the oxygen molecule in any particular orientation τ about the haem normal; the higher the energy, the less likely is the oxygen to occupy that position. The most probable position would correspond to the energy minimum, but because we are interested in the likelihood of the oxygen being aligned so as to attack one of the four methene-bridge carbon atoms, our primary concern is with the relative energies in the neighbourhoods of the four corresponding values of τ.

For myoglobin (Fig. 2*a*) the energy shows a pronounced maximum at about 325° and at the γ bridge the energy is 105 kcal mol^{-1} above the minimum. This high energy is due to the presence of the distal His residue (E7) which renders the γ bridge completely inaccessible to the bound oxygen molecule. Of the other three bridge positions, α has by far the lowest energy (Table 1) as it is only 10° away from the minimum in a relatively flat part of the curve. The energies corresponding to the δ and β positions are much higher because of interactions with E11 Val and CD1 Phe respectively, suggesting that the β and δ orientations would be adopted only by a very few molecules. Thus, degradation of the α methene bridge would be very strongly preferred over degradation of the other bridges, which agrees with experiments.

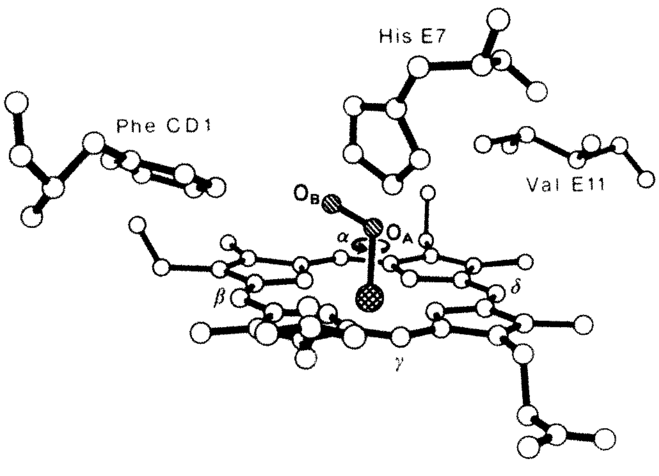

Fig. 1 Oxygen binding site in globins. The side chains shown are those primarily involved in interactions with the oxygen molecule and occur in generally similar, though not identical, positions in the three globin chains studied. The arrow indicates the torsion angle τ through which the oxygen molecule is rotated about the Fe–O_A bond. The four methene bridges are labelled α, β, γ, δ.

Table 1 Contributions made by subunits of haemoproteins to isomers formed by coupled oxidation

Haemoprotein	% Isomer formed by coupled oxidation				Energy above lowest minimum (kcal mol^{-1})			
	α	β	γ	δ	α	β	γ	δ
Sperm whale myoglobin	100	—	—	—	0.25	14.1	105	9.6
Human haemoglobin (α subunits)	55	45	—	—	0	0.6	129	10.8
Human haemoglobin (β subunits)	75	25	—	—	0	2.0	1,240	7.7

Results for α and β subunits are from ref. 160

The profile for the haemoglobin α chain (Fig. 2*b*) is grossly similar to that for myoglobin with a very high barrier due to the distal His and a relatively high energy corresponding to the δ bridge. The low energy region from $\tau = \sim 160$ to $\tau = 280°$ is much broader than in myoglobin and encompasses both the α and β positions. The actual minimum is exactly at the α bridge but the energy at the β position is only 0.6 kcal mol^{-1} higher. This suggests that both α and β bridges would be susceptible to attack, with the α bridge marginally favoured.

For the β subunits also, the γ and δ positions show a very high energy and the lowest minimum occurs precisely at the α bridge. The region between $\tau = 160$ and $\tau = 280°$ is different in profile from that for the α subunit, with an energy barrier between the α and β methene bridges. At the β bridge, the energy is 2 kcal mol^{-1} above that at the α bridge, so that more α isomer and less β isomer would be formed from haemoglobin β chains than from α chains. However, taken together, our calculations are clearly consistent with the experimental observation that the biliverdin produced by coupled oxidation of whole haemoglobin contains 65% α and 35% β isomer.

While these calculations were being carried out, Docherty[16] determined the separate contributions made by the α and β subunits to the isomer pattern obtained by coupled oxidation of haemoglobin. His results (Table 1), which showed that the β subunits produce some β isomer but not as much as do the α subunits, conformed well with our predictions.

Our observations strongly favour the intramolecular theory of haem degradation both in explaining the absence of γ and δ isomers and in accounting for the variation in proportion of the α and β isomers. Further support has been obtained from studies of the coupled oxidation of some abnormal haemoglobins[17]. For example, in haemoglobin Zürich, E7 His (the residue that blocks access to the γ bridge) is replaced by Arg, which is displaced from the haem pocket. We therefore predict that the γ methene bridge might be accessible to attack, which agrees with the experimental result that the γ isomer is present in the products.

Our energy profiles vary rapidly in the region of the β bridge so that relatively small changes in protein structure can greatly affect the amount of β isomer produced; this may explain the variations observed in the amount of β isomer in the degradation products of animal haemoglobins (S.B.B., unpublished) and plant leghaemoglobins[18].

There are several uncertainties in our calculations which cannot be readily resolved: (1) the coordinates used refer strictly to the aquo-met forms of the haemoproteins rather than the oxy forms; (2) the geometry of the oxygen molecule in the transition state of the reaction may differ from that assumed; (3) the

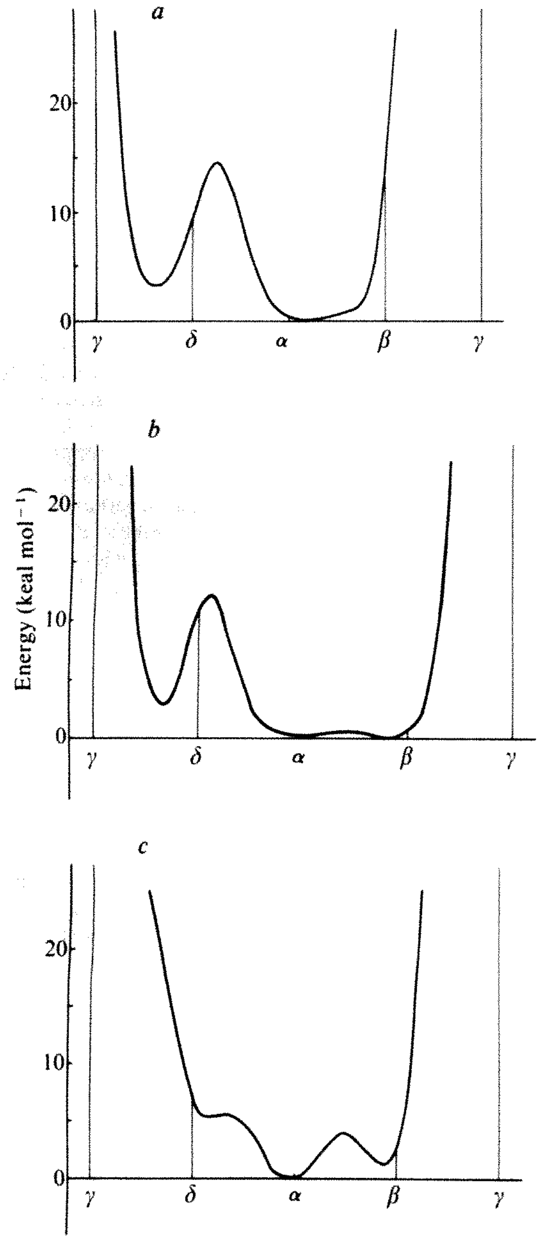

Fig. 2 Variation of interaction energy with rotational angle τ for several haemoproteins. The energy values refer to an arbitrary zero corresponding to the minimum in each case. Rotation is such that the α, β, γ and δ bridges correspond to τ values of 180, 270, 360(0°) and 90° respectively. *a*, Sperm whale myoglobin; *b*, human haemoglobin (α subunits); *c*, human haemoglobin (β subunits).

oxygen may be suitably disposed to attack a methene bridge within a range of τ values, necessitating integration of the energy functions; (4) we ignored electrostatic interactions and (5) it is now known (S.E.V. Phillips, personal communication) that the haem rings are not coplanar but rather puckered. Clearly, we would not have obtained the present level of correlation if these effects were too large, but we would be cautious about a more quantitative interpretation until data on other haemoproteins become available.

Finally, in all three haemoprotein chains studied, the minimum energy position is coincident with or close to the position of the α methene bridges. As there is no intrinsic reason that the energy minimum should correspond to any of the methene bridges, we wonder whether the situation is advantageous. It seems unlikely, although not impossible, that this feature of haemoproteins has evolved to facilitate the production of α isomers of bile pigments after degradation. Perhaps an 'open' α methene-bridge region may favour access of oxygen to the iron atom in the normal reversible interaction of haemoproteins with oxygen.

We thank the MRC for the award of a Project Grant to S.B.B. and the SRC for support to A.C.T.N. A.A.C. was supported by a Wellcome Research Studentship.

Are archaebacteria merely derived 'prokaryotes'?

Carl R. Woese & Ramesh Gupta

Department of Genetics and Development, 515 Morrill Hall,
University of Illinois, Urbana, Illinois 61801

The archaebacteria are a group of prokaryotes which seem as distinct from the true bacteria (eubacteria) as they are from eukaryotes[1–4]. The evidence on which this conclusion rests is of two types: genotypic (quantitative)—that is, comparative sequence studies, and phenotypic (qualitative)—that is, differences in various organismal characteristics. The differences between archaebacteria and true bacteria are so great, both quantitatively and qualitatively, that the two bacterial groups should be considered as representing separate primary lines of descent, each tracing directly back to the universal ancestor[1,4]. Furthermore, this ancestor itself seems not to be a prokaryote; rather it was a far simpler type of organism, one properly called a progenote[5,6]. If this is true, the discovery of archaebacteria marks a major advance in the biologist's attempts to understand the basis for the evolution of the cell.

Recently van Valen and Maiorana have challenged this interpretation[7]—they consider that the archaebacteria represent merely one branch of a general prokaryotic phylogenetic tree. Their interpretation requires the archaebacteria to have undergone more extensive evolution, both quantitatively and qualitatively, than have other prokaryotes. They also claim that archaebacteria are the forerunners of the so-called eukaryotic 'host cell', the presumed entity which housed the endosymbionts that later became eukaryotic mitochondria, chloroplasts, etc.[7]. Their interpretation is a conservative one—it seeks to retain the conventional prejudices regarding the evolution of bacteria and the origins of the eukaryotic cell (for example, prokaryotes are monophyletic; fermentative metabolism preceded autotrophic or phototrophic metabolism in prokaryotes; there are only two basic types of living system on Earth, eukaryotes and prokaryotes; the eukaryotic ancestor was a prokaryote that lost its cell wall[1,7,8–10]). A clearcut choice between the conservative and the radical interpretation of the facts cannot be made without more evidence than now exists. Our purpose in discussing the two interpretations, therefore, is

0028-0836/81/020095—02$01.00

not to eliminate one, but to stress the differences between them, thus preparing the ground for a future decision when more becomes known about the archaebacteria.

First, consider the genealogical relationship of archaebacteria to true bacteria ('prokaryotes' as the molecular biologist defines them). The issue is whether archaebacteria constitute a line of descent within the phylogenetic tree defined by the true bacteria[7], or whether the archaebacterial line branched from the common stem at a point before the ancestor of all true bacteria had evolved, and if the latter, whether the ancestor common to true bacteria and archaebacteria was itself a prokaryote or a simpler form, a progenote in our terminology[1,6]. Are prokaryotes of monophyletic or polyphyletic origin?

Those properties shared by (most) true bacteria must be largely ancestral. When defined in moderate detail many of these presumed ancestral properties are found to be absent in archaebacteria, which instead have different but equivalent properties. The conservative view is that archaebacteria have lost these ancestral 'prokaryotic' properties and have re-evolved their equivalents: for example, archaebacteria (on the basis of this conservative view) would have had to lose the typical bacterial cell wall and evolved new types of walls[3,5,11,12]; have drastically altered the characteristic sequence of 'prokaryotic' rRNA (ref. 3); changed the characteristic pattern for nucleotide modification in both rRNA and tRNA[2,4,13]; evolved ether-linked, branched chain lipids, discarding ester-linked, straight chain lipids in the process[14,15]; changed the subunit structure of RNA polymerase[16,17]; and they would have had to discard many of the antibiotic sensitivities that are typical of prokaryotes and of eukaryotic organelles, again acquiring different ones[2]. Were archaebacteria as well characterized as are the true bacteria, this list of changes in true bacterial characteristics, ostensibly wrought during archaebacterial evolution, might be enormous. If we extrapolate from the little knowledge we have of archaebacteria, it seems that true bacteria and archaebacteria differ significantly in the details of almost all molecular processes[2,4].

The conservative explanation attempts to account for the many molecular disparities between archaebacteria and true bacteria by invoking a period of 'rapid evolution' at an early stage in the line of archaebacterial descent[7]. This explanation is too plastic and ill-defined; seemingly any outcome can be rationalized. Peculiarities of archaebacterial niches alone could not seemingly account for this supposed rapid evolution. Species of eubacteria cohabit some niches with archaebacteria; for the former, there is evidence of only minor, local changes in molecular processes as a result of adaptations[18]. Examples of apparently rapid evolution among true bacteria have been encountered—the true mycoplasmas are one. (These organisms are actually highly derived offshoots of the clostridia[19].) Although they are unique, the mycoplasmas retain a great deal more genotypic resemblance to true bacteria than do the archaebacteria[19]. The eukaryotic organelles are another example[20,21]—in the case of the animal mitochondrion perhaps more drastic than might be expected from a free-living organism. However, even the highly idiosyncratic animal mitochondrion, which has the least rRNA sequence homology with eubacterial rRNAs of all organisms[5,20], shows a marked resemblance to true bacteria—for example, in the details of its respiratory chain[22], antibiotic sensitivities[23], modified nucleotides in tRNA[24], and perhaps in the secondary structure of its rRNA (H. F. Noller and C. R. Woese, unpublished).

The issue here is the extent of the differences between archaebacteria and true bacteria. Is it possible that once the cell's basic molecular processes have been established (and are well integrated into the fabric of the cell), that an organism can proceed along an evolutionary course and encounter niches that cause it to alter almost all these processes in significant ways? We consider the amount of change that can be effected in the basic molecular processes once they are established is quite limited, and if our present knowledge of archaebacteria does not exceed these limits, then our future knowledge of them certainly will. For this reason, it has been suggested that the archaebacterial and true bacterial lines of descent separated from one another during the stage at which the cell's basic molecular processes were still evolving and being refined[4-6]. Each line separately completed the evolution of the various molecular functions, as it evolved from the progenote to the prokaryotic state[1]. (One of the predictions of the radical view is that archaebacteria should possess very different genetic control mechanisms from true bacteria[2,6], in that genetic control is largely a series of refinements in basic gene expression mechanisms.)

The conservative interpretation is that the archaebacterial line of descent gave rise to the eukaryotic cell, that is, the putative host in which the endosymbionts reside[7]. It is not unreasonable that archaebacterial genes and structures are found in the chimaera that is the eukaryotic cell, like true bacterial genes and structures are[4] (C.R.W., in preparation). In fact, one of the archaebacterial ribosomal proteins shows a distinct specific sequence homology with its eukaryotic counterpart[25]. Archaebacteria do share a number of properties specifically with eukaryotes[2,4,26,27]. However, we consider that such a suggestion is unwarranted, for several reasons. Few facts are known and they do not strongly support the argument. Archaebacteria have as many properties in common with true bacteria as they do with eukaryotes, and true bacteria also share properties specifically with eukaryotes[2,28,29]; also the eukaryotic 18S rRNA seems to be no more closely related to its archaebacterial than its eubacterial counterpart[1,4]. Furthermore, archaebacteria already have a disturbing number of dissimilarities to eukaryotes[2]. Too little is known about the way in which eukaryotic cells evolved to justify this specific conclusion[7]—we do not know enough about genealogies of various eukaryotic (and bacterial) genes. We are not even certain that there was such a thing as the ancestral eukaryotic 'host cell', as it is now envisaged[7,8]. We do not know the extent to which endosymbioses are responsible for the chimaeric condition of the eukaryotic nucleus (C.R.W., in preparation). It is more useful at this stage to state merely that archaebacteria as well as true bacteria seem to be represented in the eukaryotic chimaera, and that other lines of descent, other groups, may be represented there as well (for example, the 18S rRNA)[2,4]. The ways in which the various lines are so represented, the evolutionary stages at which the associations occurred and the number of such events involved are all open questions, to be decided by comparative molecular analyses of eukaryotes, eubacteria and archaebacteria.

MATTERS ARISING

Pyroclastic sulphur

FRANCIS *ET AL.*[1] recently commented on the apparent rarity of pyroclastic sulphur in terrestrial eruptions. They described sulphur-rich ejecta from Poás volcano, Costa Rica, and mentioned the presence of myriads of small, sulphur spheres. Similar spheres have been reported in tephras erupted from Ruapehu[2–4], New Zealand, and may well be common at many volcanoes where an active vent is occupied by a crater lake.

The Ruapehu spheres range from 50 μm to 1 mm, but most are 125–750 μm in diameter. They have a lustrous, granular surface, and comprise solid, black, orthorhombic sulphur with disseminated silicate, and iron sulphide dust, a few small vacuoles and rare, yellow sulphur crystals. Some are globular, some are fused double-spheres, but most are almost perfectly round 'rough[5] spheres'. They were ejected in abundance by phreatomagmatic eruptions in 1971, and one fine ash collected 15 km downwind comprised 12% by volume of spheres[2]. Sulphur also occurs in Ruapehu tephras as uncommon, angular, yellow fragments, and sulphur drip on ejected blocks. Rafts of spongy sulphur float on the lake in quiet or eruptive periods.

Vent morphology and activity of Ruapehu[6] and Poás appear similar, and a subaqueous liquid sulphur lake has been postulated for both volcanoes[7,8]. I agree with Francis *et al.*[1] that this is unlikely. Much consolidated, volcaniclastic/chemogenic sediment has been erupted from Ruapehu, and in some siltstones ejected in 1971, sulphur occurs as globules in cavities, and veins crossing the bedding. This I believe is evidence that sulphur is 'sweated' out of sulphurous sediment, whence it may enter superheated steam fumaroles and be discharged violently into muddy lake water to form black droplets. The lack of coarse, clastic or scoriaceous sulphur suggests that there were no large accumulations of liquid sulphur present when the lake bed was fragmented during phreatomagmatic eruptions of Ruapehu.

FRANCIS REPLIES—We were not aware of the existence of small sulphur spherules in the material ejected by the Ruapehu eruption of 1971, and are grateful to Wood for bringing it to our attention. We agree that such spheres may well be common in active volcanoes with crater lakes, and would welcome any further observations of these and related phenomena.

Recombination intermediates

IN the summary of their elegant demonstration of adenovirus recombination intermediates, Wolgemuth and Hsu[1] state: "To the best of our knowledge, this is the first visualization of *in vivo* recombination intermediates of discrete DNA molecules isolated from eukaryotic cells". They appear to have overlooked the paper published last year by Bell and Byers[2] which presented an equally clear demonstration of Holliday-type recombination intermediates involving the 2-μm plasmids of *Saccharomyces cerevisiae.* Although this earlier case might be held to be atypical of recombination in general, in that it involved inverted repeats within the same molecule rather than homologous regions of different molecules, it was, in another respect, more relevant to meiotic recombination, because the Holliday structures were found specifically in cells at the prophase stage of meiosis.

WOLGEMUTH AND HSU REPLY—As stated in the text of our paper, our study does indeed represent the first example, to the best of our knowledge, of visualization of *in vivo* recombination intermediates in *animal* cells and we are sorry that the word eukaryotic in the summary was misleading. We would like to emphasize Fincham's point that our observations are more typical of recombination in that they are inter- rather than intramolecular. Our failure to cite the paper by Beck and Byers in our discussion was totally inadvertent and we had contacted them previously in this regard.

Common ancestry for birds and crocodiles?

A PSEUDOSUCHIAN origin for birds and crocodiles, independent of dinosaurs, has been proposed by Whetstone and Martin[1]. They described two 'derived' characters of the otic region of the skull, a fenestra pseudorotunda and periotic sinuses, which were claimed to be unique to crocodiles and birds and thus evidence for their common ancestry. It is well known that crocodiles and birds possess a similar otic morphology[2,3]. Any hypothesis of their common ancestry independent of dinosaurs therefore depends critically on the assertion that dinosaurs do not have similar shared features, or that if they do, the features are not homologous. In this respect, we think that Whetstone and Martin's evidence is equivocal and should be treated with caution.

Whetstone and Martin note that in primitive reptiles the perilymphatic duct exits from the cranium through the vagus foramen (fissura metotica), accompanied by certain cranial nerves. In crocodiles and birds, however, the perilymphatic duct has a separate exit, and terminates in a small membrane that closes the fenestra rotunda, or, more correctly, the fenestra pseudorotunda[2]. The fenestra pseudorotunda lies very close to the fenestra ovalis.

Based on their interpretations of casts of the inner ear structure, Whetstone and Martin concluded that dinosaurs did not have a fenestra pseudorotunda. Casts of four of the seven genera studied were illustrated: the sauropod *Brachiosaurus*, the hadrosaur *Lophorothon*, the ankylosaur *Ankylosaurus* and the theropod *Allosaurus* (see ref. 1, Fig. 2 *a–d*, respectively). We question how the authors can be certain that the single trunk identified in *Lophorothon* and *Ankylosaurus* does in fact represent both the perilymphatic duct and certain cranial nerves. Why should it not represent the perilymphatic duct alone? In *Lophorothon*, for example, could not the first trunk (labelled perilymphatic duct plus nerves X–XI) represent the perilymphatic duct exiting alone, and

0028–0836/81/020097—02$01.00

ending in the fenestra pseudorotunda? The next trunk could then represent nerves X and XI and the third trunk nerve XII. The point here is that Whetstone and Martin's interpretation of a complex morphological structure from casts is questionable, and alternative explanations are possible.

Notwithstanding these questions of interpretation, which simply reflect the shortcomings of attempts to reconstruct the soft anatomy of fossil organisms, it is interesting that other workers have reported a fenestra pseudorotunda in the theropods *Dromaesaurus*[4] and *Gallimimus*[5], and in the pachycephalosaurians *Prenocephale* and *Homalocephale*[6]. In *Dromaeosaurus*[4] remnants of the stapes confirm the interpretation of the fenestra ovalis, and the adjacent aperture, identified as the fenestra (pseudo) rotunda (though identified as the IX foramen by Whetstone and Martin), bears a relationship with the fenestra ovalis which is strikingly similar to that illustrated by Whetstone and Martin for *Hesperornis* and *Alligator* (compare ref. 4, Fig. 7*a*, and ref. 1, Figs. 3*a*,*b*).

Whetstone and Martin marshalled evidence from embryology to support their case that the 'round window' (fenestra pseudorotunda) of birds and crocodiles is a homologous feature unique to them. Although other living vertebrates (mammals and lizards) also have round windows, they argued that the structure had a similar embryology in birds and crocodiles, and that this differed from that of other vertebrates. However, if some dinosaurs do indeed have a fenestra pseudorotunda, then the embryological evidence in support of its homology in birds and crocodiles is less compelling. The similar embryology of the otic regions of crocodiles and birds may only reflect their archosaurian ancestry.

The other character described by Whetstone and Martin, periotic sinuses associated with bones of the middle ear cavity, also may not be unique to crocodiles and birds. Depressions have been described in the lateral wall of the braincase of *Saurornithoides*[7] that seem to be associated with the middle ear.

Thus, we find that the evidence presented by Whetstone and Martin to support an hypothesis of common ancestry of crocodiles and birds independent of dinosaurs is equivocal. It is sobering to recount Baird's[8] summary statement in 1970: 'Parallelism and convergence in the tympanic regions of living reptiles are common, and only a few reptilian ears are yet known in detail.' Thus, even if Whetstone and Martin are correct in their assertion that a fenestra pseudorotunda and periotic sinuses are unique to birds and crocodiles, it remains to be determined whether this is due to common ancestry or convergence. In view of the extensive evidence compiled by Ostrom[9-14] for common ancestry of birds and dinosaurs, the otic features mentioned by Whetstone and Martin may best be ascribed to homoplasy.

WHETSTONE AND MARTIN REPLY—The fundamental difference between the otic capsules of *Sphenodon* and those of a bird or crocodile is in the course of the perilymphatic duct. In *Sphenodon*, it turns medially, enters the endocranium and passes along a groove before being exposed to pharyngeal tissues[1]. In birds and crocodiles, it turns laterally and is exposed to the tympanic cavity. Either condition requires a correlated suite of osteological structures. We have used these structures in attempting to determine the course of the duct in dinosaurs[2]. Hadrosaurs and *Ankylosaurus*, for example, are like *Sphenodon* but unlike birds or crocodiles, in having an open 'vestibule' to the endocranium, a groove between the vestibule and vagus foramen, and no confluence between the external cranial openings. Whether or not the duct left the cranium alone (as suggested by McGowan and Baker) is irrelevant to the problem at hand. Either interpretation presumes a primitive (medial) course for the duct, along the braincase wall.

By using a bird or crocodile as a model for fossil archosaurs, some workers have restores a fenestra pseudorotunda in dinosaurs. The foramen indentified[3] as the 'round window' in *Gallimimus* is not on the otic capsule, but is far up on the paroccipt. In the type of *Dromaeosaurus*, the right otic capsule has been destroyed, along with the footplate of the stapes. The resulting hole and the remnants of a nerve canal were labelled 'Foramen Rotundum' in the original restoration[4]. The ear regions of the cited pachycephalosaurs are indeterminate. The best candidate for the presence of this structure is the ornithischian, *Hypsilophodon*. Were a 'window' present in dinosaurs, it would not lessen the embryological evidence for the homology of the fenestra in birds and crocodiles, but might indicate that the homology evolved in a more remote ancestor.

Ostrom's evidence for a theropod origin for birds has been well summarized[5]. The evidence for a 'sister-group' relationship to crocodilians, first suggested by Walker[6], is still being developed by Whetstone, but the following derived features seem to be homologous: a fenestra pseudorotunda; a pneumatic quadrate; a foramen aerosum in the lower jaw; periotic pneumatic cavities in the dorsal, central and rostral positions: a quadrate cotylus at the anterior base of the paroccipt; a bipartite quadrate articulation with dermal and endochondral bones—anteriorly with the prootic, squamosal and laterosphenoid, posteriorly with the prootic and otoccipital; a squamosal shelf over the ear region; anterio-medial origin of the temporal musculature; two pneumatic cavities surrounding the cerebral carotid; unserrated teeth with a constricted neck[7]; bony tooth roots with an enclosed, oval resorption pit[7]. None of these features is known in theropod dinosaurs. The 'lateral depression' of *Saurornithoides* has no similarity to the periotic sinuses.

On the basis of present evidence, we feel that an argument of close relationship to crocodilians is the most parsimonious hypothesis available for the ancestry of birds.

BOOK REVIEWS

History and non-history

Dorothy Hodgkin

Sage: A Life of J. D. Bernal. By Maurice Goldsmith. Pp.288. (Hutchinson: 1980.) £8.95.

Popperfoto

J. D. Bernal at the inauguration of a new building of the Institute for Structure Research in Germany, March 1962. Dorothy Hodgkin is in the background.

WHEN he spoke in memory of J. D. Bernal in January, 1972, Lord Snow said "I strongly advise that his biography should not be written until the end of the coming decade . . . there is so much in this rich life to learn about and to interpret". The decade is coming to an end, a large amount of material connected with Bernal's scientific and other work and some personal papers have been sorted out, and a catalogue — nearly ready — is being prepared in the archives of Cambridge University library. So, on Lord Snow's prescription, a serious book on Bernal could now be written; and, perhaps, the sooner the better, while there are still many living who knew him.

Maurice Goldsmith's book is not the book that is needed. It is not even a good forerunner of that book. It is too confused and inaccurate. Goldsmith does not understand Bernal well enough as a person, what he cared for and particularly his scientific work and achievement. This Bernal himself felt, when, semi-paralysed, he was visited by Goldsmith and learned that he wanted to write his biography. Bernal asked his wife to discourage Goldsmith from writing, which she did as far as she could, arranging for an alternative biographical study to be made and refusing Goldsmith access to the Cambridge archives. Knowing something of the state of the archives in the past few years I have every sympathy with her. Knowledge of its contents would not have removed the major defects of this book.

The book sets out to cover Bernal's life and work in 14 chapters, from his childhood in Ireland, where he was born in 1901, to his death in London in 1971. The early part is largely taken from autobiographical sketches written by Bernal, much of the rest from conversations with friends and colleagues, from newspaper reports of the time and some from Bernal's own writings. So there are many stories which bring back vivid memories of him, of his early passion for science and experiments at home, at school and Cambridge, of Sir William Bragg and the Royal Institution, and the beginning of the X-ray analysis of crystals, of Max Perutz coming to work with him at Cambridge, of his war work on air-raid precautions and with Lord Mountbatten. It was at Cambridge that Bernal acquired the nickname Sage which many of his early friends used and which gives the book its title. He read widely and to his undergraduate friends seemed extraordinarily learned. Goldsmith himself knew him best at a later stage of his life, through their common interest in the use of science, science policy, the social function of science and the science of the sciences; these are subjects dealt with at some length. There are also chapters on Bernal's relations with the Soviet Union, on the development of international organizations for science and for peace after the War, on the political controversies that troubled both his early and later career, and on his work on science in history.

Unfortunately the text is scattered with inaccuracies — in most cases easily avoidable — confusions and misconceptions. For example, it is recorded that Desmond Bernal had one brother and two sisters; he had, in fact, two brothers, Kevin and Godfrey, who are still alive; one of his two sisters died in infancy. Later the text runs: "In June 1945, Bernal was in Moscow for the 220th anniversary of the Academy of Sciences. His friend Frédéric Joliot-Curie was also there . . . together with Joliot, Bernal began discussions with a few Soviet scientists on a proposed new international body". Actually Bernal was prevented from going to the Moscow celebrations by the British government — later it is said, quite correctly, that the visit he made to Moscow in 1949 was the first since 1934. Then, about the long paper by Bernal and Fankuchen on tobacco mosaic virus: "It was most fortunate that Fankuchen finally wrote up that important paper, because Bernal would never have done so". This is invention. Anyone who knew them both would know only Bernal could have written the major part of that paper. Fankuchen was an excellent experimentalist, but his role at the end was to add a few exact figures and get the paper accepted for publication.

From childhood Bernal was passionately interested in science, in carrying out experiments himself, thinking about his own finds and those of others. As the dustcover says, "although primarily a crystallographer, he produced and provoked ideas over almost the entire range of scientific enquiries". Yet only one chapter of the 14 is devoted to the main body of his scientific work and this is extraordinarily confused and full of doubtful comments. What was really involved in his first crystallographic measurements on the sterols, and how these were linked with the work on oestrin and affected the general stream of chemical research, is never clear. Nor is the

---

Dorothy Hodgkin is Emeritus Professor at the University of Oxford, and a Fellow of Somerville College and Wolfson College, Oxford.

significance of his discovery of the conditions under which proteins and viruses could give detailed X-ray diffraction effects, work which opened the way to the elucidation of their structures and to much more, the solution of the structure of DNA and the understanding of molecular biology as we know it now. I read again the review Bernal wrote in 1968 of Watson's book, *The Double Helix*, and did not find it embarrassing as Goldsmith suggests. Bernal says specifically: "My name does not appear, and rightly, in the double helix story". That he should feel, all the same, that he had so many clues that he should have been able to see the solution himself was only natural — Pauling felt just the same on reading the book; and Bernal had an added reason in that he had himself taken X-ray photographs of nucleic acids as long ago as 1937. Incidentally, the remark that Furberg established the structure of DNA is so wrong it must be a misprint.

Other Goldsmith comments: the implication of the sentence "his own major, purely scientific contributions were made before 1939" that Bernal's work was either not his own or not major — is surely wrong. After the war Bernal set up a number of very good research groups at Birkbeck, which he left much to themselves — he strongly believed, from his early work with Sir William Bragg, that independence was a good thing — he himself working mainly on the liquid state; it was from this research that his 1959 paper on the structure of liquids emerged, arguably the most brilliant he ever wrote. Another serious misunderstanding: "he had a hurting yet non-deliberate blindness about key work done by members of his staff". Characteristically, Bernal was the most generous of colleagues, generous with ideas, help and credit (as indeed is said elsewhere). Any blindness of the kind mentioned was extremely rare with him — as with children in many large families, his scientific children sometimes felt they had less than they would have liked of their parents' attention. To most he seemed kind beyond their deserts.

Many of the failings of Goldsmith's treatment of his scientific work apply to other sections; his judgement seems to me often very wrong. He relies too much on casual, sometimes malicious, gossip. John Desmond Bernal's life and work deserves a very much more serious study and appraisal. □

More *Drosophila*

Peter Lawrence

The Genetics and Biology of Drosophila, Vol.2d. Edited by M. Ashburner and T.R.F. Wright. Pp.702. (Academic: 1980.) £54, $124.50.

THIS volume is the last in the series dealing with the genetics and biology of the individual fruit fly. Volume 3, which is in preparation, will take us away into the biology of populations, taxonomy, ecology and evolution.

I have already taken the opportunity this multi-authored work has given me to malign multi-authored works in general (*Nature* **283**, 116; 1980). One criticism of the earlier volumes was the way topics are jumbled up, which makes it necessary for the specialist to buy several volumes when he may only want to read a chapter or two in each. Another was that there appeared to be a lack of discipline which led to chapters being over-long and containing evanescent material, making the individual volumes unnecessarily bulky and expensive. Although I think Vol.2d is a legitimate target for the same attacks, it contains several good chapters which cover related topics and is therefore easier to defend.

This volume covers lampbrush chromosomes, sex determination, dosage compensation, oogenesis and spermatogenesis. There are chapters on the structure and development of the epidermis, nervous system and tracheal system and three chapters which appear eccentric in this company — on neuromuscular physiology, fly pigments, and even one on viruses.

Most chapters are strong, concentrating in the main on useful facts rather than idle discussion. There are many good things, for instance tables of enzyme activities in flies bearing different X-autosome ratios, pictures and drawings of the central nervous system and new illustrations of the larval cuticular sensilla, tables referring the reader to papers on the structure of the imaginal discs, discussion of the types of cell junctions found in epithelia, drawings of the ramifications of the tracheal system, and a very useful compendium of the effects of eye colour mutants. Examples of idle discussion of the abstruse are much of the chapters on sex determination and viruses, and the sections on the rate of oogenesis in umpteen species of *Drosophila* and on cell lineage in ommatidial development. This volume, like bits of its predecessors, will be a valuable resource. Editing huge books like this is no delight, so please raise your glasses to Ashburner and Wright! □

Peter Lawrence is on the staff of the MRC Laboratory of Molecular Biology, Cambridge, UK.

Gut reactions

G.J. Dockray

Gastrointestinal Hormones. Comprehensive Endocrinology. Edited by George B. Jerzy Glass. Pp.1008. (Raven: 1980.) $85, $115.60 outside the USA.

TEN years ago secretin, gastrin and cholecystokinin were the only hormonal peptides to have been isolated from the gut and characterized. Today we know the structure of over a dozen distinct biologically active gut peptides. The function of most of these is still uncertain. However, it seems likely that while some function as true hormones, others may act locally by diffusion to nearby cells (paracrine effects), and still others are secreted by nerves and have neuro-regulatory roles. The editor of this book has rightly taken a broad view of gastrointestinal hormones, and has included chapters on both the classical hormones (secretin, gastrin, cholecystokinin) and a wide range of other active peptides.

Gut endocrinologists have not been reticent about reviewing the rapid advances in their field, and at least five other books (generally conference proceedings) devoted to the gut endocrine system have appeared in recent years. The value of the present book lies in its comprehensive approach to the subject, and in this it lives up to the title of the series.

There are 42 chapters contributed by workers from 33 different laboratories, all active in this area. The division of the chapters into sections has been rather arbitrary and the greater part of the book is essentially a systematic coverage of the localization, isolation, characterization, biological properties, receptor binding, physiology and measurement of gut peptides. A final series of chapters deals with those "candidate" hormones which have not been isolated but whose existence is inferred from physiological studies, and also with new peptides which are in the process of being isolated from hog intestine by Viktor Mutt and his collaborators.

In the not too distant future it seems probable that we will know of 20 or 30 chemically defined and biologically distinct peptides which may control digestion. This field is obviously moving quickly, and it is therefore welcome to see that the publishers have managed to produce the book quite rapidly (some references are barely a year old). Although it is inevitable that much of the book will soon be out of date, it is still essential reading for anyone who wants to keep up with advances in this area. It will also provide an invaluable source for understanding developments not just in gut endocrinology, but also in the study of peptides in central and peripheral nerves. □

G.J. Dockray is Reader in Physiology at the University of Liverpool.

Diagenesis by numbers

R.G.C. Bathurst

Early Diagenesis: A Theoretical Approach. By Robert A. Berner. Pp.241. (Princeton University Press: 1980.) Hardback $25, £13.70; paperback $9.50, £5.25.

THIS most readable and helpful book should be welcomed by all who wish to understand chemical processes in diagenesis, be they students, teachers or research workers. Berner's approach is rigorously logical: he selects various problems in early diagenesis, shows how these may be clarified and simplified, and how to pose sensible questions about them, and, finally, indicates how to derive models that are both testable quantitatively and valuable as guides to prediction. His mode of thought combines a rigorous quantitative approach (calculus at the level of simple integration) with a careful appreciation of such seemingly unquantifiable processes as bioturbation and bacterial decay. Above all, he is concerned with the rates at which different processes work. In this book he deals only with diagenesis in the first 100m or so of burial, thus avoiding complicating factors such as higher temperatures, uplift, weathering and metamorphism.

In Part I there are five chapters devoted to theory. After a short introduction, he presents a quantitative approach to basic concepts such as rates of burial, steady-state diagenesis and diffusive and advective fluxes. Next he examines in detail the quantitative expression of compaction, rate of deposition, rate of flow of water across a sediment–water interface, molecular diffusion and the application of Fick's laws, and how to accommodate bioturbation into a quantitative model. The following two chapters cover various chemical processes that are the driving forces for diagenetic change. These include adsorption, ion exchange, radioactive decay, microbial metabolic reactions, the energetics of precipitation, nucleation, crystal growth, transport control and dissolution, and the general matter of diagenetic redistribution, with a section on causative factors in authigenic processes.

Part II is about applications and in it Berner discusses and enlarges upon work that has been carried out in real situations. He starts with a consideration of marine sediments of the continental margins; topics include diagenesis within the zone of bioturbation, relying on work done in Long Island Sound, touching upon such matters as irrigation and molecular diffusion of ammonia into burrows constantly flushed with oxygenated water, bacterial sulphate reduction, ammonia formation, phosphate diagenesis and methane formation. He then comes to pelagic (deep-sea) sediments, dealing with carbonate dissolution and the lysocline and compensation depth, burial flux and compaction, the dissolution of opaline silica, the diagenesis of suboxic organic matter and of radioisotopes, and volcanic–seawater reactions. The final chapter embraces non-marine sediments (fresh to brackish water) and treats salinity fluctuations, iron and manganese diagenesis and hypersaline sediments. There is a 13-page bibliography and an efficient index. The chapters each have running headlines and these, combined with clear paragraph headings, make it easy for the reader to find his way around.

Berner's writing is superbly clear and readers should find the book both interesting and stimulating. It excels as an exercise in controlled scientific imagination and sets a high standard for future studies of recent diagenesis. □

R.G.C. Bathurst is Professor of Geology at the University of Liverpool and of Petroleum Geology (II) at the University of Bergen.

Attractions of magnetic interactions

B. R. Coles

Interactions in Magnetically Ordered Solids. By K. P. Sinha and N. Kumar. Pp.180. (Oxford University Press: 1980.) £12.50, $36.50.

THIS short book covers a lot of ground, although the authors explain at the outset that they have restricted themselves to localized moments in insulators and semiconductors. They reveal some ambivalence, however, towards conduction electrons, recognizing their importance as mediators of magnetic interactions (albeit in a rather concentrated treatment in which the sudden appearance of the word "impurity" may confuse many readers) but rather oddly entitling their last chapter "Conduction electron magnon interaction in ferromagnetic *insulators*" — a contradiction in terms not clarified by a brief final paragraph on spin-disorder resistivity which introduces de Gennes and Friedel's treatment of magnetic metals.

The problem of over-compression of the subject matter runs right through the book, perhaps the most glaring example being a section of one and a half pages of text and three figures which is introduced as "a brief survey of the thermodynamic properties of magnetic insulators".

As a result, it is difficult to see for whom the book is intended. Any given topic is dealt with so briefly as to constitute little more than a signpost to an area of interest, any real understanding of which by a student will require extensive reading elsewhere. Furthermore, the guidance to such reading is often very limited. For example, no reference to the book of Marshall and Lovesey (from the same publishers) is given in the short chapter on neutron–magnon interactions, which devotes two pages to magnon dispersion relations and nothing (in spite of the section introduction's claim) to magnon lifetimes. Perhaps the more theoretically inclined graduate student will use this book to pick up hints about arenas in which he can flex his mathematical muscles without having to acquire much feeling for the nature of the materials in which the fascinating phenomena of magnetism manifest themselves. □

B. R. Coles is Professor of Solid State Physics at Imperial College, University of London.

Art of catalysis

D.E.W. Vaughan

Heterogeneous Catalysis in Practice. By C.N. Satterfield. Pp.416. (McGraw-Hill: 1980.) $36.30, £16.15.

IN this book Professor Satterfield has squeezed into less than 400 pages the essential characteristics of catalysis and many of the major industrial catalytic processes. He has not attempted to be either up to date (there are few references later than 1976), or comprehensive in his coverage, but instead presents overviews that give the reader an appreciation for the processes and the associated practical problems ever present in "real" systems. The "art" side of catalysis is given a fairly complete coverage. Throughout, the references are secondary rather than primary; for example, few patents are cited. Overall, the treatment is directed toward the chemical engineer rather than the chemist.

The first half of the book deals with the necessary physical–inorganic chemistry of catalysis and catalysts, with chapters on sorption, kinetics, catalyst preparation and characterization. These are brief, and often only define the terms, nomenclature and methods of catalytic chemistry. The reader is supplied with appropriate references if a deeper understanding is desired, both in the form of chapter bibliographies and a general literature overview at the end of the book. Throughout, the emphasis is on practicality, real problems and working systems. The chapter on catalyst preparation and manufacture (avoided in most books) is a reminder of the multitudinous problems that can be built into a catalyst before measurements or tests are made on it — a sobering reminder that a knowledge of the preparation details is often essential to a complete interpretation of catalyst evaluation data.

The second part of the book surveys areas of industrially important catalytic chemistry, with chapters on supported metal catalysts, acid and zeolite catalysts, catalytic oxidation, processing of petroleum hydrocarbons, and synthesis gas and associated processes. These chapters trace the development of process catalysts up to present practice, focussing on details of catalyst composition and process conditions. The chapter on synthesis gas is particularly timely in view of the renewed interest in CO and H_2 as sources of synthetic chemicals, and includes discussions of steam reforming, Fischer-Tropsch synthesis, water-gas shift reactions, methanation, methanol synthesis and ammonia synthesis. Details are generally accurate.

The final chapter on experimental methods covers the engineering details of reactor design, heat and mass transfer, and various types of reactors useful in the laboratory. This is useful to the chemist in that it is reminder of many important non-catalyst effects on experimental results.

The book is eminently readable, in the sense that the author gets to the point in clear prose, and moves on to the next subject. In addition to use in courses in catalysis, the book will provide a valuable review of the subject for the experienced worker in the field, in that its broad coverage of pratical catalyst systems makes it a good initial reference for catalysts and process conditions.

D.E.W. Vaughan is a Research Associate with the Exxon Research and Engineering Company, working in the areas of sorbent and catalytic materials.

Interactions of binary stars

R. J. Tayler

Close Binary Stars: Observation and Interpretation. Edited by M. J. Plavec and R. K. Ulrich. Pp.598. (Reidel: 1980.) Hardback Dfl.130, $68.50; paperback Dfl.60, $31.50.

BINARY stars have always been important for astronomers because the only direct way of determining stellar masses involves the application of Kepler's laws to the observed motions of the components. In addition, a study of eclipsing binaries can give information about stellar radii and variation of brightness across a stellar disk. It has, however, become clear only fairly recently that close binary stars are involved in some of the most violent and exotic phenomena in the Universe.

These phenomena are associated with mass transfer between the components. Most stars increase in size during their life history and a member of a close binary may become so large that its surface layers are attracted to the companion star; this is called Roche lobe overflow. In addition, some stars lose mass continuously and some of this may be captured by the companion. This exchange can have important effects on the evolution of the system. If the initially more massive star becomes the less massive, an ill-matched binary can result in which it appears that the lower mass star has evolved more rapidly than the more massive, in contradiction to basic ideas about stellar evolution. The most dramatic effects occur when one of the component stars is a highly compact star, a white dwarf, a neutron star or a black hole, when a very large release of gravitational energy accompanies mass transfer. This process is important in many X-ray sources, novae and cataclysmic variables.

This book is the proceedings of a symposium held in Toronto in the summer of 1979. It contains over a hundred contributions and there are few papers which contain as many as ten pages. As a result, the non-specialist may have some difficulty in discovering what are the key questions and which are the most important papers. I am sorry that there is not a small number of lengthy reviews, since it is clear that there are some important unsolved problems which merit fuller discussion than they receive here. For example, the manner in which close binary systems are formed is not clear and there are some particularly difficult problems and sharp controversies relating to the structure of binaries that are so close that they really form a single star with two nuclei. Further, most calculations of stellar evolution involving mass transfer have assumed conservation of mass and angular momentum by the system, whereas an uncertain amount of each will escape.

Although close binaries are of wide general interest to astronomers, this book is most suitable for those who are already working in the subject.

R. J. Tayler is Professor of Astronomy at the University of Sussex, author of three elementary astronomy textbooks and Managing Editor of Monthly Notices of the Royal Astronomical Society.

Andean archaeology

John Coles

Guitarrero Cave: Early Man in the Andes. Edited by Thomas F. Lynch. Pp.328. (Academic: 1980.) $20, £13.60.

FOR some years now it has been an archaeological conceit to speak of interdisciplinary projects as the sole way of comprehending any ancient site, settlement or landscape. In few cases have these concepts been achieved, and instead the archaeological world has been presented with rather feeble attempts to coordinate and integrate the variety of natural scientific techniques that can be brought to bear upon most archaeological sites or areas. In the present book we have just such an effort, one which succeeds in part — but not wholly — in demonstrating the virtues of an interdisciplinary approach.

The cave of Guitarrero lies high (2580m) in an intermontane valley bounded by the Cordillera Blanca and C. Negra in Peru. The archaeologist will see the possibilities for an ecological research project, with dramatic seasonal variations in environmental conditions presumably being welcomed by the ancient inhabitants, and indeed this form of project is what was conceived and executed. The site was excavated, and its stratigraphical deposits dated by radiocarbon to a period which on balance seems to fall between 10,000 BP and 7,000 BP. The environmental implications and attempted reconstruction of the ancient landscapes are heavily reliant on pollen analyses, and there is relatively little on geomorphological processes which one could conceive of as affecting the landscape to a significant degree. Nonetheless, this initial section of the book sets the scene for the major thrust of the project, the study of the quite extraordinarily abundant remains of plants. This is explored through exhaustive analysis of maize and beans, with essays on the origin and early development of cultivation in highland Peru.

A third section provides a full description of the multifarious stone artifacts from the major stratigraphic phases of the cave occupation, and is somewhat tedious in approach. More interesting by virtue of rarity are the bone and wood artifacts, and remains of cordage, basketry and textiles which conditions in parts of the cave have allowed to survive. The final summary and overview of the site emphasizes this organic content which alone would have made the excavation worthwhile.

Yet, as regards disciplines, multidisciplinary it is, interdisciplinary it is not. Archaeologists may never be able to achieve the latter if they remain content with the former.

John Coles is Professor of European Prehistory at the University of Cambridge.

CORRESPONDENCE

Continued from p. 8

most of the students and younger zoological systematists (and now even some botanists) have adopted this strategy of dealing with the empirical world in the belief that they were coming to understand something new about the hierarchical structure of nature. Of course, we should have known all along that something was amiss since most of our older colleagues from an earlier and wiser generation had told us that the spread of cladistics will have an extremely deleterious effect on Mayrian (or Simpsonian, or Darwinian) taxonomy. Well, the damage is done: their taxonomy will never be the same again — wiped out, as it were, by an epidemic of cladistics brought on by thoughtless, unhygienic and scientifically irresponsible cladists.

Some of my colleagues doubtless (in the old sense) will consider it premature for me to write such congratulatory lines about Dr Halstead on the grounds that he knows almost nothing, and appears to be unfamiliar with the literature, of cladistics. But I remind them that with Halsteadian Truth, knowledge of cladistics is irrelevant for cladistics is a theoretical matter. So I say to Halstead that there can be no serious doubt (in the new sense, for I actually seem to be getting the hang of it!) about the importance of his discovery of false doubt to systematics and evolutionary biology. Application of Halsteadian Truth suddenly reveals why all those serious doubters have questioned the usefulness of gradualism as a doctrine. This is because, poor souls, they imagined that (1) the modern doctrine of gradualism as derived from population genetics has no known empirical relationship to the hierarchy of organisms, (2) that population genetics theory was designed to rescue Darwin's theory of natural selection when it faltered because of its untestability, and (3) that the applicability of gradualism as an explanation of taxic diversity is achieved by a simple extrapolation from artificial selection experiments and the changes in gene frequencies observed in nature. I am forced also to include among the serious doubters a variety of embryologists and developmental geneticists who, before the coming of Halsteadian Truth, were thought to be rather distinguished.

The innate wisdom Halstead shows about cladistics and evolutionary theory extends to his philosophy of science and politics. On the thinnest of pretexts he tries to convince us that his certain knowledge that evolution is gradual constitutes a perfect, and necessary, refutation of Marxist doctrine. Would Halstead, I wonder, imagine that the massive extinctions that have taken place in his gradualistic world also carry sinister implications for us? The class struggle? Or did Darwin only predict the end of his own theory? Halstead, this great seeker of truth, must really be rebuked for deliberately confounding science and politics and for attributing the troublesome notions of Social Darwinism to the entirely ethical and clear-thinking scientists and educators of the British Museum.

Donn E. Rosen

Department of Ichthyology,
American Museum of Natural History,
New York

Sir — Beverly Halstead has drawn attention[1] to the ideological basis of the present exhibition policy at the Natural History Museum, and its implications. Other aspects of present policy are scarcely less disturbing. They relate to the display of the museum's collections and to the use of the building in which they are housed.

The museum's original exhibits were systematically arranged and a great number of genera and species were shown. The building in which they were housed was designed by Alfred Waterhouse (1830–1905), one of our greatest Victorian architects. It is a superb building and is listed as a Grade I Historic Building by the Department of the Environment. Waterhouse himself took great pains over the exterior and interior detailing and the whole building has an impressive unity.

The original exhibition galleries, whose plan and detailing reflected the order and hierarchy of nature, as then perceived, remained in use until the outbreak of war in 1939. The war led to closure of some galleries, and after the war nothing much happened for a long time. Museums generally were reacting against the old cases and galleries stuffed with objects, and the authorities of the British Museum (Natural History) did not seem to know what to do about the old systematic displays.

Eventually a policy seemed to emerge, exemplified by the new Fossil Mammal exhibit opened in 1972 in what was the old Fossil Mammal Gallery. In place of the dramatic long vista past mounted skeletons of fossil elephants, the continuity of the gallery was broken up and its original architectural character subdued, though some of the detail is still visible. Scientifically the new exhibit is much better than the old one, with a great deal of information on the animals and on the rocks from which they came, attractively displayed. As Halstead has pointed out[2], everyone, from a specialist to a child, can get something out of it.

So far, the museum had pursued the policy of showing a representative series from the collections which are its *raison d'etre.* In this connection it is interesting that the British Museum Act 1963 makes no reference to the public exhibition of the collections. The explanations must be that in the eighteenth century, when the original acts were framed which the 1963 Act replaces, it was self-evident that a museum existed for this purpose.

Those who hoped that Fossil Mammals heralded the modernization of other galleries were soon to be disappointed. There was an abrupt change of policy. The museum's report[3] for 1972–74 said that "Unhappily, the existing public exhibition does not match the museum's purpose . . . it has lagged far behind this century's revolution in the natural sciences. . . .it fails to give a clear picture of natural history as the study of the world in which we live with principles which lie at the groundwork of our technologies, and which are the first principles of rational living". The failure seems disputable–the original exhibits largely gave such a picture, and the rest of the sentence is gibberish. (What are the first principles of rational living?)

The report outlined a new exhibition "much larger than the old" designed to "reflect all aspects of modern biology". It gave four themes which were to be the basis for the new exhibition: Ecology; Life processes and behaviour; Evolution and diversity; and Man. The Hall of Human Biology (opened in 1977; actually a warren rather than a hall), Ecology (1978) and the new exhibits on Man and Dinosaurs criticized by Halstead, are the first fruits of the stated policy.

It is debatable to what extent the museum should set itself up to be the fountainhead of the fashionable parts of modern biological education. In the case of the new Dinosaur exhibit, the sequence of arguments presented in the exhibit is repeated almost word for word in the accompanying booklet. This exemplifies the pointlessness of the new exhibition policy, which employs a great deal of expensive equipment to put over concepts which are better expounded on paper, and which are but distantly related to the collections and function of the museum. There is no coherent relationship between the new exhibits, the collections and the building. The recent exhibits make minimal use of actual specimens (none at all in Human Biology) and are unsuited to the exhibition space provided by Waterhouse's building. Human Biology was built inside former galleries, which it conceals completely, and Ecology was set up in the former gallery of living mammals. (It has recently been moved to the Fossil Reptile Gallery, soon to be demolished, where it looks even more out of place.)

Yet for all these unpromising omens, the museum apparently does intend to show its collections. The "Evolution and diversity" exhibits will, it is stated, "contain most of the material now on show in the Museum", exemplifying 5,000 to 10,000 species. They "will continue to provide . . . the most entertaining aspect of the Museum, halls of monsters and a stuffed zoo." Now this is exactly what the Waterhouse galleries were designed to do. It seems the height of perversity not to use them for the purpose. On the contrary, it is proposed to dismantle the 1972 Fossil Mammals exhibit (an admirable exposition of evolution and diversity) and to demolish a large range of the original galleries. Surely it would be better to do the obvious thing, use the original galleries for displaying the collections, and put exhibits such as Human Biology in a communicating building outside the original structure.

It is clear that the authorities of the museum are, at best, embarassed by the splendid interiors they have inherited. They do not know what to do with them, or how to make use of them constructively. At worst they appear to regard them merely as an impediment to be concealed and, if possible, removed.

Worse than this, there appears never to have been any coherent plan for the development of the buildings and the site as a whole. Both the original building, admirably suited to its original purpose but quite inadequate for research and storage, and the site are large, but not inexhaustible. For example, the new Palaeontology building (opened 1977) is splendid and fairly well suited for its purpose of research and storage, but it has used up the last available building plot next to the main building . This piecemeal approach exactly parallels the present attitude to the use of the interiors — exhibits and other facilities being placed wherever there happens to be some space that can be occupied. The whole problem of space and buildings at the museum is in urgent need of review, preferably by an independent body since the Trustees seem to be unable to see the wood for the trees.

1. Halstead, L.B. *Nature* **288**, 208 (1980).
2. Halstead, L.B. *Nature* **275**, 683 (1978).
3. *Report on the British Museum (Natural History) 1972-74*, 75 (HMSO, London, 1975).

SIR—Halstead[1] has criticized the current exhibition policy of the British Museum (Natural History) on the grounds that the new dinosaur and fossil man exhibits are vehicles for the didactic presentation of a cladistic interpretation of evolution and taxonomy. He goes on to suggest that cladism and a saltationist interpretation of the history of life provide support for a Marxist view of history by progressive revolutions.

The political argument was questioned by Hughes-Games[2] and Rothman[3] and is, really, a diversion from the main issue. Marxists and creationists may find support for their ideas in cladism and punctuated equilibria, but the interpretation placed on fact or hypothesis by people with a particular axe to grind should not affect the development of primary research.

Patterson[4] presents some arguments on the validity of cladism and its relationships to evolutionary theory. This is an area that will probably continue to be discussed for many years (no doubt to the amazement and disgust of all non-participants).

However, the main issue is the exhibitions policy of the Museum. This question can be split into two: "Are the new exhibits balanced reflections of current scientific opinion?" and "Do the exhibits satisfy the public?".

The first point is answered with a resounding "no" by Halstead, and, I think, a partial "yes" by Patterson. Patterson states that "amongst scientists in the Museum there are many different viewpoints on the value and generality of cladistic methods", but this is not reflected in any exhibit yet. Is there any plan for a presentation of the views of "classical taxonomists" who regard cladism as an important analytical tool, but not as the sole aim and guiding principle of their research, or of numerical taxonomists (again with provisos as to applicability)?

The second question has not been asked yet. The new exhibition policy was started in the mid-1970s with the important aim of presenting a dynamic view of biological processes and it was stated that ". . . the scheme will be worthily carried out only if we can provide instruction and pleasure to the population as a whole . . ."[5]. Is this aim satisfied?

I will comment only on the dinosaur exhibition. This occupies the prime gallery of the Museum — the main entrance hall. Large skeletons attract the visitor and strategically placed stalls market books, postcards, badges and models. The alcoves on either side contain the teaching parts of the exhibit and show examples of contemporaries of the dinosaurs and the much-criticized presentation of cladism. However, the interested visitor will search fruitlessly for information about life-style, function and physiology of dinosaurs. My experience from presenting lectures to school children, natural history societies and adult education classes is that all these groups of laymen want to know if dinosaurs were warm-blooded, why they were so big, how they used their horns, spines and frills, how we collect them, why they died out, and so on. When I mention taxonomy there is a general glazing of eyes, fidgeting and covering of mouths. This may be an indictment of my teaching methods, but I think that it is also a reflection of what people consider interesting.

If the Public Services Department plans displays on dinosaur biology (functional anatomy, ecology, behaviour), I apologise for these remarks. If not, I don't.

Halstead replies

SIR — In view of the seriousness of the criticisms[1] levelled against the Natural History Museum, it seems a little surprising that they failed to elicit any response from the Director or even the Head of the Public Services Department. The only letter from the museum was from a senior member of the Palaeontology Department[2], who appears to be concerned with roundly condemning the very policies which were the subject of my initial protest.

Patterson[2] insists that "cladistics is not about evolution" and that there is "no connection between cladistics and one view of the evolutionary process". The "cladistic literature" to which he refers to support these assertions comprises only papers by Platnick[3] and himself[4], and these deal with what is known as "transformed cladistics". This is most definitely not the kind of cladistics being portrayed in the public galleries of the Natural History Museum, to which Patterson appears to be resolutely opposed. The museum's Public Services Department in fact accepts the classic version of cladistics as set out originally by Hennig in *Phylogenetic Systematics*[5]. The title of his book is frequently taken as a synonym of cladistics[6], a term which refers specifically to the importance of the branching process (speciation) in phylogeny[6]. Hennig's view of the origin of new species involved the splitting of the ancestral species as a consequence of geographical isolation (allopatric speciation)[5].

The long recognized (in spite of Patterson's contrary assertion[2]) connection between cladistics and punctuated equilibria, a fundamentally "leap" or saltation view of the process of evolution, has recently been emphasized by Cracraft[7] and noted by others[8,9]. Eldridge and Gould[10] formulated the theory of "punctuated equilibria: an alternative to phyletic gradualism" by applying the concept of allopatric speciation, as used by Hennig, to the fossil record. In a subsequent review of the topic and the controversy it had engendered, Gould and Eldridge[11] contrasted the concept of gradualism "embedded in the modern history of Western cultures" with that of the "official 'state philosophy' of many socialist nations" where the "laws of change are explicitly punctuational", quoting Engels and the official Soviet Handbook of Marxism–Leninism to this effect. Their basic Marxist approach to evolution has been generally recognized as such, by *inter alia* Gray[12] and Hughes-Games[13]. The latter and Lewin[14] hold the view that the concept of punctuated equilibria is on the way to becoming the orthodoxy of the future. This being so, it is not unexpected that many of its new-found adherents may well be unaware of the philosophy behind the cause they are espousing.

The major controversy regarding the process of evolution and the fossil record concerns the notions of the origin of new species by sudden splitting (Hennig[5], Eldridge and Gould[10,11]) — the Marxist model, as against the gradualist model associated with Darwin[15], Mayr[16] and Simpson[17]. I am associated with the latter model, not from uncritically accepting the authority of Mayr and Simpson but on the basis of my own research experience.

The death of scholarship in the Natural History Museum is not in my opinion marked by the advocacy of cladistics or even Marxism in the public galleries, as Patterson[2] seems to imagine, but rather in the manner of the advocacy. The exhibits on dinosaurs and fossil man together with their accompanying books avoid any discussion of the gradual evolutionary versus the revolutionary "leap" concepts, by the simple expedient of accepting the basic assumptions of one and ignoring those of the other[18]. It is this crude partisanship which is indeed the unacceptable "strident voice of authority".

The insistence on a chosen received dogma, such as that no fossil species can be considered ancestral to any other, has led the Public Services Department into its obvious differences of opinion with the museum's Sub-Department of Anthropology over *Homo erectus*. That "there is not any serious doubt about *Homo erectus* being ancestral to *Homo sapiens*" is contrary to the rules of the cladistics as applied in the exhibit but is in fact the considered opinion of the scientific staff of the museum's own Sub-Department of Anthropology, and certainly the literature that immediately comes to hand appears to agree with this, including as it does cladistic analyses[19-24]. The most telling evidence, however, comes from within the covers of the museum's own book, *Man's Place in Evolution*[25]. I have already drawn attention[1], in this context, to the vitally important Petralona skull, the phylogenetic position of which was recently discussed in detail by Stringer, of the Natural History Museum[19] and by others[26,27]. The skull figures in the book, but curiously has been excluded from the exhibition itself. It would have served as a dramatic illustration of a transitional form exactly intermediate between *Homo erectus* and *Homo sapiens* but would at the same time have destroyed the credibility of the cladistic dogma being promoted. In the museum's public galleries, it now transpires that, unlike elsewhere in science, "ugly facts" are not to be permitted to "slay beautiful hypotheses".

The Director in his preface writes that, like the exhibit, the book "was planned with the guidance of Museum experts, particularly from the Museum's Sub-Department of Anthropology"[25]. This gives the entirely misleading impression that what is on display and published by the museum represents the considered views of the museum's own anthropologists. This is most certainly not the case and one cannot help but wonder whether the Director is actually aware of what is going on in the institution which he heads.

Finally, lest it be thought that my previous letter might be construed as "dangerous to the unfettered development of science" [28], in my estimation it is the current policies of the Public Services Department of the Natural History Museum that are already having just such an effect. I am not opposed to the public presentation of a reasoned case for cladistics, be it transformed or classical, as I have demonstrated by employing cladistic analysis in my own research[29]; nor have I any objection whatsoever to the presentation of a Marxist interpretation of the history of life, if done in the open and scholarly manner of a Stephen Jay Gould.

My objection is to a major public scientific institution, renowned internationally for its scholarship, to be seen to be abusing its authority by attempting to impose on the general public, against the scientific judgement of its own experts, controversial concepts not by argument or discussion but simply by unsubstantiated assertion.

Science and values

Sir—Between November 27 and 30 1980 I attended, as an observer, the 9th International Conference on the Unity of Sciences (ICUS) in Miami Beach. It was host to 640 participants from 85 countries. The concensus of the overwhelming majority of those who attended was that the conference, under the banner "Absolute Values and the Search for the Peace of Mankind", was a great success. Imagine, then, the consternation with which I read your editorial comment (*Nature* 27 November p.310) on ICUS "Best not to attend on Mr Moon", which launched scathing broadsides on the founder, seemingly, the aims of the conference, and, indirectly on the integrity of the participants themselves.

Science and values, naturally, reside in different worlds. One cannot understand man's spiritual quest (for liberty, truth, beauty etc.) by empirical laws nor can one restrict scientific endeavour with religious dogma. Yet who can pretend, in a world exhibiting both desperate physical need and social disintegration, that they have nothing to do with each other? This is where I consider the ICUS makes its unique contribution — as an interdisciplinary forum where scholars can freely exchange ideas developed in their own fields about the pressing needs of the world. Few would consider this an "extraneous cause". Are we to understand then, that in referring to Moon's addresses as "vacuous", and implying the term "values" to be meaningless, the editorial policy of *Nature* is to preserve the steps up the ivory tower of scientific learning unsullied by the muddy boots of morality and social responsibility?

Another point of contention is the assertion that "the participants . . . are (not) the group ideally suited for the discussion of the broad themes . . .". If eminent academics in the fields of science, philosophy and the humanities are *not*, then who is?

The conclusion of one committee chairman at the end of the Miami conference was that probably more questions had been raised than answered. I would agree with this. The aims of a body like the ICUS are not easily achieved but the challenge to the academic community to work towards the unity of the sciences can only have positive results, more than satisfying merely an intellectual appetite.

NSF and cryptology

Sir — In view of the extensive recent discussion of the respective roles of the National Science Foundation (NSF) and the National Security Agency (NSA) in support of cryptological research (see, for example, *Nature* 4 September, p.2) , I believe it may be useful to restate the foundation's established policy in this area.

The essential points of our policy with respect to cryptological research are these:

(1) Since mid-1977 we have routinely referred proposals with relevance to cryptology to NSA for review. We will continue to do this. The practice serves to keep NSA informed of NSF's activities in this area, and gives NSA an opportunity to make technical comments on proposals which can be useful in making funding decisions. It is not a "clearance" process; whatever comments NSA may make are advisory.

(2) NSF has long had a policy of encouraging other agencies to support basic research in areas relevant to their missions. We have specifically encouraged NSA to establish an unclassified basic research programme, and stand ready to assist that agency in this effort. We believe it is fundamentally healthy to have alternative sources of support in important areas of science, and anticipate no difficulties in maintaining close coordination between NSF and NSA.

(3) In cases in which alternative sources of support are available, we routinely encourage principal investigators to apply to such sources as well as to NSF. However, if an investigator prefers to apply only to NSF, we will consider the proposal in the usual manner, without prejudice, and reach a decision on funding using our usual criteria and peer review process.

(4) NSF does not expect that the results of the basic research which it supports will be classified, except in very rare instances. NSF does not currently have classification authority, but it has responsibility, under routine executive orders issued by both the current and previous administrations, to refer any information which it believes might require classification to the agency with appropriate subject matter interest and original classification authority. For cryptological research, that agency is NSA. The important point here is that it makes no essential difference, in terms of the likelihood of classification, whether research is supported by NSF or NSA. This policy is of long standing, and applies to all areas of research.

(5) NSF has long-established reporting requirements which allow it to meet its responsibility for prudent use of public funds. These might not be adequate in all cases where research might have special relevance to national security, and in such cases we may consider special reporting requirements. We have not done this in the past, and we may not have to do it in the future. If we did have to establish such reporting requirements, however, we would regard this not as a change in policy but simply as a change in administrative procedure necessary to apply a long-standing policy to a changed situation.

In summary, the foundation will continue to support cryptological research, will continue to coordinate such research with NSA, and will continue to encourage NSA to develop its own basic research support programme. The results of such research have not been classified in the past, and we do not expect them to be in the future, but we will ensure that our reporting requirements are adequate to allow us to meet our responsibilities with respect to possible classification. Most importantly, the foundation has a basic policy of supporting the best research it can find in all areas of science and engineering, with the fewest possible restrictions on investigators.

Behind the fridge

Sir—It is highly likely that the reservoir at the back of a self-defrosting refrigerator provides an excellent breeding ground for microorganisms (*Nature* 20 November 1980, p. 208). However, your correspondent's suggestion that these organisms might cause pulmonary infections such as Legionnaires' disease neglects to consider that they would first have to be dispersed in the form of an aerosol. It is difficult to imagine how this might happen other than when the machine is subject to violent movement.

Old *Nature*'s almanac for 1981

In early times the beginning of each year was marked by the publication of almanacs intended to chronicle events in the succeeding months. Most of these documents were necessarily blends of fact and fiction. The following, however, is an authentic chronicle of the new year.

January: Bitter weather. President Ronald Reagan (20 January) says at inauguration that "we have nothing to hope for but hope itself", and commits the United States to "making the shuttle work within this decade". Dr William Nirenberg appointed chairman of reconstituted President's Science Advisory Committee. Yugoslavia establishes biotechnology enterprise (capital $20 million) with licence to manufacture insulin from "porcine pancreatic tissue". *Nature* publishes 25-page human mitochondrial DNA sequence. Earthquakes in Tashkent. Mercury and Mars ill-placed for observation.

February: Bitter weather (except in Southern Hemisphere). General Alexander Haig reaffirms opposition to Salt II at Senate confirmation hearings on nomination as US Secretary of State. Mass of neutrino measured at Savannah River reactor experiment as 30±35 electron volts; US Department of Energy announces "riddle of Universe all but solved" and President Reagan gives new go-ahead for Clinch River fast reactor. *Nature* publishes first instalment of DNA sequence of human chromosome 7 (F.Sanger); Unesco announces "emergency meeting" of journals editors (Addis Ababa, 1985) to consider "sequence pollution". Interim report of Swinnerton-Dyer committee on organization of University of London says that university must save money "or face prospect of radical change". Earthquakes in Hellenic arc. Venus and Mars ill-placed for observation.

March: Bitter weather; much flood. American journal *Science* begins publication of nucleotide sequence of human chromosome 7 (W. Gilbert); Senator William Proxmire announces public hearings on question "Are sequences necessary?". US General Accounting Office recommends that Shuttle Tile Repair Module be adapted as skyscraper window-cleaning machine. Neutrino mass estimated as 50±55 electron volts by observation of diffuse ultraviolet background; NASA announces "mystery of Universe now cleared up". British universities told that in future, *all* students must pay economic fees. General Alexander Haig (at continued Senate hearing) reaffirms opposition to Comprehensive Test-Ban Treaty. Earthquakes in Caribbean. Mercury, Venus and Mars ill-placed for observation.

April: Sakharov writes to announce arrival of Spring in Gor'kii. *Nature* begins publishing errata to Sanger chromosome 7 sequence. Tanzanian Secretary-General of Addis Ababa conference on sequences calls for extension of terms of reference to include measurement of neutrino mass, and charges that present practices of journal editors discriminate against developing nations. First shuttle flight crew sues NASA over early retirement terms. British Chancellor of Exchequer levies Value Added Tax on university fees, but affirms "monetarism is working". Professor Milton Friedman appointed Companion of Honour. Earthquakes in the Levant. Mercury, Venus and Mars ill-placed for observation.

May: Unseasonable weather. Soviet government accedes to Sakharov's request to be put on trial, but postpones formal charges. Dr Edward Parkes (chairman, UK University Grants Committee) says "no compelling reason" why British universities should be closed, but confesses anxiety about recurrent grant. Centenary celebrations of British Museum (Natural History) pass off without incident; cladists and opponents silenced by Royal presence. Dr F. Sanger forswears nucleotide sequencing until "somebody decides what to do with the data". President Reagan, by executive order, merges Clinch River and shuttle projects, offering management contract to Government of France. General Haig tells Senate confirmation committee that US Administration will "seek to repeal" Anti-Proliferation Act. Earthquakes in Andes. Mars ill-placed for observation.

June: Bitter weather in Antarctica; much flood elsewhere. Merrison committee on "dual-support system" for UK academic research argues that because academic research has continued even though the system has "long since" broken down, there is no special need of new mechanisms for research support. Proxmire Senate committee condemns sequencing research as "pork-barrel biochemistry" and proposes legislation denying federal funds to institutions defining sequences of "more than 52 contiguous nucleotides". General Haig confirmed as US Secretary of State after promising to press for early signature of Comprehensive Test-Ban Treaty and ratification of "upgraded Salt II". Rockwell International (main shuttle contractor) announces development of Shuttle Tile Repair Kit as personal space transport module. Earthquakes in Italy. Mercury and Mars ill-placed for observation.

July: Inclement weather. House of Lords committee on "Science and Government" urges reorganization of UK science with separation of research councils from Department of Education, appointment of minister with reponsibility for science and re-creation of Advisory Council on Scientific Policy. UK biotechnology company Celltech takes licence on Yugloslav insulin process. Committee of Vice-Chancellors and Principals announces "agreement in principle" with British Tourist Board that universities will put facilities and staffs at disposal of tourist industry during future extended long vacations in exchange for commission on tourist receipts; growing anxiety about future of Salford and Aston universities. NIH reaches compromise with Proxmire committee on safeguards procedure for regulation of sequencing work. Eclipse of Sun (31 July) visible in Middle East and central Asia. Mercury ill-placed for observation.

August: Improbable weather. NASA commissions Boeing design of reusable long-distance transport system based on 747 with "orbital operation development capability". US Department of Energy dedicates Clinch River site as "national center" for measurement of neutrino mass. Second Voyager approaches Saturn; Jet Propulsion Laboratory announces that "mankind has learned more about the Solar System in the past month than in the previous twelve". *Nature* finishes publishing errata to Sanger chromosome 7 sequence (see April). Europe on vacation. Mercury, Mars and Saturn ill-placed for observation.

September: Bitter weather. Sakharov trial postponed. British universities postpone *sine die* opening of new academic year in plan to avoid shutdown. UK government abolishes posts of chief scientist in government departments, but denies abandonment of Rothschild "customer–contractor" principle, pleading only "further steps in battle against public expenditure". Legality of NIH Advisory Committee on Nucleotide Sequences tested in US Supreme Court; Senator Proxmire agrees to modify bill for fear that "United States will lose out to foreign sequencers". Neutrino mass held "indistinguishable from zero" on basis of tritium decay measurement; Clinch River site re-dedicated as "National Nucleotide Sequence Repository". Mercury, Jupiter and Saturn ill-placed for observation.

October: Bitter weather. Interim shuttle modification programme approved by NASA; US General Accounting Office complains that the Orbitwise Re-entry Module Assembly Kit will leave no room in the cargo bay for payload, and that the decision that the shuttle vehicle itself should be disposable will have "negative economic consequences except in California". UK research councils say in annual reports that they have survived better than feared in worsening economic climate and that abandonment of grant-making is only temporary. Dr J. L. Gowans, Secretary of Medical Research Council, denies at press conference statement attributed to him that "medical research is mostly good luck" (see *Nature* 1/8 January, p.2); rather, says Gowans, "inspired guesswork". Mercury, Jupiter and Saturn ill-placed for observations.

November: Extremes of climate. Nobel prizes: Medicine, Dr César Milstein (for monoclonal antibodies); Chemistry, Dr Fred Sanger (for a method of sequencing carbohydrate macromolecules); Physics, Professor F. W. Reines (for drawing attention to the problem of the neutrino mass). NIH announce further relaxation of sequencing guidelines; joint NIH-EMBO sequence bank commissions advanced computer design from Rockwell International. No planets ill-placed for observation.

December: Weather mixed. Swinnerton–Dyer report on organization of University of London offers "stark" choice between expulsion of and management by Imperial College; university Senate resolves that changes of function unwelcome to those affected should not be effected. Vice-chancellors announce British universities will begin academic year once cold weather is ended (to avoid excessive heating bills) and "certainly no later than beginning of tourist season". Boeing claims "synchronous orbit capability" for 747; proposes development programme for returning flying machines to Earth. Proxmire committee begins investigation of "neutrino mass boondoggle". Harvard University converts P3 laboratory to squash-court. Eathquakes in Tashkent. Mercury again ill-placed for observation.

nature

15 January 1981

4/1/82.

Too soon to build laser weapons systems

The belief that science fiction must inexorably be transmuted into fact appears partly to account for the wave of interest in laser weapons which has recently been sweeping the United States. Ever since Darth Varda (the villain in *Star Wars*) showed how easily opponents could be evaporated with a flick of a ray gun, it has been a question only of time before the Pentagon and its counterparts elsewhere should be discovered to be working on weapons systems based on lasers. In reality, the Pentagon has been spending about $200 million a year for the past few years on the technology of high-energy lasers, and development may accelerate (see page 111). Some kind of laser system is likely to be one of the first military payloads to be carried aloft by the shuttle system. And there is an expectation (not yet falsified) that the new president will be more willing to put money into novel weapons systems, even harebrained devices, than his immediate predecessors. It is no wonder that laser weapons seem like weapons systems whose time has come.

A measure of scepticism is therefore in order, and has fortunately been provided in the past few weeks by a document (*High energy laser weapons — a technical assessment*) by M. Callaham and K. Tsipis of the Massachusetts Institute of Technology. The document is no more than a review of how laser weapons might be used and of the problems that will have to be solved before practical weapons systems could be put to work. Would-be Darth Vardas may regard it as a promise of goodies round the corner. More sober reading of the text suggests that even if the formidable technical problems which are all too apparent can be solved, there will persist serious physical limitations of what can be accomplished by laser weapons. In other words, there seems no immediate reason why anybody should fear that the already fragile framework of international relations is about to be transformed by yet another new technology.

The uses suggested for the non-existent laser weapons would gladden any Darth Varda's heart (if he, she or it has one). Offensive uses include the delivery of large amounts of energy on the heads of troops on battlefields and the destruction of other people's Earth satellites. But, on paper, laser weapons could also be used defensively for intercepting hostile missiles or at least aircraft. Laser systems can in principle be based on the ground or carried aloft, either in aircraft or satellites (and the United States has at present at least one Boeing 747 fitted out with equipment designed to study the propagation of laser beams in the upper atmosphere). In all cases, the objective is to exploit the coherence and potentially large energy intensity of a beam of laser radiation to damage objects or people. On paper, at least, directing a laser beam at chosen targets should be relatively easy, given that photons have no inertial mass. Perhaps fortunately, there are snags.

One is a snag well educated schoolboys will be aware of. Although it is customary and usually fair to suppose that a beam of laser radiation is a parallel pencil beam, Huygens's principle is not suspended for the benefit of military planners. The best-ordered laser beams spread out to some degree, and the effects are far from insignificant when people talk (as some do) of using lasers based in geosynchronous orbits for damaging objects at ranges of several tens of thousands of kilometres. In most of the applications dreamed up so far, damage is determined by the maximum intensity of the beam. At a range of 1,000 kilometres, the intensity of the infra-red beam from a carbon dioxide laser with an initial aperture of a metre would have declined by a factor of 400 even in transmission through a vacuum. Propagation through the atmosphere entails more rapid degradation as a result of Rayleigh scattering by molecules, by turbulence and by absorption and scattering by water droplets or particles of dust. Operations below the stratosphere will be impeded by haze and clouds (although it is entirely feasible that laser beams could be made powerful enough to burn through some meteorological obstacles). But even in a clear atmosphere, the beams of high-powered lasers are degraded for reasons rarely encountered in the laboratory. Inevitably, there is a temperature gradient and thus a gradient of refractive index across an intense laser beam and the result is, predictably, that the beam is further broadened. The chances are that a good part of the Pentagon's expenditure on military laser systems is spent on the study of this phenomenon of "blooming". The obvious remedy is to work with ever shorter pulses of radiation, but there are limits to what can be done — if the power transmitted is to remain unchanged, there is a risk that increasing field strengths will turn the atmosphere into a plasma and thus render it opaque, or generate out of the surface layers of the target a similarly protective plasma skin.

Other physical obstacles to the development of laser weapons, problems of energy supply not least among them, promise to be just as daunting. Directors of science fiction films do not fully appreciate that lasers, like other sources of energy, themselves consume power. Even supposing ideal efficiency within a laser itself, which supposes that problems of heat dissipation within the optical system are somehow solved, the quantities of energy that must be beamed about the sky in the pursuit of military targets are certain to be huge. If, for example, the objective is to deliver something like 100 joules of energy to each square centimetre of the surface of a target at a range of 1,000 kilometres, the output of a laer would have to be some 400 megajoules, allowing for the spreading of the beam from a one-metre mirror. On paper, a few kilogrammes of hydrogen fuel (and eight times as much oxygen for combustion) might be sufficient for a single attack of such a kind. Such a rate of energy consumption might be tolerable for a ground-based weapon but would be entirely out of court, at least with present technology, for a system based in some orbit around the Earth. It is therefore not surprising that the calculations that Callaham and Tsipis have carried out, admittedly back of an envelope stuff, suggest that laser weapons systems might have masses of several thousands of tons. No doubt, by ringing the changes on pulse length, mirror diameter and the like, the people at the Pentagon would be able to arrive at better compromises, but there seems no doubt that laser weapons will be huge constructions, a little like particle accelerators in the complexity of their power supply.

Such obstacles are unavoidable. Others may be more susceptible to research and development but remain, as things are, quite overwhelming. One curious aspect of the recent excitement about laser weapons is the continuing uncertainty about the best way of using a laser beam to destroy a target. The simple notion that its surface might be melted or even vapourized entails that large quantities of energy should be delivered to the target. The mechanical shock caused by a pulsed laser beam may be a more economical way of causing damage, but is less predictable. This is clearly one area in which the military have ambitions for research and development. The technology of picking out targets at which to aim is another. Laser beams themselves may have no inertia, but the mirrors which fashion them are material objects that must be pointed in a direction

0028-0836/81/020109-02$01.00

which is likely to intercept the intended target. Given the kinds of targets the planners have in mind, however, the computational and mechanical tasks that they must solve are formidable.

This is why the issue that will face the new Administration in Washington, and its counterparts elsewhere, is whether the game is worth the candle. For whatever virtues laser weapons may eventually be shown to have, there is no doubt that they will be uncommonly susceptible to relatively simple countermeasures. A simple false skin on every warhead would do the trick, while laser weapons would themselves be put off their stride by much less powerful hostile lasers. These are the reasons why even hawks in Washington are now asking that Mr Reagan should not decide to spend even larger sums of money than at present on the development of laser weapons. For the time being at least, there are better ways in which the Pentagon could spend large sums of money. The time for going all out for laser weapons is not now but later, perhaps when somebody has a clear idea for a laser weapon system that could perform a tangible if limited role in the foreseeable future. Mr Reagan's opponents on laser weapons cannot, however, have it both ways. If the technical problems are as formidable as they say, and the opportunities as negligible, there is little danger that wasting money in this way would further disturb arms control negotiations with the Soviet Union. If there were a prospect that, say, a workable anti-ballistic missile system based on a laser might be developed within a decade, it would be a different matter. On present form, that danger is remote.

What if Britain wants not to change?

The Centre for Technical Change has made a brave start on a daunting problem — the diagnosis and, with luck, the cure of Britain's chronic problem of turning research and development into prosperity (see page 114). Sir Bruce Williams, the newly appointed director of the centre, is a prize catch. His appointment should go a long way to still some of the muttering about the centre's chances of success. Even so the centre's wellwishers will keep their fingers crossed. British institutions, but especially the civil service, habitually resist gratuitous advice, which is why organizations like the Brookings Institution have not flourished in the United Kingdom. The most obdurate of the problems which the new centre will have to solve is that of making people listen to what it has to say. To do this, it will need guile but also an imaginative, even a radical, agenda. Where should it begin?

There is no shortage of conventional accounts of what is wrong with the British economy, and with the linkage between the economy and technology. For the past thirty years, public support for research and development has been generous, even profligate, but only in retrospect has it dawned on people that much of this effort has been misplaced. Defence research, especially in aerospace and electronics, has taken the largest share of public funds. Throughout this period it has been assumed, in the face of experience and against reasonable expectations, that work carried out in secret in government laboratories would somehow filter through to revivify the civil economy. In retrospect, nobody is surprised that this has not happened, that the British aircraft industry has an annual turnover smaller than that of Boeing or that the British government is having to spend public money on last-minute attempts to foster the design and manufacture of microprocessors. Yet the huge defence laboratories remain more or less intact, ageing slowly as their staffs approach retirement.

During the past thirty years, British governments have inconsistently tried to remedy this state of affairs. They have encouraged the production of graduates in science and technology (1955–65) in the belief that such people would make a market for their services. They have encouraged the creation of large technical companies (1964–70) in the vain hope that the conglomerates would seize the opportunities which technology presents. They have wasted money and, worse, people's talents on glamorous projects with no economic benefit such as the Concorde project (inherently uneconomic) and nuclear power (where even successful innovations have been pigeonholed until recently). Throughout this period, governments have sought without conspicuous success ways of encouraging technical innovation in the general run of British industry, finding only that the small and medium-sized firms best placed to profit from radical innovation are the least able to raise the necessary capital.

This depressing record shows that there is no point in hoping that research and development, or skilled manpower, can by themselves improve the exploitation of innovation by British industry. Indeed, the chances that such an old-fashioned recipe would work are less than they have ever been. Industry, especially small industry, does not lightly think of spending extra on research and development at times like these. (The exceptions are those companies, many of them in the chemical industry, which have learned in the past thirty years that research and development is not merely profitable but indispensable.) Moreover, there is little hope that the new centre will be able to produce such a more penetrating analysis than other analysts of the ills of the British economic system that the scales will fall from people's eyes, expectations of prosperity will be reduced to some amount commensurate with the Gross Domestic Product and the ills of inflation and deflation will be cured less painfully than by monetarism.

So where is the Centre for Technical Change to look for an agenda if these obvious fields of enquiry are likely to be ineffectual? Fortunately, not every hopeful door is shut. There are two particular fields in which the centre could do sterling service. First is the British education system, now most of all distinguished by its eccentric and inexplicable differences from other educational systems in other industrialized states. British first degree courses are shorter than elsewhere, but those who embark on them have to demonstrate in advance that they have already covered much of the ground. The result is that too many narrowly educated people, mock-specialists before their time, are turned out into a world in which their teachers are constantly declaiming the need for continuing education to meet changing needs. Throughout the educational system, the pursuit of academic excellence is properly regarded as a virtue. Improperly, the use of the educational system for the pursuit of something else, say wealth or even happiness, is regarded as a kind of sin. Occasionally, out of subliminal recognition that there may be an inconsistency somewhere, people like Sir Monty Finniston are persuaded to preside over inquiries into the parlous condition of this or that profession (engineering in his case). Perhaps they are lucky, since their inquiries are always so confined that governments usually decide not to act on their recommendations or (as in Sir Monty's case) to act halfheartedly. For a nation as preoccupied as the British with education, it is increasingly ridiculous that so much of what is said should make so little sense.

The second field in which the Centre for Technical Change should take an interest is closely related. British civility is, of course, renowned, and is probably also a product of the educational system. People do not openly seek to embarrass one another. The result is that casual acquaintances need not fear that they will have to disclose their salaries at dinner parties, which makes for congeniality. Unfortunately, the same principle applies in the real world. People in industrial research make their reputations by publishing in academic journals; occasionally they become (unpaid) visiting professors at a neighbouring university. Salesmen sell first to their sales managers, and afterwards to their customers. Rarely is it allowed that the pursuit of pound notes can be a seemly occupation — or that the consequences of success can ever be worthwhile. The problem for the centre, in tackling such a subject, is twofold. Is it capable of objective analysis and presentation? And would such an analysis, however rigorous, merely persuade the genteel British that things are better as they are?

Reagan assailed by laser weapon lobbies

Hawks say go: doves argue caution

Washington

An early confrontation seems to be brewing between the Administration of incoming president Mr Ronald Reagan and members of the scientific community concerned with international arms control over plans to develop laser weapons for use in space.

Key congressional Republicans are said to have been told by members of Mr Reagan's transition team for the Defense Department that he wants to increase research and development on the use of lasers to destroy incoming ballistic missiles. One report claims that an early launch of the National Aeronautics and Space Administration's space shuttle will test an aiming device for a space-based laser, a project code-named Talon Gold.

But these rumoured plans are coming under strong attack from scientists who claim that laser weapons systems would not only be extremely costly and of dubious technical value, but that an accelerated research programme could upset the chances of negotiating an agreement over how such weapons should be controlled.

Speaking at last week's meeting of the American Association for the Advancement of Science (AAAS) in Toronto, for example, Dr Richard Garwin, chief scientist at IBM's Thomas Watson Research Center, claimed that excessive emphasis on directed-energy space weapons diverts funds and talent from more serious and more effective threats.

Mr Reagan's quoted views are compatible with a report from the science and technology subcommittee of the Senate Commerce Committee, which says that if rumours of an impending commitment by the Soviet Union to develop laser weapons are to be taken seriously, then there should be a significant increase in support for the Defense Department's research programme in the area.

The Senate committee admits that there is an "unsettling" diversity of opinion within the US scientific community about the technical and economic feasibility of high-energy lasers in a wide variety of potential applications, including defence, but it points out that the present Department of Defense budget allocations for high-energy laser research are not sufficient to achieve operational weapons as early as would otherwise seem possible. An increase in funds and commitment by the department would, it says, "significantly accelerate the achievement of directed energy weapons systems", a view apparently shared by leading members of Mr Reagan's defence transition team.

The Senate report provides some insight into the controversy about US efforts in laser weapons research that has simmered within the Pentagon for several years. The controversy surfaced in 1979 with reports in *Aviation Week* that the Soviet Union had begun to build a large high-energy laser at Sary-Shagan, a weapons testing area near the Chinese border, and that this appeared to be the first step towards a full-blown laser weapons system able to destroy both satellites and incoming missiles.

Defence officials have been divided on how to respond. Some — in particular, Dr William Perry, Under-Secretary of Defense for Research and Technology — have played down the potential threat, arguing that the gap between theory and practice was so large that the Soviet Union was unlikely to have a weapons system in operation until the 1990s, and rejecting claims that the Soviet Union had a significant strategic advantage in this area.

Others in the Pentagon have been dissatisfied with this reaction, and have been pushing for an aggressive laser weapons research programme, demanding substantial increases over the current $215 million a year being devoted to the high-energy laser research, primarily in the Air Force and by the Defense Advanced Projects Agency.

The dominant thinking within the Carter Administration has been that the main emphasis should remain on research. The report of the Senate committee — apparently now in agreement with Mr Reagan's advisers — is that research alone is not enough, and that "a balance between technology development and weapons system development" is needed.

The committee suggests, for example, that a special office be created within the Department of Defense to manage and direct the overall high-energy laser programme of the department, rather than distributing its research and development efforts across the different services. And it endorsed a bill introduced by Senator Howell Heflin of Alabama to create a National Laser Institute to coordinate all laser research and development.

Fears that such enthusiasm may be allowed to flourish relatively unbridled under the new administration are prompting the members of the arms control community to argue strongly that the national security implications of even an accelerated research programme should be carefully considered.

In a recent report from the department of physics at the Massachusetts Institute of Technology, Kosta Tsipis and Michael Callaham point out that, over and above the severe technical and economic hurdles facing the development of a full laser weapons system, even a research programme could be upsetting to strategic arms limitation talks, since it would be difficult to tell whether the research was for defensive or offensive purposes.

In his paper to AAAS, Dr Garwin argued in a similar vein that space-based lasers would be highly vulnerable to attack by anti-satellite rocket vehicles, which could be developed with a fraction of the resources required to install the space weapons.

David Dickson

European science portfolios still for grabs

Brussels

The division of portfolios among the new members of the European Commission last week has left scientific research in the dark. The next few days should give the *cabinets* of the principal commissioners, Etienne Davignon and Ivor Richard, the new British commissioner, a chance to sort out their division of responsibilities.

So far it seems that Davignon, a Belgian viscount, will be taking over responsibility for all energy and industrially related matters, while Ivor Richard will take over the rest of research, science and education. This will involve some reshuffling of the bureaucracy, but nobody is prepared to predict what effect these changes at the top will have on policy.

Davignon, now entering his second four-year stint as commissioner in charge of industrial affairs, has become one of the most powerful figures in Brussels through his handling of the steel crisis. He takes over responsibility for energy from the now departed German, Guido Brunner, and has already made it clear that he aims at a tough energy-orientated policy to revive European industry.

His chief interest in research is likely to be the development of energy-efficient technology, alternative energy sources and research aligned with industrial innovation. A notable advocate of Community programmes in telematics (the marriage of chip technology and telecommunications) and bioengineering, it is doubtful whether, with the broadening of his responsibilities, he will have much time to devote to the poorer aspects of Community research programmes.

This leaves Ivor Richard in charge of the joint research centres, education and training, which will tie in neatly with his responsibility for employment and social affairs. Another new commissioner, Karl-Heinz Narjes from the right-wing German CDU party, has been given undefined portfolios for industrial innovation, nuclear safety and environment and consumer pro-

0028-0836/81/020111-02$01.00

tection. Narjes, like Davignon a lawyer by training, is regarded as being for nuclear power and, with little in his past to suggest that he will be particularly radical in his approach to environmental issues, his coming is regarded with some apprehension.

Ivor Richard's past experience in the Labour government includes the post of parliamentary under-secretary of state for defence in 1969–70 and deputy spokesman on foreign affairs between 1972 and 1974. He was the British ambassador to the United Nations from 1974 to 1979. Previously he had been a Council of Europe delegate and, during the same period, 1965–69, had been with the West European Union.

The new commissioners as a whole are largely right-wing men with legal backgrounds. They include nobody with previous experience in scientific affairs. It may be an advantage, however, that Richard, without any other major responsibilities, will be in a position to give his full attention to promoting the interests of his directorates-general. Davignon is certainly keen to increase the Community's influence on the industrial research programmes of the member states. It will clearly be some time before the new Commission settles down and begins to exert an appreciable influence on Community policy; undoubtedly the immediate problems associated with the budget and the form of the Common Agricultural Policy will take precedence for the time being. **Jasper Becker**

Nucleotide sequences

Too many banks?

The US National Institutes of Health (NIH) and the European Molecular Biology Organization (EMBO) seem well on the way to founding a computerized bank of nucleotide sequences, but would-be competitors have not yet withdrawn from the field. The joint NIH/EMBO plan springs from meetings in Bethesda (Maryland) and Heidelberg last year, both of which acknowledge that nucleotide sequencing techniques now in use are likely to generate more information than can be assimilated informally.

For the time being, nucleotide sequences are being collected at EMBO headquarters in Heidelberg by Mr Greg Hamm. Other centres interested in the collection of nucleotide sequences include the George Washington University, Washington DC, where Dr Margaret Dayhoff plans to broaden the scope of her collection of amino acid sequences; the Los Alamos Scientific Laboratory; and Professor Richard Grantham's CNRS *Laboratoire de Biometrie* at Lyon.

The work now being carried out at Heidelberg is regarded as a necessary preparation for an eventual long-term decision by EMBO and NIH. It is by no means certain that the two institutions will continue to collaborate, although such an arrangement is seen as a potentially valuable precedent. In the meantime, the Heidelberg collection is being compiled and made available informally.

The outstanding technical problems are more concerned with molecular biology than with computer technology. Storing, retrieving and comparing nucleotide sequences stored in computer language can be tackled with existing programs, but decisions have yet to be made about the criteria by which sequences should be considered authentic, while the problems of merging incomplete sequences with each other, and of accommodating and authenticating variations, will entail something like a critical evaluation of data in molecular biology.

The NIH/EMBO plan assumes that nucleotide sequences will eventually be made available to all suitably qualified scientists, but also supposes that the effective management of a sequence repository will require the continuing presence of a small group concerned with the analysis of sequence data.

Professor Richard Grantham's plans are similar. His bank is said to contain all published sequences of more than 150 nucleotides, but tRNA and 5S rRNA sequences are not included because of their variability. At the end of September, the Lyon bank included 200 mRNA sequences together with 10 complete genome sequences and 100 untranslated sequences. A description of the bank and a list of its contents can be had free of charge from Université Lyon 1, 69622 Villeurbanne Cédex, France.

It is hoped that the future of the NIH/EMBO project will be decided early this year, after consultations with other interested parties. One of the potentially contentious issues is that of whether bodies such as EMBO and NIH should centralize an activity recognized to be essential but traditionally left to individual research workers relying on grants from similar bodies.

Polish pollution

Smelter shuts down

Poland's new Ecological Society has won a major triumph in its battle to halt pollution in Krakow — a ministerial promise that the Skawina aluminium works, one of Poland's two major producers of the metal, will be closed down entirely. The campaign against the Skawina works has been going on since the society was founded last September.

The post-war industrialization of Krakow, beginning with the building of the giant Lenin steel mills at Nowa Huta, has brought major pollution problems. By the end of the 1970s, Krakow, which lies in a hollow with little natural circulation of air, annually received an estimated 95,000 tonnes of dust and 70,000 tonnes of sulphur dioxide a year from Nowa Huta to the east, and 33,000 tonnes of dust and 33,000 tonnes of sulphur dioxide from the Skawina complex (a coal-fired power station and aluminium plant) to the south-west. Ecologists working on the former Royal Forest of Niepolomice some 20 km from Krakow had to recommend measures such as aerial spraying with lime to neutralize the acid rain.

Outside the technical journals and reports, little was published on the problem, although the local population could see for themselves the outpourings of smoke (new electrostatic precipitators were constantly being promised) and there were increasing fears of the health hazards of locally grown vegetables. The first real public hint that there was an even greater gas hazard than that of sulphur dioxide came in the autumn of 1979, with the revelation that gold art treasures in the Wawel Castle museum were becoming corroded.

A year later, however, the new Ecological Society, whose membership includes representatives of the "interested public" as well as experts, was demanding a "truthful report" on Krakow's monuments and environment including public health issues. The society's memorandum, published in the Krakow newspaper *Gazeta Poludniowa* of 20 November, demanded in particular that all processes emitting fluorine and hydrogen fluoride must be shut down until this hazard could be eliminated. In fact, both the Skawina works (the main source of fluorine pollution) and the Nowa Huta steel mill were already scheduled for modernization — at costs of 120 million zloty (£2 million) and 7,500 million zloty (£125 million) respectively. Preliminary work on these projects, it was promised, would begin during 1981.

But the debate continued and was taken up by the national television network. By the end of December, the Minister of Metallurgy, Zbigniew Szalajda, had agreed to a partial cut-back in production, and ordered 35 obsolete electrolysis tubs to be taken out of service. The Mayor of Krakow, Josef Gajewicz, increased the number to 160, cutting hydrogen fluoride emission by 60 per cent and aluminium production by almost half. On 5 January this year, the minister told the press that Mayor Gajewicz's action would produce a "very difficult situation" for manufacturers requiring aluminium. Ways would have to be found to step up production from Poland's other smelting plant at Konin. The ministry's plans for the future of the Skawina plant, he said, would be outlined shortly. Two days later, after a meeting with community representatives and journalists in Krakow, the minister announced that, "taking into account all the circumstances, the demands of the community and the economic aspects", the plant would be closed and the project "totally abandoned". **Vera Rich**

Human experimentation

Indian rules

Lucknow

To help Indian investigators plan their clinical studies the Indian Council of Medical Research (ICMR) has formulated guidelines for conducting medical research on human subjects.

The guidelines have been prepared by the ICMR Central Ethical Committee whose chairman is a legal expert and whose members include the Drugs Controller of India. Briefly, they seek to ensure that the rights and welfare of subjects participating in a trial are protected, that the benefits accruing from the research outweigh the risks to the individual, that the "informed consent" of the subject is obtained before the start of the trial, and that the investigator has the competence and experience to conduct the trial.

ICMR has forwarded the guidelines to the Indian government and hopes that they will be followed by all institutions engaged in clinical research in the country. Institutions under the aegis of ICMR have already been instructed to follow the guidelines. It is suggested that, to implement the new code, each institution conducting clinical research should form its own committee, which would consist of five to seven experienced clinicians and non-medical persons able to give advice on legal and ethical matters. These committees would then evaluate each proposal for research on human subjects by following a nine-point code. ICMR recommends that, if the ethical committees are to be effective, they should be independent bodies.

Recognizing that it may take some time for each institution to form its own committee, ICMR has offered to provide the services of an ethical committee to evaluate projects during an interim period of one year. This new role for ICMR will enable Indian institutions which do not have ethical committees to apply for funds from international agencies such as the World Health Organization, which will not consider a proposal for research support unless approved by an ethical committee.

The ICMR guidelines stress the importance of obtaining the informed consent of each subject. Although the details for obtaining consent are left to individual committees to work out, ICMR insists that the subject or his guardian should be given as much information as possible about the drug to be studied, including its side effects, and that it should be made clear to him that he is free to refuse to take part in the trial.

Indian law demands that the permission of the Drugs Controller of India is obtained before a clinical trial is performed on a new drug. ICMR proposes to hold meetings with other organizations involved in clinical research, to formulate ethical safeguards that will prove generally acceptable. **Zaka Imam**

Vitamin deficiencies

Rickets at bay

Vitamin D-deficiency rickets appears to be on the decline among Britain's Asian community. The Department of Health and Social Security last week reported* a fall in the incidence of rickets among Asian children in the past ten years, but says that the disease remains a problem. Seeking to eradicate the disease, a department working party recommends vitamin D supplements for children at risk rather than the fortification of specific foods, milk or chapatti flour.

Once known as the "English disease", rickets was common in Victorian England with as many as a half of the children in poor areas in Leeds said to be suffering from it at the end of the nineteenth century. In the period 1926–42, the incidence was still high, with some 2–8 per cent of children in British cities with the condition. During the Second World War, however, rickets was almost eradicated by a programme (begun in 1943) in which all children received vitamin D in the form of cod liver oil supplements. The hope now is that the same approach could work among Asian children now at risk.

Rickets and its adult equivalent, osteomalacia, were first documented as a serious problem in the Asian community in Glasgow in the early 1960s, and since then has been observed in most of the larger Asian communities in the United Kingdom. Neither disease is notifiable, however, and data collection is not easy.

The recent decline of incidence is suggested by figures from the Hospital In-Patients Enquiry Programme and from a survey involving 130 general practitioners in areas with large immigrant populations. In 1977, in the Midlands and north of England, ten Asian children in 1,000 under the age of 16 had rickets, compared with only four per 1,000 in London. The risk factors are said to be lack of sunlight, strict vegetarian diet, poor rural background and a family history of rickets or osteomalacia. As both bone diseases are common in the Indian subcontinent, the report suggests that immigrants may bring it with them.

Thus, the department says, it should not be difficult to identify those at risk, which is why its report recommends vitamin D supplements backed up by health education. The decision against food fortification has been recommended by the department's Committee on Medical Aspects of Food Policy, which has studied the problem for four years, but will not satisfy all clinicians responsible for treating rickets in the Asian community.

The case for the more radical programme of fortifying specific target foods has fallen because legislation would be required before vitamin D could be added to specific foods such as milk or flour, and because the food policy committee has argued that there are sound medical reasons for not taking such a course. Thus there might then be excess vitamin consumption and, as a consequence, the risk of hypercalcaemia in children and possibly of cardiovascular complaints in adults.

In retrospect, the hypercalcaemia observed in young infants in Britain in the 1950s was almost certainly due to vitamin D overdosing. The department's report says that if milk were to be fortified with vitamin D, some children could well receive too much, especially if concerned parents also choose to provide vitamin supplements.

Technical problems complicate the fortification of chapatti flour — the target food best suited to the needs of the Asian community in Britain. Although vitamin D is stable in the flour, up to 50 per cent can be destroyed in cooking. Choosing the correct amount to add to flour is therefore difficult and the concentration of vitamin D needed to prevent rickets in young children might well prove a health risk to teenagers and adults. **Alastair Hay**

Research development

Soliciting custom

The National Research Development Corporation (NRDC) is trying to improve its image. To that end it held a meeting in Manchester last week to spread its message among leading academics, industrialists and financiers in the north-west. The meeting was the second of its kind, the first having been held in Cambridge about a year ago, and it is unlikely to be the last.

NRDC, which exists to help exploit technological innovation in industry, clearly believes that not enough demands are being made on its funds and services and that more universities, and especially industries, should be coming to it with their ideas. It supports fewer projects in relation to the number of higher education and research establishments and industries in the north-west than in any other region — hence the choice of last week's meeting venue.

To judge from their criticisms, however, few of those involved in the business of technological innovation regard NRDC as a particularly helpful body. Many academics, who are obliged to offer NRDC first refusal of inventions resulting from publicly funded research, say that it is too bureaucratic, especially in securing legal protection for non-patentable inventions such as computer software. It is also criticized for not being sufficiently aggressive in marketing inventions, and for taking both too few and too many risks. Its high failure rate, as much as 80 per cent in some fields, can be taken either as a healthy

0028-0836/81/020113-02$01.00

sign of its willingness to take risks or as a reluctance to match its patent portfolio to its financial resources.

Most of the inventions communicated to NRDC which later result in commercial success come from government research establishments, universities and industry. In the year up to March 1980, 1,786 inventions were communicated to NRDC, 68 patents were assigned to it, 56 licence agreements were completed and 157 development projects were set up. For those working outside industry, the corporation offers to patent ideas, put up funds for further development to the point of commercial exploitation and then licence the inventions with industry.

NRDC's aims seem laudable enough, but academics in particular feel that the practice does not match the theory. Those who have been able to approach industry directly with their inventions often report greater success, largely because they are able to negotiate relatively informal deals which do away with the legal wrangling often associated with NRDC negotiations. Universities have also become increasingly aware of their science and technology departments as potential revenue earners.

For industry, however, NRDC's services may seem more attractive and it was at industry that last week's conference was primarily aimed. If academics criticize NRDC for not driving hard enough to exploit ideas, the NRDC may equally accuse academics of lacking motivation. Appealing to industry itself to come forward with its own inventions might be more productive. **Judy Redfearn**

British technology

New direction

The Centre for Technical Change, the technological think-tank set up in Britain last summer, has brought off a considerable coup by the appointment of Sir Bruce Williams (aged 62), Vice-Chancellor of the University of Sydney, as its first director. The appointment, announced last week, will take effect full-time when Sir Bruce bows out of his post at Sydney at the end of June, two months early.

The centre was set up with a grant of £1.5 million from the Leverhulme Trust and with the promise of further substantial funds (up to a total of £2.25 million over five years) from the Science and Social Science Research Councils. Its origins lie in the conviction of its sponsors that pure reason may help to explain the poor industrial performance of the United Kingdom in recent decades, especially in the exploitation of technical innovation.

One of the ironies of Sir Bruce Williams's appointment is that it is almost exactly 25 years since the appearance of a report on the same set of problems produced under the title *Science and Industry* by Williams and Dr (now also Sir) Charles Carter, recently retired Vice-Chancellor of the University of Lancaster and now director of research at the Policy Studies Institute, London. That document raised the question of why Britain, one of the principal spenders on research and development, should apparently derive so little benefit as a consequence.

Detailed planning of the centre's work is still incomplete. It has however been decided that the centre should be based in London, not (as some had hoped) in a university town.

It was also announced last week that the deputy director of the centre will be Dr A.J. Kennedy, research director of Delta Metal Company Limited. Dr Kennedy, who is 59, has a background in academic life (Cranfield) and in industrial research. The centre is managed by a council whose chairman is Lord (formerly Sir Michael) Swann, now Provost of Oriel College, Oxford. Its future is for the time being assured only for five years, but it is hoped that it will be able to recruit extra funds during that period and also to persuade its sponsors that it deserves a longer life.

Williams — back to a sinking ship?

Latin America

Freedom lost

Washington

As one of a set of new initiatives designed to help persecuted scientists in Latin America, officials of the American Association for the Advancement of Science (AAAS) intend to monitor loans provided by international development banks to research and training institutions in the subcontinent.

This action is a response to evidence presented to a workshop held during AAAS's annual meeting in Toronto last week that several loans may have been granted to Latin American institutions to compensate for the loss of scientists who have fled abroad.

There was particular concern over two loans — $66 million lent to Argentina in 1979 by the Inter-American Development Bank (part of the World Bank) to train scientific and technological research workers at nine regional institutes, and a $32.5 million loan last autumn to the University of Uruguay.

According to participants at the meeting, one of the purposes of the Uruguayan loan is to employ foreign faculty and consultants on a temporary basis. These workers would help to rebuild science programmes, particularly in agricultural research, that had disintegrated following the recent wave of political repression, when many university teachers had been imprisoned or had left.

The workshop recommended that scientific organizations should encourage international lending institutions to consider human rights when granting loans to educational and scientific institutions. They stressed the need to establish beyond doubt that scientific and academic freedom would be preserved.

The workshop's recommendations were made in the light of evidence that the repression of scientists in particular — and educationists in general — is becoming a chronic problem in many Latin American countries.

Several participants admitted that the situation in some of the countries had improved slightly in the past few years. There are fewer reports of repression from Brazil and Chile than in the early 1970s, and even in Argentina — Buenos Aires physicist Dr José Westerkamp said things were no worse than in the past.

But Dr Westerkamp added that there was still widespread fear that the repression might come back again. And AAAS's Committee on Scientific Freedom and Responsibility, which sponsored last week's workshop, has turned its attention to countries such as El Salvador and Guatemala, citing evidence of "generalized violence" against university and other teachers.

The evidence presented of a general decline of academic and scientific freedom in Latin American countries, including the dismissal of many scientists from teaching and research posts, was sufficient to persuade the AAAS Council, meeting last week to call for "the exploration of new initiatives to protect scientists".

One of these initiatives is likely to be the setting up of a Latin America Regional Centre for Human Rights — possibly in Venezuela — to monitor the state of scientific and academic freedom in the subcontinent, since several participants stressed the need to involve indigenous scientific societies.

Meanwhile AAAS officials said that the association hoped to invite officials from the Inter-American Development Bank to a meeting of its scientific freedom committee, and pointed to the success of international conservation groups in slowing down one loan because of its potential environmental consequences as evidence that bank officials seemed willing to discuss such issues. **David Dickson**

CORRESPONDENCE

Explosive reaction

Sir — Lovins'[1] review "Nuclear weapons and power-reactor plutonium" lacks mention of prior rebuttals to his position[2,3]. Moreover, in following the transition of this article with a widely circulated draft (personal communication, 20 March 1978), one senses a *post hoc* justification for his testimony at the Windscale nuclear-fuel reprocessing hearings.

The conclusions drawn by Lovins are unsupported by the analysis. He implies that "power reactors are not an implausible but are rather potentially a peculiarly convenient type of large-scale Pu production reactor". If power reactors were such practical sources, nuclear-weapons states would not be operating special-purpose military plutonium production reactors — they would be buying up reactor-grade plutonium for their weapons programmes, instead of storing it in pools. Reactor-grade plutonium is a dangerous substance, able to sustain a nuclear explosion. But Lovins fails to quantify its military value.

For governments that contemplate becoming nuclear-weapons states, the accessibility of plutonium is only one factor: others are the quality of material, the availability of facilities, and the possibility of nuclear-explosive testing. There are numerous disincentives too.

For "amateurs", there are hurdles not mentioned by Lovins. In general, plutonium generated in power reactors is not suited for military applications, and unauthorized access has been severely restricted by physical safeguards. His superficial treatment does not help our common goal of minimizing the propagation of nuclear weapons.

There are some specific technical objections: His introductory paragraphs are not justified by the subsequent analysis. He applies such terms as "unsuitable", "usable", "inferior", and "less than optimal", to power-reactor Pu. He generates a list of "assumptions" that represent selected extremes, later to render them "false". Although he says "We must know exactly what 'less than optimal' [Pu for bomb-making] means", he does not define it. Lovins eventually admits that there is "somewhat greater technical difficulty in using power-reactor Pu for effective military bombs."

His "conservative assumption" that arbitrarily high even-isotope content will not affect his arguments has been challenged, although Lovins does not mention the contradiction. On that assumption, Lovins proposes that "Pu discharged from power reactors will. . . have major military potential". His Table 2 does not reach high concentrations of the even-plutonium isotopes, thereby preventing the reader from making independent judgements on the efficacy of isotopic denaturing at higher even-isotope concentrations. Independent estimates of dramatic reductions in explosive yield that accompany isotopic dilution[3,4] are not included in Table 2.

He categorizes his choice of parameters as "realistic", thereby dismissing the deleterious effects of other forms of denaturing. Lovins claims that my "analysis of weapons physics seems deeply flawed". That is the entire support he gives to the charge. Yet, his own "weapons physics" is sparse, lacking any equations, and sustained mainly with citations from sources which I consider discreditable.

There are many misunderstandings, oversimplifications and omissions in Lovins' treatment of near-critical fissile masses: the difference between reactivity and excess reactivity; the role of synergistic effects; and his inability to distinguish between laboratory and field developments. I have identified and studied eight phenomena that can adversely affect the yield of an explosive configuration: critical mass dilution, metallurgical phase change, radial compression, subcritical multiplication, predetonation, generation time, reactivity limit and surface leakage. Lovins ignores most of them.

The interpretation that "the least favourable moment cannot get any less favourable" for an explosive yield is contradicted by Poisson statistics — a predetonation contour that Lovins notes but fails to apply. His repeated conception that the "worst case, minimum, 'fizzle' yield is still. . . 'militarily useful' ", is inconsistent with probability theory.

Examination of the citations taken by Lovins from Wohlstetter and Gilinsky indicates the origin of his circular arguments regarding plutonium denaturing. Of the limited official information generally available, most current reviews depend heavily on R.W. Selden's unpublished conclusions, which are self-contradictory.

It is incorrect to state "*categorically* that bombs from reactor-grade or deliberately 'denatured' Pu are less effective, less powerful or less reliable than those made from weapons-grade Pu". On the other hand, using a term from Lovins, it is "disingenuous" to deny that those attributes may be applied to the average properties of denatured plutonium. I estimate that plutonium can be isotopically denatured as effectively as ^{235}U or ^{233}U at a given fissile fraction. All reactor fuels and reactor types pose comparable levels of difficulty regarding weapons application, given corresponding safeguards and fissile fractions. Weaknesses of one or the other should be identified and remedied. However, the relative reactor usability and supply of isotopically denatured plutonium is another matter.

The point that the "marginal time and money required to use civil reactors for military production are orders of magnitude less than those needed for dedicated military facilities," has an element of truth mixed in with carefree terminology. One must differentiate between base power reactors and small research reactors. Research reactors do indeed provide a hedge, a "civilian cover" for some weapons-grade plutonium production; however, power reactors are self-protected and inaccessible under an appropriate safeguards regime.

Institutional and technological safeguards can minimize diversion and proliferation. As our respective nations expand their arsenals of destructive weapons, such misplaced concern only adds to irresolution. One can transcend some of the dispute by noting that international safeguards and a ban on all testing of nuclear weapons are the most prominent and effective steps that should be taken.

Role for ESF?

Sir — One aspect of its work that the European Science Foundation (ESF) could substantially expand (*Nature* 20 November 1980, pages 202, 204) is the sponsoring of scientific conferences and schools, especially in interdisciplinary areas.

The association of NATO Advanced Study Institutes and NATO Summer Schools with the NATO military pact is a matter of continuing shame to the academic community. Scientific organizations should be pressing the national governments to agree to the ESF taking over NATO's role in conference sponsorship and funding in Europe. The US side could presumably be accommodated via bilateral NSF–ESF arrangements.

Let's end the shameful military link with scholarship forthwith!

Theories of cancer

Sir — In reviewing my book *The Politics of Cancer*[1], Peto[2] charged that one table (Table 6.4) selectively and deliberately omitted data that would otherwise have questioned the conclusion that low dietary doses of saccharin (0.01 per cent) are carcinogenic in rats. This statement is incorrectly based on comparison of Table 6.4 with data in an appendix to the report of the Office of Technology Assessment[3]. However, the caption of Table 6.4 clearly states that it is based on another table, prepared by Melvin Reuber for use in the congressional testimony on saccharin by the Health Research Group on 21 March 1977[4]. Peto persisted in publishing this serious allegation in spite of two warnings.

Peto also appears unfamiliar with the content of the Office of Technology Assessment's report, which he cites as the basis for his charges on saccharin. This report explicitly discusses Reuber's low-dose data and his conclusion that "the increased incidence of lymphosarcoma of the thorax in rats at the 0.01 per cent . . . are highly significant in the saccharin study"[5]. Reuber also emphasizes that the carcinogenic effects of saccharin in various studies were not always dose-related.

Contrary to Peto's impressions, inversions in dose–response data are not uncommon in both experimental and epidemiological carcinogenicity studies. Reasons for such inversions include competing risks, heterogeneity in tested populations, and statistical fluctuation, particularly when dose–response curves are shallow. Peto also fails to recognize that saccharin has produced tumours in experimental animals at low as well as at relatively high doses.

Contrary to Peto's impression that "it is not surprising that so many chemicals (such as saccharin) at such (high) doses can cause cancer in animals", there is an overwhelming consensus in the qualified, independent scientific community that high-dose testing does not produce false positive results, and that this is necessary to reduce the insensitivity of carcinogenicity tests, reflecting the small number of animals tested compared with large human populations at presumptive risk[6]. It is also well recognized that carcinogenicity testing in excess of maximally tolerated doses (MTD) can produce false negatives due to competing toxicity.

Peto's charge of selective omission of the saccharin data is not his only misrepresentation. After his circulation of drafts of his review to various US experts in the autumn of 1979, Schneiderman, then Associate Director for Science Policy of the National Cancer Institute (NCI) and co-author of the government report on the importance of occupational carcinogens[7], explained in a letter to Peto that breast cancer correlates as well with Gross National Product as fat, that occupation had been ignored in studies exclusively associating lung cancer with smoking, that there have been major recent increases in lung cancer among non-smokers and that there have been "big and frightening" recent increases in cancer incidence which cannot be accounted for by smoking or other lifestyle factors.

Similarly, Upton, then Director of NCI and a co-author of the report[7], challenged the erroneous charge that a "4–5" multiplication factor was used to inflate the 1978 government estimates of cancer anticipated from occupational exposures. ". . . This simply is not true . . ."

Repeatedly, Peto dismisses as personal views statements in *The Politics of Cancer* to which he takes exception, rather than recognizing that they are based on fully referenced primary sources and without attempting to challenge these sources directly. For instance, he disparages the conclusion "that the cure rates for major cancers have not been improving much over recent years" without noting that this reflects cited NCI data. Peto refers to the "claims that cancer costs the US economy over $25 billion per year" without recognizing that such figures are derived from NCI sources. Similarly, Peto criticizes as "misleading or unbalanced" references to the term "medical–industrial complex" without attribution to its source, referenced and identified in the text (p.77), as the caption of an editorial in *The Lancet*[8].

Peto charges that the book denigrates the value of short-term carcinogenicity tests, which he asserts is a "most inexplicable error of scientific judgement". While problems of such tests, particularly the limited associations between carcinogenicity and Ames test data for compounds from a wide range of structural classes[9,10] are recognized, the book concludes (p.68) that there is a "range of useful applications" for these tests, particularly when incorporated into battery protocols.

Peto accepts that industries "delay or obstruct any hygienic measures which will cost money, . . . (and) that the scientific literature is not immune from distortion by financial interests". Peto apparently also accepts the wide range of case studies in *The Politics of Cancer*, which document a common pattern of constraints, including manipulation, distortion and destruction, in health, safety and economic data generated or interpreted by industry and its consultants. Yet he seems willing to accept studies sponsored or endorsed by industry as authority for the nearly exclusive lifestyle theory of cancer causation. Moreover, he is opposed to further regulatory controls on grounds of costs, professed "inactive conservatism", and because "for most toxic chemicals, we now have both qualitative and quantitative uncertainty about the health benefits of restriction". This seems a questionable basis for prudent public health policy.

Spanish science

SIR — The publication (*Nature* 23 October 1980, p.674) of the *Manifesto* on the status of science in Spain issued by leading academics and scientists of universities and research institutes is a major event. I would like to make a few comments from the viewpoint of a scientist who has been working closely for over ten years with colleagues at Spanish universities.

This is a time of great expectations both nationally and internationally for Spanish science and engineering. Democratic changes and heightened national expectations have opened the door for a major strengthening of scientific, engineering and technological work. The largely dormant past in universities and the undeveloped governmental infrastructure for science are giving way to a healthy stirring throughout the whole system. A recent visit to Madrid confirms a vigorous self-examination of the structure of research and teaching with significant organizational changes proposed.

There is, of course, no unique set of circumstances that will guarantee motivation of faculty and students, but there generally appear to be three essential elements. Scientists must be assured of government respect for scientific work without political interference; there must be reasonable financial support and job opportunities for researchers and graduate students; and there must be adequate and respected links between government, universities and public and private research institutions. Only the first element is now firmly in place. Difficulty in providing the second element is not unique to Spain, but occurs in many industrial countries of moderate size where the number of research positions is limited. At the moment, for this reason, some of the best Spanish science and engineering graduates see their future abroad.

Academics might themselves develop research institutes within the universities directed to national needs such as high technology, engineering services, mitigation of earthquake and other natural hazards, and agricultural improvements. Although such efforts are exhausting and time-consuming, entrepreneurship to draw in industry, provincial governments and private funds is an essential part of scientific vigour. The *Manifesto* appears to address largely the central government. No doubt, realistically at this stage, the major funding for research must come from Madrid, but, in the long run, a diversity of support would appear to be the most fruitful.

The third element should be easier to achieve since it does not in itself entail much expenditure. The need to examine critically scientific goals and infrastructure related to national needs has in other countries led to the establishment of something like a Royal Commission with independent powers to probe, report and recommend. Strengthening and linking government institutes undertaking research, similar to the highly effective scientific and industrial research organizations of Australia, New Zealand and elsewhere might be considered. There appears to be a need to integrate government scientific institutes more closely with universities, given the new social climate in Spain in which protection from debilitating political agitation is not required.

From my own experience, it is crucial for scientists and engineers in Spain to organize themselves systematically so that their professional societies and academies are representative and respected. The work of such associations can clearly demonstrate to the body politic (of all parties) that among the many competing interests in a modern state, science should have a high priority on both economic and cultural grounds. Rather than an emphasis on "rights", continual demonstration is needed of the way that scientific enquiry really maintains itself in a free society. Again, from my own experience, it is important to cultivate those members of the *Cortes* who are scientists, engineers, technologists and economists. If they are to accept the responsibility of speaking for the Spanish scientific community they must have the necessary contacts and realistic proposals that can be argued effectively.

Finally, as a sympathetic outsider, I am struck by the role that Spanish science and technology might play in the developing world. Much of Central and South America lies open, one would suppose, to the establishment of close ties with Spanish scientists and institutions. The value of common language and other heritages cannot be overemphasized. Although some cultural and scientific ties have been forged, there are exciting possibilities for an expansion of teaching, scientific exchanges, bilateral scientific and technological agreements.

Through such channels, the idealism and abilities of many Spanish science graduates could find a natural place that serves not only national self-interest but also the global responsibility of all scientists. Might we not look forward to a vigorous Spanish science that belongs not only to Europe but also to the Americas? Part of the answer lies in the force of the *Manifesto* itself.

NEWS AND VIEWS

Strife over visual cortical function

from D.M. MacKay

IT is just over 20 years since Hubel and Wiesel[1] reported that cells in the striate cortex of cat show a preference for edges or bars of luminance-contrast at specific orientations. It seemed attractive to think of such cells as edge- or line-detectors, performing the first steps towards pattern recognition by analysing the retinal image into an array of oriented line-elements. When it was discovered that the cells also respond preferentially to gratings of specific spatial frequency-bands, however, a rival theory was advanced that they were 'really' frequency-filters analysing the image into its spatial Fourier components[2].

Complementarity of spatial and frequency analysis

But is this a genuine either-or? A simple cell can be thought of as a device for sampling the spatial distribution of luminance on the retina. As such it is subject to some limitations as first elucidated by Gabor[3] in the context of communication engineering. He showed that if we want to represent a communication signal by a succession of elementary signals (samples) in the time domain, we have to accept a compromise between the 'spread' of each sample in time and in frequency. The imprecisions of our representation in frequency (Δf) and time (Δt) are related by an 'uncertainty principle': $\Delta f . \Delta t \geq \frac{1}{2}$(ref.4). For the product $\Delta f . \Delta t$ to be a minimum, the elementary samples should not have sharp cut-offs in time or frequency. The best compromise is a sine- or cosine-wave whose amplitude is modulated by a gaussian function. It was later[5] argued for analogous reasons that functions of space (such as optical images) would be most economically analysed in terms of elementary spatial functions with gaussian profiles. Four examples of such functions, adapted from Gabor[3], are shown in Fig.1a, b, with their spatial-frequency spectra in Fig.1c. This means that any linear system with a spatial response profile of the kind illustrated in Fig.1a, b is bound to show a preference for a restricted band of (spatial) frequencies. The narrower the spatial profile (Δx), the poorer will be the frequency selectivity.

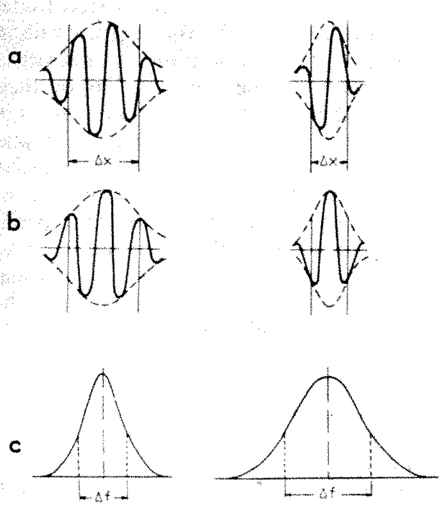

Fig.1 Analogues in the spatial domain of Gabor's sampling functions of (a) 'sine' and (b) 'cosine' type, with (c) their corresponding spatial-frequency spectra (adapted from ref.3). Note the reciprocal relation between the 'spreads' in space (Δx) and in spatial frequency (Δf).

As it happens, the receptive field profiles of simple cells (Fig.2) are remarkably similar to the right-hand examples in Fig.1 a, b. Some are 'sine' in type (Fig.2a); others 'cosine' (Fig.2b). To the extent that they respond linearly, then, simple cells cannot help showing some selectivity also in the spatial-frequency domain[6]. In communication-engineering terms, their spatial 'spread' (Δx) is of the order of X (Fig.2). Their spatial-frequency spectrum is also near-gaussian, with a 'spread' of $\Delta f(x)$ given by the 'uncertainty relation': $\Delta x . \Delta f(x) \geq \frac{1}{2}$. Taking Δx as approximately the wavelength (λ) of the sinusoidal grating that would best fit the spatial profile, this would predict a spatial-frequency bandwidth (Δf) of the order of $1/2\lambda$ — roughly one octave. As this is the order of magnitude of the bandwidths reported[7,8] for simple cells, the receptive fields of these cells seem to represent a near-optimal solution to the problem of sampling optical images in *both* the frequency and the spatial domains. Their relatively wide bandwidth (low 'Q') suggests that at this stage the inevitable information-theoretic compromise is weighted in favour of spatial resolution; but to argue whether they are 'really' concerned with one or the other would clearly be inept. The two aspects are logically complementary.

'Crucial' experiments?

In view of all this, it is surprising to find experiments that demonstrate the predictive power of Fourier analysis of stimuli still being presented as if they help decide between 'edge-detector' and 'frequency-filter' models of visual information-processing. To take a recent example, DeValois *et al.*[9] attempted "to discriminate between two models of the response characteristics of simple and complex cells of the striate cortex" by comparing responses to gratings and chessboard patterns. A chessboard has its main spatial-frequency components oriented at 45° to the edges of its squares. If the cells of striate cortex were detectors of oriented bars or edges, it was argued, they should respond best when the edges of the chessboard squares lay at their preferred orientation. If they were spatial-frequency filters, they should prefer the edges to lie at 45° to it. In the event, DeValois *et al.* found the latter result, and claimed thereby to

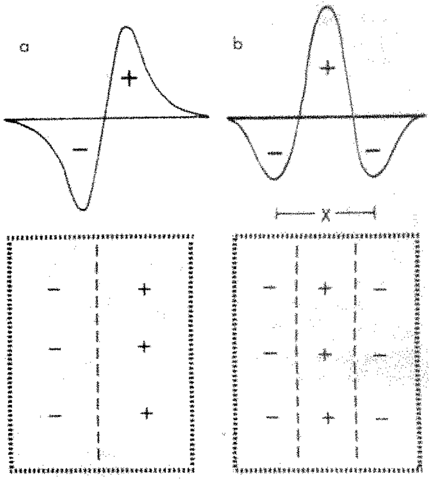

Fig.2 Typical receptive field profiles (above) and idealized field maps (below) for simple cells with (a) one 'on' (+) and one 'off' (−) zone; (b) a central 'on' (+) and two 'off' (−) zones. The ordinate denotes the contributions to the excitability (or the firing rate) of the cell made by an optimally oriented light line, as a function of distance across the field. (For cells which are silent when unstimulated, such curves can be obtained by maintaining a steady background level of activity with an auxiliary stimulus.)

0028-0836/81/020117-02$01.00

have confirmed the 'frequency-filter' hypothesis.

It is easy, however, to see how such results could be predicted without recourse to Fourier analysis. Considering first a single line of black squares (small compared with the separation of 'on' and 'off' zones) with a common diagonal (Fig.3a), everyone, including 'bar-detector' theorists, would expect the best response when the common diagonal lay parallel to the on–off boundary. Only if the squares were so large that one edge spanned the receptive field (Fig.3b) would the cell respond best when that edge was parallel to the on–off boundary. If we assume that light/dark gradients summate algebraically (even if non-linearly) over the receptive field, partial cancellation could be expected to occur in the case of Fig.3c, so that the response would be doubly position-dependent. Again, with a row of smaller squares as in Fig.3d, cancellation would be predicted[10]. With two diagonal lines of small squares (Fig.3e), Fig.2b would predict a maximal response for a critical separation (X) roughly equal to the spacing between 'off' zones — still with the diagonals parallel to the 'length' axis. With bigger squares (Fig.3f), the stimulus becomes a diagonal strip of chessboard pattern. The addition of further strips will introduce subsidiary maxima into the polar diagram at orientations giving a sufficient difference between the net excitation in the 'on' and 'off' zones. Thus none of the results presented as crucial by DeValois *et al.* requires Fourier theory for its explanation.

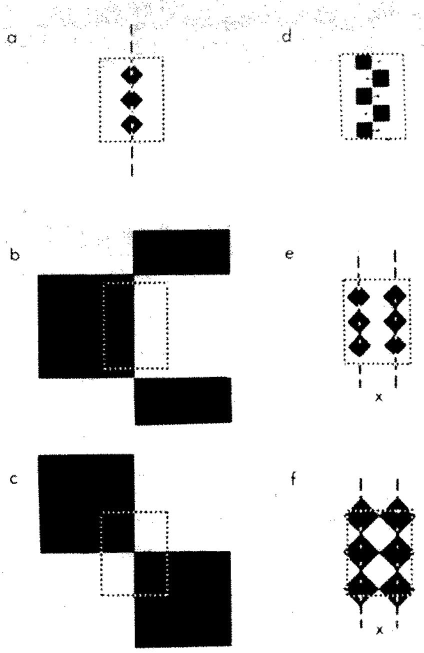

Fig.3 (a) For a line of squares small compared with the receptive field, the preferred orientation should lie along the common diagonal.
(b) For larger squares, the preferred orientation will be parallel to the edge; but
(c) If the common corner of two squares falls within the receptive field, some cancellation can be expected.
(d) A row of small black and white squares will offer oppositely oriented contributions which should cancel out.
(e) Two optimally oriented lines of small squares should be spaced by a distance X (Fig.2) to match the receptive field profile.
(f) A chessboard can be regarded as a special case of Fig.3e.

The direct calculation of net excitation for various orientations and spacings, however, is laborious and inelegant. Fortunately, a mathematical technique is available to simplify and systematize such calculations. Its name — Fourier analysis. The fact that Fourier analysis predicts the polar diagrams speaks neither for nor against the theory that the *cortex* operates as a Fourier analyser[12]. It shows only that the cell's response is (approximately) linear.

Empirical issues?

Is this then entirely a bogus issue, or are there genuine questions to be settled by experiment? Three empirical points may be noted:

Firstly, although all such cells are selective both for location and orientation and for spatial frequency, it is their relative *precision* in each domain that shows to what extent they could be useful (or useless) as filters. The frequency-selectivity of most simple cells is by engineering standards abysmal.

Secondly, the predictive success of Fourier analysis of stimuli does rule out some kinds of *non-linear* models of simple-cell function. For example, the evidence of DeValois *et al.*[9] is clearly against any idea of 'edge-detectors' as cells so non-linear as to be insensitive to the polarity of luminance edges. (Talk of oriented edges as 'trigger features' for cortical cells may have contributed to this misconception.)

Thirdly, whether the firing of any single cell *signifies* to the CNS the presence of a specific feature is an empirical question of cortical information-engineering design on which data are still scanty but thought-provoking. Hammond and MacKay[13], for example, have found that the response of even simple cells to bars can be modulated by motion of a textured background, and have shown that most striate complex cells have different polar diagrams for motion of texture and of bars[14]. Again, recent work with multielectrode recording by Gerstein and Michalski[15] suggests that more information may be represented by the pattern of temporal relationships between the firings of neighbouring units than by the firing patterns of any unit in isolation.

On both experimental and theoretical[16] grounds, then, it seems timely to reconsider the possible roles of striate cortical cells in visual pattern recognition. As individual descriptors of the stimuli falling on their fields, they are imprecise or ambiguous in all the domains of space, frequency and velocity. As members of local cooperative assemblies they could collectively offer more exact descriptions. A third possibility, however, is that their job is not to provide a symbolic *description* of the visual field at all. The task of symbolizing the perceived world could well be a more central process[17], which requires from the sensory system not pictures or descriptions but an array of selective clues to help it 'home in' on the appropriate symbolic representation. If so, we must be prepared to look for quite different kinds of link between striate cortical activity and pattern recognition.

D.M. MacKay is Head of the Department of Communication and Neuroscience, University of Keele, UK.

10. Experiments in collaboration with P. Hammond have shown some degree of algebraic summation of gradients for simple cells, and also for those complex cells that respond poorly to random texture. The assumption does not however hold for another class of complex cells (ref.11) which respond strongly to motion of textured fields that do not excite simple cells. Such complex cells may even respond better to a chessboard with edges *parallel* to their preferred axis than to one at 45°. Thus generalizations about the response characteristics of 'striate complex cells' cannot validly be made without specifying the subclass in question.

Yeast genetics and molecular biology

from Terrance G. Cooper

LOUVAIN-LA-NEUVE was the site of the Tenth International Conference on Yeast Genetics and Molecular Biology. Twenty-four plenary presentations, eighteen evening workshops and over 200 posters allowed an exhaustive exchange of information about *Saccharomyces cerevisiae* and could lead one to conclude confidently that *S. cerevisiae* is now a favourite model for studying the structure and operation of eukaryotic cells.

RNA splicing was a major topic at the meeting and provided a focal point for studies of tRNA gene expression. The splicing system responsible for processing primary transcripts from eight or nine tRNA genes appears distinct from that processing mRNA. Mutants unable to remove intron sequences from *SUP4* tRNA primary transcripts had mutations in all portions of a recombinational fine structure map of the *SUP4* locus. This led to the conclusion that the entire three-dimensional structure of the intron-containing tRNA is probably important for recognition by the splicing enzyme system; this may act to provide a final opportunity for 'proof-reading' before activation of the newly synthesized tRNA.

Production of the var1 polypeptide (a component of the small ribosomal subunit from mitochondria) may involve yet another example of RNA–RNA splicing. A genetic element has been identified which in some way specifies the size of a transcript, but is not contiguous with the DNA coding for it. The var1 polypeptide is found in polymorphic forms ranging from 40,000 to 44,000 in molecular weight. A *var1* determinant, shown to be responsible for the polymorphism, is situated between the *ery* and *oli1* loci on the mitochondrial genome. However, complementation studies demonstrated that the *var1* determinant acts in *trans*. DNA sequencing studies revealed that the determinant does not possess apparent coding capacity (it is AT rich with no open reading frames) and is far too small to code for the var1 transcript. Normal amounts of the var1 transcript are found in petites containing only repeated copies of the *var1* determinants (these strains carry no other mitochondrial DNA) and hybridization experiments show a sequence homology of only 200 to 250 base pairs (bp) between the 1,900 to 2,000 bp var1 transcript and this petite mitochondrial DNA. These observations have been used to suggest, by elimination, that the *VAR1* gene is located in the nucleus; a directly testable hypothesis.

The search for the promoter region occupied the attention of those trying to unravel the control of primary transcription. The results emphasized once again that control of gene expression in eukaryotes differs markedly from that in prokaryotes. A deletion ending 140 bp upstream from the ATG of the *his3* gene (transcription begins at position −45) resulted in loss of gene function as did a deletion ending 250 bp upstream from the ATG of the *cyc1* gene. Insertion of a *Ty1* sequence 161 bp upstream from the ATG of the *his4* gene (transcription begins at position −63) similarly eliminated transcription. In the case of the *gal* gene cluster, transcription of the contiguous *gal* 1 and *gal 10* genes diverge from a single region of approximately 700 bp. It is not yet known whether or not transcription of the two genes is initiated from the same point. From these results it appears that a surprisingly large region might be required for effective promotion of transcription. However, it is important to note that deletions do not simply remove stretches of DNA. They also fuse the flanking sequences that remain and it may be important to ascertain the consequences of these fusions.

In a related area, four laboratories reported the structural characteristics of cloned genes (*adh2, car1, cyc2, dur1,2*) derived from mutant strains in which production of an enzyme was rendered constitutive by a mutation situated close to the structural gene. Constitutivity at these loci was observed in *MATa* and *MATα* haploid strains and *MATa/MATa* and *MATα/MATα* diploid organisms, but constitutivity was lost in *MATa/MATα* diploids. In each case analysed there appeared to be an insertion in or near the mutated gene. In two instances the inserted DNA was shown to be related to *Ty* sequences. Pertinent to these observations is the fact that RNA hybridizing to *Ty* elements has been reported to be the most abundant transcript expressed in parallel with mating-type specific functions, that is, such RNA is present in *MATa* and *MATα* cells, but is diminished in *MATa/MATα* diploid strains. While this raises the possibility that the constitutively expressed genes have been placed under the control of a new promoter as a result of the DNA rearrangement, transcripts derived from wild-type and constitutive *ADH2* mutants exhibiting the mating-type effect have been compared on northern blots and found to be the same size. It is also important to point out that insertion of *Ty* sequences into the 'control' region of a gene does not always result in its constitutive expression or association of expression with mating-type functions. Two mutants unable to express the *his4* gene (*his4–912* and *his4–917*) were found to harbour *Ty* elements upstream from the transcribed sequences. A His$^-$ phenotype was observed both in haploid and homozygous *MATa/MATα* diploid versions of these mutants.

Association of *Ty* sequences with a major proportion of the chromosomal rearrangements analysed so far prompted a search for other genetic elements associated with the influence of these mobile elements on genes in their proximity. This was done by selecting His$^+$ revertants of the *his4–912* and *his4–917* mutants just discussed. One class of mutants (*spm2* and *spm3*) suppressed the effects of the *his4–917* mutation, but were incapable of suppressing the *his4–912* lesion. However, the reversion frequency of the latter mutation was increased 100-fold in Spm2$^-$ and Spm3$^-$ strains. Analysis of representative revertants revealed that recombination had occurred between the two directly repeated δ sequences flanking the inserted *Ty* element leaving behind a single copy of the δ sequence in place of the entire *Ty* element. Such revertants were found to be cold sensitive in a wild-type background, i.e. His$^+$ at 37°C, but His$^-$ at 22°C. In Spm2$^-$ or Spm3$^-$ strains cold sensitivity of the revertants was suppressed. A second class of mutations (*spm1*) suppressed the effects of both *his4–912* and *his4–917* mutations and cold sensitivity of the *his4–912* revertants. In formal terms these observations share several characteristics in common with the two-component *spm* control system of maize.

Several landmark events were identified for sporulation. Premeiotic DNA synthesis occupied the first 1.5–2 hours. Meiotic recombination was shown by direct measurement to occur at 4-6 hours, thus correlating with the pachytene stage. A novel and useful system for the manipulation of recombination-deficient mutants was presented. It has been difficult to diagnose recombination deficiency because of non-disjunction at meiosis I and the resulting spore inviability. These problems are circumvented with the *spo13* mutation. Strains harbouring such a mutation enter meiosis, undergo recombination and then, by-passing the reductional division of meiosis I, proceed

---

0028-0836/81/020119-02$01.00

directly to a single equational division of meiosis II. The latter division does not require recombination. Therefore, by coupling *spo13* to a putative recombination-deficient mutation, it is possible to follow recombination and sporulation independently.

Gene conversion was suggested to be the basic signal of meiotic recombination. The different types of segregation observed are then a function of how the recombination-heteroduplex is corrected. The *rad52* gene product was shown to be required for many recombination-associated processes including: mating-type switching, meiotic recombination, γ-radiation repair, meiotic and mitotic gene conversion. However, sister-strand exchange, plasmid integration into a chromosome and excision of an integrated plasmid occur normally in Rad52⁻ strains. Mutants defective in the latter two processes were isolated and in one case found to be defective in all forms of mitotic recombination assayed. Transformation requiring plasmid integration (Ars⁻) was 25-fold lower in this strain. Also isolated were four classes of mutants (*cor*) exhibiting elevated frequencies of meiotic recombination. Cor⁻ mutants were not sensitive to radiation and did not affect meiotic map distances or the frequency of initiating gene conversion. However, correction of heteroduplex intermediates generated during recombination was markedly reduced and the length of the correction tracts appreciably reduced.

The phenomenology and genetics of DNA repair is rather complex. Approximately 100 mutants have been isolated and characterized. This, however, may represent an overestimate of the genetic elements participating in repair, because allelism tests have not been completed. The results of characterization studies in many laboratories have led to the conclusion that five repair systems seem to exist. One mutagenic (error-prone) and two non-mutagenic systems are involved in the repair of radiation damage. Work with anti-mutator mutants suggests the existence of two mutagenic repair systems. One of these systems is identical with the mutagenic repair system associated with radiation damage. However, the second system appears to be independent of radiation damage. A fifth system appears to be needed for the repair of damage generated by the DNA alkylating agent, methyl methane sulphonate (MMS). This suggestion is based on the observation that some MMS-sensitive mutants are insensitive to radiation. The repair of psoralen-generated cross-linked DNA requires both non-mutagenic repair systems associated with repair of radiation lesions (the *rad3* and *rad51* systems). A new assay system has also been developed which permits one to follow the repair of DNA cross-links in 2 μm circular DNA. This system should prove useful for studying DNA repair at the molecular level.

Finally, two reports describing very interesting types of DNA were presented. First was the centromeric DNA (*CEN3*) from chromosome III which was isolated on a 1.6 kb segment of DNA located near the centromere-linked *cdc10* locus. When present on a plasmid carrying a yeast chromosomal replicator (such as *ars1*), *CEN3* DNA enabled the plasmid to segregate as a chromosome both mitotically and meiotically. In meiosis the plasmid segrated 2+:2− rather than the 4+:0− characteristic of other unintegrated plasmids. In addition, plasmids containing centromeric DNA were found to be strikingly more stable. This stability would be a most desirable characteristic in transformation cloning vectors. Such vectors are now being constructed. The second interesting type of DNA was reported to exist as a naturally occurring plasmid in *Kluyveromyces lactis*. This organism appears to harbour two linear DNA plasmids of molecular weights 5.4 and 8.4 × 10⁶ respectively. They represent the first non-circular DNA plasmids reported in yeast or any other organism. Strains possessing the two linear plasmids were shown to kill both *S. cerevisiae* killer and sensitive strains. Non-killing *K. lactis* strains both sensitive and resistant to being killed themselves were also found.

Remote sensing of the oceans

from D.J. Webb

NEW techniques for remote sensing of the ocean surface have been tested in two cooperative experiments — the Marineland experiment off the coast of Florida and the West coast experiment off California — and the results reported in a recent issue of the *Journal of Geophysical Reseach* (**85**, 1980). The experiments were carried out in 1975 and 1977 and used centimetre radar, high frequency (HF) radar, optical and surface buoy measurements.

A variety of techniques have been successful in sensing properties of the oceans. Sound can be used at long range — sonar techniques give bottom topography, doppler shifts give the water velocity and changes in sound paths detect the movement of density surfaces. The use of electromagnetic sensors is limited by the high conductivity of sea water but comes into its own for monitoring the sea surface. Passive infra-red sensors can monitor sea surface temperatures and optical techniques can be used to measure the slope of ocean waves.

Recently, active sytems have been developed, many using radar waves of between three and thirty cm wavelength. When directed vertically onto the sea surface the radar waves are scattered in a manner analogous to Sun glitter. In the SEASAT-1 radar altimeter the scatter can be used to give information on wave height and large-scale undulations of the sea surface[1]. If altimeter and positional errors can be reduced below 10 cm such a system can also be used to detect tides and strong surface currents.

When radar is used at an angle of more than 30° from the vertical, reflection occurs mainly by Bragg scattering from the short surface waves. The height of these waves and thus the back-scattered cross-section depends on the wind field, the long waves they are riding on and possibly on the turbulence and surface tension of the surrounding water. Any changes in these underlying parameters may be detected by the radar signal.

HF radar using wavelengths of tens to hundreds of metres may also be used. The radar signal is Bragg scattered by ocean waves of half the radar wavelength and interpretation of the returned signal is relatively simple. The method may be used to measure both the directional wave field and, from the doppler shifts, the surface currents, over distances of tens to hundreds of kilometres from the transmitter.

However, HF radar cannot be used from satellites because the signal is reflected by the ionosphere. Centimetre radars can be used but it is necessary to make sense of the complicated physics involved in the scattering process. It was this problem that led to the setting up of the 1975 and 1977 co-operative experiments.

In the first experiment[2], it was found that during a period of wave growth the power spectra for waves of between 1 and 5 seconds period did not depend on frequency to the power of −5, as the text books say, but instead the exponent lay between −3.5 and −4.5. The same experimental group using HF radar, with its accurate directional resolution, found evidence for the Phillips' mechanism of wave growth affecting waves of up to 25 m wavelength. These are rather larger than the catspaws on still water to which the theory is usually applied.

The HF technique was also used to study wave sheltering by islands[3]. A local Loran-A transmitter with a wavelength of 154 m was used and a directional aerial synthesized by driving a van at a fixed speed along nearly straight stretches of a suitable highway. The study showed a reduction in the wave energy behind the islands, but the

0028-0836/81/020120-02$01.00

residual energy was greater than could be explained by refraction or diffraction. The authors suggest that non-linear wave interactions may be responsible.

The island study also made use of synthetic aperture radar (SAR) using centimetre waves. A similar system used on SEASAT-1 had an all-weather resolution of 20 m, and around the UK showed swell waves off Northern Scotland, ships and their wakes in the Straits of Dover, disturbances produced by sand waves in the North Sea and internal tides propagating out into the Atlantic from the continental shelf edge.

The classical explanation of why swell waves are seen by such a system is that their orbital motion strains the short gravity waves and changes their amplitude. However, Wright and his co-workers[4] found this explanation to be incorrect for typical ocean waves and suggest that it is the local wind field around the waves which is responsible for the observed signal.

Pawka and co-workers[5] compared the directional wave spectrum obtained from SAR images with the spectra from a high resolution array of pressure sensors. They concluded that when waves could be imaged, the SAR gave useful information on the direction and directional spread of the waves.

Similar results were obtained by McLeish *et al.*[6]. This group also found that, when normalized at the peak, the high frequency part of the SAR spectrum lay between the spectra obtained from wave height and orbital velocity measurements. The SAR system also showed swell being refracted by the Gulf Stream[7] and swell being refracted and scattered by bottom topography as it approached the shore[6].

When the same system was used in the much lower resolution scatterometer mode[8], some gross changes were found on crossing the Gulf Stream. The authors conclude that this was due to changes in the surface stress due to the wind. This could arise because of the lower atmospheric stability over the Gulf Stream.

Finally, scatterometer measurements over a larger area were used to study how the back-scattered cross-section depends on the relative direction of the wind[9]. A much larger cross-section is observed when looking up or down wind than when looking across the wind, and a development of this technique was successfully used in the recent SEASAT satellite to measure the wind field over the ocean.

When the experiments were carried out the radar systems were all at an early stage of development. Since then the altimeter, scatterometer and SAR have all been successfully used in the SEASAT-1 satellite and commercial versions of the HF radar are being developed for coastal monitoring. Versions of these instruments are also planned for future satellites and one might predict that over the next 10 to 15 years the altimeter and scatterometer will become the standard instruments for measuring wave climate and winds over the oceans.

Multiple methylation and bacterial adaptation

from Judith Armitage

THE ability of bacteria to sense, respond to and adapt to chemical stimuli provides a simple model system for the study of sensory transduction is general. It has been known for some time that protein methylation is a key factor in the process of adaptation to new chemical environments and now, a series of papers shows that methylation reactions are more complicated than had been previously thought and allow a much more flexible range of responses.

In an unchanging environment bacteria swim in a random fashion with periods of smooth swimming interrupted by transient bouts of tumbling, caused by reversal of the direction of flagellar rotation. When a gradient of an attractant or a repellent is encountered, tumbling is suppressed when the bacteria are moving towards the attraction or away from the repellent resulting in overall migration towards positive or away from negative stimuli. A sudden change in attractant or repellent concentration produces similar behaviour; the small size of bacteria requires that they sense all gradients as temporal rather than spatial. However, in this case, after a short time bacteria adapt to the stimulus and resume swimming even though the chemical is still present.

If bacteria are starved of methionine they can still respond to changes in the environment but they lose this ability to adapt. Mutants with aberrant behaviour, either tumbling continually (*Escherichia coli, che* B) or never tumbling (*E. coli, che* X) have also been found. The mutants can, however, be induced either to swim smoothly, or to tumble but fail to then adapt; *che* X mutants will continue to tumble for hours after repellent stimulation. The mutants proved defective in enzymes required to methylate or demethylate a specific group of inner membrane proteins.

These proteins, the methyl-accepting chemotaxis proteins (MCPs), are now known to be responsible for adaptation. Methyl groups are transferred to glutamyl residues on the MCPs from s-adenosyl methionine, in the presence of attractants, using a specific methyl transferase, creating a glutamyl methyl ester, or are removed in the presence of repellents using a methyl esterase. A high level of methylation is maintained as long as the attractant is present at a constant concentration, blocking the signal from the bound receptors. There are certainly two and probably three different groups of MCPs in *E. coli* and *Salmonella typhimurium* with molecular weights between 50,000 and 65,000, each cell probably having several hundred copies of each. Each group of MCPs responds to a specific set of chemosensory receptors which may be part of or able to bind to the MCPs and they provide parallel, almost independent pathways from their respective groups of receptors to the flagella.

Initially it was assumed that there were just two forms of MCP, one methylated and active, the other demethylated and inactive, controlling the function of a so-called 'tumble-generator'. However, on high-resolution polyacrylamide gels each MCP runs as a characteristic set of multiple bands.

While devising a method for methylating MCPs directly with labelled methionine in permeabilized cells, Paoni and Koshland (*Proc. natn. Acad. Sci. U.S.A.* **76**, 369; 1979) noticed that addition of attractants not only increased the intensity of MCP labelling on SDS gels but that the pattern of labelling within the bands changed, suggesting sequential methylation.

This observation has now been followed up in three papers published almost simultaneously and producing what seems to be at least part of the answer to the multiple banding on SDS gels and to adaptation, but showing that adaptation in bacteria is not the simple biochemical switch previously thought.

All three papers show that the multiple banding pattern on SDS gels is the result of sequential methylation of specific sites on the MCP polypeptide. Engström and Hazelbauer (*Cell* **20**, 165; 1980) used *in vivo* labelling and two-dimensional gel

Judith Armitage is in the Department of Botany and Microbiology, University College London.

0028-0836/81/020121-02$01.00

electrophoresis. The other two groups, DeFranco and Koshland (*Proc. natn. Acad. Sci. U.S.A.* 77, 2429; 1980) and Chelsky and Dahlquist (*Proc. natn. Acad. Sci. U.S.A.* 77, 2434; 1980) used recombinant genetics to introduce phage-directed cloned MCP-coding genes into *E.coli* and examined the labelling pattern of these MCPs in permeabilized cells. All the papers showed that stimulation with an attractant resulted in more heavily labelled faster-migrating bands, often with the appearance of a new fast band. However digestion of each band gave the same peptide pattern. At least three distinct peptides were shown to be methylated. Complete backbone labelling of the MCP by DeFranco and Koshland also revealed an additional slower-migrating band, corresponding to the unmethylated protein.

Sequential methylation of the MCP in response to an attractant, or demethylation in response to a repellent suggests that the number of sites methylated corresponds in some way to the number of receptor sites bound. The MCPs remain at the same level of methylation as long as a specific number of receptor sites is filled, inhibiting further response to that chemical at that concentration, but allowing responses to changing levels of that chemical or to new stimuli up to saturation. This obviously allows flexibility within an otherwise limited system. Each MCP must, however, be able to interact with more than one receptor molecule at a time, or the stoichiometry of the receptor per MCP methylation must be greater than one.

Interestingly, both Hazelbauer and Dalquist showed that chemoattractants such as maltose and aspartate which produce different levels of bacterial response also gave different MCP banding patterns. This may help to explain why attractants with similar numbers of receptor proteins vary in their efficiency in eliciting a response.

The question remains of how the binding of a chemical to the receptor–MCP complex controls sequential methylation or demethylation. A recent paper from Adler's laboratory may provide the answer (Black, Hobson & Adler *Proc. natn. Acad. Sci. U.S.A.* 77, 3879; 1980). They show that fluctuations in internal levels of cyclic GMP may initiate adaptation. Mutants showing defective adaptation also have defective cyclic GMP metabolism. Also, *in vitro* demethylation was inhibited by addition of cyclic GMP and cyclic GMP caused smoth swimming in the absence of chemoeffectors.

As yet the transducing signal between MCPs and flagella is unknown. It is almost certainly another function of the MCP but whether it is the release of a small molecule, possibly cyclic GMP as suggested by Adler, induced by a conformational protein change on binding, or a transient change in membrane potential or charge is not clear. It will also be interesting to discover whether bacteria are able to adapt to other tactic stimuli. Covalent modification of proteins has been found in several sensory systems in higher organisms, rhodopsin for example undergoes multiple phosphorylation when photostimulated and the methyl transferase system is involved in both stimulation of hormonal secretions in some higher organisms and leukocyte taxis. Sequential modification of proteins may therefore be a general biological phenomenon in signal tranduction.

Photosynthesis in the Greek sunshine

from B. Halliwell and M. C. W. Evans

THE rapid advance in our understanding of the photosynthetic reaction centres has come about mainly through work on bacterial systems but knowledge of the plant reaction centres is now fast catching up. Components analogous to those in bacteria have been identified in photosystem II. Ke and Klimow (Yellow Springs, Ohio) have detected a pheophytin intermediary electron carrier, which was also reported in barley mutants by Nugent and co-workers (University College London). There is strong evidence that the subsequent acceptor is a quinone probably associated with an iron atom. Manipulation of the redox states of these components gives rise to EPR signals, absorption spectra and chlorophyll triplet states, indicating a mechanism much like that in purple bacteria (Rutherford, Urbana). Nugent *et al.*'s work on barley mutants also showed the importance of the donor to P680 as a source of the EPR signal of Photosystem II.

In Photosystem I, reviewed by Ke, EPR and endor measurements have shown that the pheophytin intermediate is replaced by a chlorophyll *a* monomer and the quinone acceptors by a group of iron-sulphur centres. Understanding of the purple bacteria is much more advanced, however. For example, Shuvalov (Puschino, USSR) and Parson (Washington) proposed a role for the B800 chlorophylls in the sub-picosecond primary photochemistry. Our knowledge of electron transfer outside the reaction centre is also best in the purple bacteria. A specific quinone involved in the oxidation of the Rieske iron-sulphur centre has been identified. This seems to exclude a Q-cycle system and requires a linear electron transport chain. However, a paired electron flow is indicated by the gating effect which can be observed in the oxidation and reduction of the secondary quinone acceptor (Q_2) and how these observations can be reconciled is not yet clear.

In chloroplasts the isolation of a cytochrome *bf* complex, analagous to the *bc* complex of mitochondria, suggests a similar mechanism in the quinone oxidation system. Since Z remains unidentified, however, the problem of a Q cycle versus a linear electron chain is unresolved. Different schemes were proposed by Bouges-Boucquet (Paris), Rich and Bendall (Cambridge, England) and Hind (Brookhaven). The problem is further complicted by the conflicting requirements of cyclic and non-cyclic electron transport in chloroplasts. As discussed by Bendall, there is no definitive explanation of the function of the *b* cytochromes, particularly the two forms of b_{559}. Hence, while most participants at the Congress continued to accept the 'Z-scheme' of two light reactions in series, alternative arrangements have been proposed (for example, by Arnon at Berkeley, California). Indeed, there is room for some modification, since according to Bjorkman (Stanford) the relative numbers of photosystem I and II reaction centres and electron transport chains can vary with the growth conditions of the plant.

Perhaps the most disappointing part of the Congress was that dealing with water oxidation, which is still the least-well

---

*The Fifth International Congress on Photosynthesis was held at Halkidiki, (near Thessaloniki), Greece, from September 7th to 12th 1980, in appropriately sunny weather. The Congress dealt with all aspects of research in photosynthesis, from physiological ecology through carbon metabolism to the extreme limits of time resolution in the sub-picosecond photochemistry of the photosynthetic reaction centres.

Interstellar media in other galaxies

from a correspondent

A recent international workshop at the European Space Agency's (ESA) Villafranca tracking station (Vilspa) near Madrid brought together those studying the interstellar medium in our own galaxy and those concerned with extragalactic problems, in particular the quasar absorbtion lines. Data from both the International Ultraviolet Explorer (*IUE*) satellite, which is controlled from Vilspa during its European observing shift, and Copernicus, as well as from ground based telescopes were discussed. The *IUE* has just begun making important observation of interstellar media and, with the demise of Copernicus at the end of 1980, will be the prime instrument for interstellar studies until the launch of Space Telescope.

Ted Snow (Colorado) reviewed work on the abundances of elements and their depletion in the interstellar gas as a result of intensive studies of particular sight-lines with the Copernicus ultraviolet spectrometer. While gas-phase abundances of some species, in particular carbon and oxygen, are little depleted and this sets limits on grain composition, the refractory elements are more highly depleted, consistent with either grain condensation in a high-density environment or preferential accretion of these species onto grain mantles by dynamic processes in interstellar clouds. Stuart Pottasch (Groningen) noted that, for a few species, the existence or degree of depletion depended on the cosmic abundances adopted and these were themselves not beyond controversy. Nolan Walborn (Cerro Tololo) reported some recent work on the dynamics of the interstellar gas in the η Carina nebula; relative velocities up to 550 km s^{-1} are seen. Ed Jenkins (Princeton) discussed the presence of highly ionized gas in the plane of the galaxy. It appears that OVI lines define a component with scale height above the galactic plane of $\sim$300 pc and a velocity dispersion of 25 km s^{-1}. Their strength is correlated with reddening by dust. By contrast there is still some controversy whether the CIV and SiIV lines are truly interstellar. There seemed some evidence that the latter, at least, was in part circumstellar. Gordon Bromage (Chilton) claimed that NV lines were not seen in *IUE* data covering sight-lines to halo stars which rise out of the galactic plane so that the NV distribution looks similar to that of OVI with a scale height much smaller than that of the lower temperature CIV near 3kpc. Max Pettini (Herstmonceux) noted, however, that he had one case where NV was seen in a halo star and he added that the three-time ionized carbon abundance may be lower in the plane than just outside it.

Klaas de Boer (Washburn) reviewed the recent exciting work by *IUE* on the galactic halo with emphasis on sight-lines to the Magellanic Clouds. There is some uncertainty if gas far from the plane co-rotates with the plane but, if so, the density falls by a factor of 10 over 10 kpc and one cloud covering 7 square degrees in the direction of the Large Cloud may contain 300,000 solar masses. There is component structure in OI and FeII but the SiIV and, possibly, CIV profiles suggested the halo has a smoother, less cloudy structure than the plane. There was, however, some discussion as to whether the direction to the Magellanic Clouds (where most of the *IUE* data exists) is typical of our galaxy. Claudine Laurent (Verrieres-le-Buisson) commented also that the existence of a similar halo around the Small Cloud was in doubt as she had data showing no CIV or SiIV in an SMC star which, unlike other cases observed to date, did not have its own HII region. Chris Blades (Chilton) reported ground-based optical data from the Anglo-Australian Telescope (AAT) and found that the ratio of the neutral sodium column to dust reddening in the Small Cloud was 5 times smaller than that in our own galaxy.

Michael Penston (Vilspa) also showed AAT data of optical interstellar lines in other galaxies using galactic nuclei or supernovae as background probes. He confirmed earlier reports of CaII absorption in the Magellanic Stream. In discussion, the point was made that the (by necessity) moderate resolution on optical interstellar lines in other galaxies is similar in quality to the type of data that was available for our own galaxy in the 1940s and 1950s. While it is valid to analyse the galactic and extragalactic doublet ratios is similar ways and show that turbulent motions in interstellar media are generally characterised by velocity dispersions similar to that in our own galaxy, it was agreed that it is dangerous to deduce column densities from such material because large columns can be 'hidden' in components with low velocity dispersion. Alec Boksenberg (London) reviewed the current status of work on quasar absorptions lines. The absorption systems with metal lines can arise in galactic halos if these have radii of 100 kpc. The 'Lyman-α-only' absorption systems are not clustered like galaxies and suggest the presence of intergalactic clouds of primordial material.

On the theoretical side, Jo Silk (Berkeley) discussed other less direct evidence for intergalactic clouds including deduction from theories of galaxy formation. He proposed that slow self-regulating star-formation takes place in these clouds prior to their merging into galaxies as we know them. Joel Bregman (New York) described his 'galactic fountain' model of galactic haloes, in which hot gas of temperature T_0 at the base of the galactic corona rises, cools and turns into clouds which fall back towards the plane. Coronae of the right size are produced if T_0 is in the range one to six million degrees. A total mass of 10^{10} solar masses is required in these galactic haloes.

---

understood part of the electron transport system. Recent reports from Winget (Cincinnati) on reconstitution of this system using an isolated manganese-protein were not substantiated by other workers. For example, the reconstituted system described by Nakatani *et al.* (Imperial College London) requires a catalase-like protein rather than a manganese protein. Also, the NMR measurements of Wyrdzinski and Govindjee (Urbana) that appeared to reflect changes in the redox state of manganese were challenged by Sharp and Yocum (Ann Arbor, Michigan). Nevertheless, materials for the solution of the 'water-splitting problem' are accumulating. Oxygen-evolving preparations with increased specific activity were described by Stewart (Cambridge, England), inverted vesicles, that is, with the water oxidation system on the outside, were described by Albertsson (Lund), and Bishop (Corvallis, Oregon) has discovered mutants with defective water-oxidation systems. We cannot yet be 100 per cent sure, however, according to Metzner (Tubingen), that it is H_2O and not CO_2 that is releasing oxygen!

The sessions on chloroplast metabolism

0028-0836/81/020123-01$01.00

dealt largely with the regulation of the Calvin cycle in C_3 plants, starch and sucrose synthesis, photorespiration and nitrogen metabolism. Few advances in our knowledge of C_4 plants were reported, although both Sugiyama (Shizuoka) and Hatch (Canberra) reported that regulation of the activation and deactivation of pyruvate-phosphate dikinase in the mesophyll cells is achieved by adenine nucleotides rather than thiol-dependent mechanisms. The pathway of chlorophyll biosynthesis in chloroplasts, particularly the route from glutamate to δ-aminolaevulinic acid, is becoming clearer. Chlorophylls *a* and *b* with modified side chains in the ring structure also occur in leaf tissues (Rebeiz, Urbana).

Regulation of the Calvin cycle is achieved by several mechanisms. One possibility proposed by Buchanan (Berkeley) and Anderson (Chicago) is a light-dependent increase in the activity of certain enzymes. In spinach chloroplasts, illumination generates reduced ferredoxin which produces, via a reductase enzyme, the reduced form of the thiol protein thioredoxin. Three types of thioredoxin (m_b, m_c and *f*) have been found in chloroplasts by Schurmann (Neuchatel). Reduced thioredoxin *f* can increase the activity of some Calvin cycle enzymes assayed at physiological substrate and cofactor concentrations, and rapid rises in the activity of fructose and sedoheptulose diphosphatases on illumination of chloroplasts were reported by Leegood (Sheffield) and by Heldt (Gottingen). According to Charles (King's College London) in the case of fructose diphosphatase the rise in activity is due to an increase in the affinity of the enzyme for its substrate and cofactor rather than to a rise in V_{max}. When the light is turned off enzyme activities fall. How this is achieved has not been established. Heldt and others have shown that illuminated chloroplasts generate H_2O_2, which deactivates the enzymes and may account for the lowered rate of CO_2 fixation in chloroplast preparations illuminated in the absence of added catalase. In the presence of catalase, however, the rises in enzyme activity on illumination are too fast to limit the rate of CO_2 fixation both before and after the induction period (Walker, Sheffield). Ribulose diphosphate carboxylase shows little light activation. Hence CO_2 fixation must be controlled by other means *in vivo*. This led Halliwell (King's College London) to propose that the thioredoxin system exists to protect the reduced, physiologically active forms of certain Calvin cycle enzymes from H_2O_2 generated *in vivo*, rather than as a regulatory mechanism. According to Heber (Dusseldorf), pseudocyclic photophosphorylation, generating H_2O_2, must occur *in vivo* to correctly poise the redox state of the electron transport chain.

The major factors regulating CO_2 fixation seem to be the rise in *p*H of the stroma on illumination, and possibly a light-dependent increase in the stromal Mg^{2+} ion concentration. Increases in stromal [Mg^{2+}] from 1 to 3 mM have been reported in spinach chloroplasts, as discussed by Heldt, but Ben-Hayyim (Bet Dagan, Israel) has found no such increase in lettuce chloroplasts. There were some speculations that chloroplast Ca^{2+} ions, which powerfully inhibit fructose and sedoheptulose diphosphatases and protein synthesis, might be involved in turning off these reactions in the dark (for example, Jagendorf, Cornell).

Further developments in our knowledge of starch degradation in chloroplasts were reported by Stitt (Gottingen), who has isolated starch-loaded chloroplasts capable of degrading their starch at a physiological rate. Both amylase and phosphorylase activities are involved in this degradation (Beck, Bayreuth). Foyer (Sheffield) reported studies on the purified forms of the enzymes of sucrose synthesis. Claims by Garrett (Belfast) that isoenzymes of ribulose diphosphate carboxylase from diploid and tetraploid strains of ryegrass have different affinities for CO_2 and O_2 were fiercely contested, and more work is needed on this system.

The glycine–serine pathway is still regarded as the major pathway of CO_2 release during photorespiration in leaves, a view that was strengthened by the description of mutants of *Arabidopsis* with defects in various enzymes of the pathway (Ogren, Illinois). The ammonia generated during glycine decarboxylation is, according to Miflin (Rothamsted), assimilated by glutamine synthetase in the leaf cytosol. Other pathways of photorespiratory CO_2 release cannot be completely ruled out, however, since CO_2 evolution by direct glyoxylate decarboxylation has been reported in isolated leaf cells (Oliver, Idaho and Grodzinski, Ontario) and has been suggested by Ogren to occur at a high rate in an *Arabidopsis* mutant which cannot provide amino acids for the transamination of glyoxylate to glycine. Perhaps these alternative pathways are only important in nitrogen-deficient leaves.

The Rothamsted group also presented evidence that chloroplasts can synthesize amino acids of the aspartate family (Thr, Lys, Ileu, Met). It is now well established that ammonia assimilation in chloroplasts proceeds by the glutamine synthetase/glutamate synthetase route. Glutamine produce by cytosolic glutamine synthetase (see above) must enter the chloroplast for further metabolism by the ferredoxin-dependent glutamate synthetase. □

The (p,α) reaction

from P.E. Hodgson

THERE have recently been several studies of nuclear reactions emitting particles in an unstable or resonant state. These particles live long enough to act as a single particle during the reaction itself, but break up into two fragments soon after emission and long before they reach the detecting equipment. For example, it is possible for ^{8}Be to be emitted from a nuclear reaction, but it is unstable and soon breaks up into two alpha-particles. The energy release is only 96 KeV, and so the alpha-particles continue to move in almost the same direction as the ^{8}Be nucleus and are easily identified by their strong directional and energy correlation compared with the single alpha-particles from other reactions. Another example of such a reaction is the (α, d*) reaction with the emitted deuteron in the unstable singlet state at an excitation energy of 100 KeV.

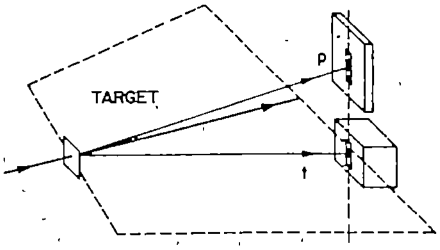

Fig. 1 Arrangement of detectors for the proton and triton from the breakup of excited alpha-particles.

It is particularly interesting to study such reactions as they extend the range of final states that can be reached and also provide an additional test of nuclear reaction theory. One reaction that was first identified a few years ago (*Nature* **266**, 121; 1977) is the (α,α*) reaction with the outgoing alpha-particle excited to the unbound monopole state at 20.1 MeV. Now a detailed study of the corresponding (p, α*) reaction has been made by Datta *et al.* at the University of Manitoba (*Phys. Rev.* **C21**, 1687, 1980). The excited alpha-particles decay into a proton and a triton, and these are detected by two counters as shown in Figure 1. The measurements were made with a 45.2 MeV proton beam on ^{12}C, and some of their results for the (p, α) and (p, α*) reactions are shown in Figure 2.

The cross-sections of many nuclear reactions can be calculated by the distorted wave theory, and this may be applied to

0028-0836/81/020124-02$01.00

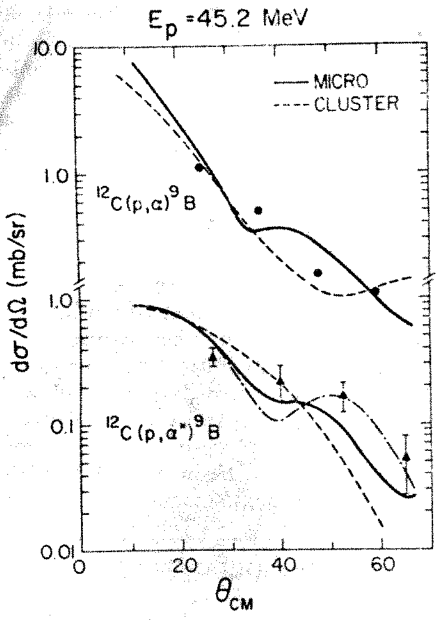

Fig. 2 Differential cross-sections for the (p,α) and (p,α*) reactions on ^{12}C at 45.2 MeV compared with distorted wave calculations with the microscopic and cluster models. Y-axis, differential cross section in mb/sr; X-axis, angle in degrees. The dash-dot curve in the lower figure shows the result of another microscopic calculation using different distorting potentials. Each calculation is separately normalized to the experimental data.

these reactions, provided allowance is made for the unbound nature of the emitted particle. This is done by expressing its wavefunction as a product of a bound s-wave function and an energy-dependent Breit-Wigner resonance factor. There are two possible ways of treating the three particles picked up by the incident proton from the target nucleus. The simplest is to treat them as a cluster, and then the theory appropriate to a one-nucleon transfer reaction can be used directly with appropriate modification for the mass and charge of the transferred cluster. The other method is to treat the transferred nucleons individually, which is more correct but considerably more complicated. The cross-sections corresponding to calculations made in both these ways are compared with the experimental data in Figure 2. It is notable that on the whole the calculations treating the nucleons individually, called the microscopic model, fit the data somewhat better, although there is little to choose between them. Both calculations reproduce quite well the general features of the cross-sections and also the ratio between the cross-sections of the *(p,α)* and (p,α*) reactions. There is some uncertainty connected with the choice of distorting potentials, but on the whole the agreement is sufficient to permit the conclusion that the (p,α*) reaction is sufficiently well understood for it to be used in studies of nuclear structure.

Precambrian orogenies and polar wandering

from J.C. Briden

[illegible] Library
Science College
Upper Circular Road

EVIDENCE that orogenic belts less than a few hundred million years old have formed (or are forming) at plate margins either at a continent/ocean interface or at a site of collision of two continents is overwhelming. It is consistent with the theory of a lithosphere made up of a small number of rigid plates in relative motion and encourages the interpretation of geology by extrapolation of the plate model far back in time. Extrapolation to more remote periods is uncertain especially because in Archaean times (beyond 3,000 Myr ago — the most remote parts of the geological record) evidence for rigid regions which might be the plate interiors is lacking. Hence notions have grown of intervals in which transitional tectonic regimes might have operated, with speculation that some or all older Precambrian orogenic belts do not mark former plate margins.

Palaeomagnetic studies have featured prominently in these arguments. The directions of permanent magnetism in continental rocks show slow systematic changes with age which can be depicted as paths of apparent wandering of the pole relative to each plate. For the past several hundred million years, the differences between the various polar wander paths are far more pronounced than any common component they may have, unequivocally demonstrating that the plates have been in motion relative to one another.

Returning to the Precambrian, much of the argument about the origin of orogenic belts relates to the degree to which polar wander paths from presently adjacent cratonic regions agree or disagree. The most serious problem is the impossibility of identifying the precise age of magnetization in Precambrian rocks, many of which have a complex history reflected in the frequent superposition of several palaeomagnetic components. Even where geochronological studies of the same rocks yield age estimates of various events in the rock history, uncertainties remain because events which leave palaeomagnetic imprint may not be synchronous with closure of isotopic systems in those rocks.

It has variously been argued (a) that the palaeomagnetic signatures from all fragments are essentially the same, being compatible either with true polar wander or coherent movement of a single super continent; (b) that they are all different and hence latter day plate tectonics was fully and exclusively operational as far back as the palaeomagnetic record goes, and (c) that similarities and differences both exist, and hence some orogenic belts mark sites of continental collision and others do not.

The supercontinent model requires a single common polar wander path. This path can only be regarded as internally consistent if many inexplicable errors in magnetic age assignment have been made. It is also extraordinarily long, even allowing for the fact that it is almost certainly already smoothed by the failure to resolve superposed magnetic components in many suites of rocks. It implies a Proterozoic history utterly different from that of more recent times — a world in which polar wander or drift of a single supercontinent operated instead of a relative plate motion; in which deformation within that supercontinent occurred instead of plate interiors being rigid; and yet a world in which motions of the lithosphere were considerably faster than in more recent time.

On the other hand it is much too easy to simply link the sequence of palaeomagnetic data from different cratons, note that they are different, and conclude that cratons behaved like latter-day plates. The polar wander paths will inevitably look different because in almost every case each path will have been sampled inadequately and at quite different instants of time.

The middle-of-the-road model presently seems to find the most favour with palaeomagnetists because some of the very few comparisons of well determined polar wander paths from neighbouring cratons really do seem to agree, for period of times which post-date the deformation of the orogenic belts now lying between them. However, this is scarcely worthy of being called a model at all, because it fails to tell us which orogenic belts are merely compressions within pre-existing plates and which had a pre-history of large relative motion of their margins. It does not predict the style of motion when displacement has been large; nor can it rule out small openings and closings where they have been small.

In this issue of *Nature*, Onstott and Hargraves (page 131) argue for a fourth style of large motion (thus exhausting the alternatives and ensuring that at least someone is right!) with adjacent cratons sliding past each other along transcurrent

fault belts with neither creation nor consumption of oceanic crust within those belts — though presumably it has to happen elsewhere in other parts of the plate-driving system. Parts of their argument are as weak as any that have gone before due to the inadequacies and paucity of the palaeomagnetic data on which they have had to rely. Nor is their interpretation unique: their data are equally compatible with a 'Wilson cycle' of an ocean which opened and subsequently closed. Yet their model serves as an important reminder that this transcurrent style of tectonics is possible and draws attention to evidence consistent with it in Proterozoic times — there are substantial examples in the Phanerozoic, particularly in the evolution of the Caledonian and the Hercynian belts in Europe.

This element of relative plate motion is easily missed in tectonic analyses of orogenic belts as it is dependent on discovering a few surface traces of large faults parallel not only to the structural grain but most likely parallel to the grain of sedimentary facies as well. If one looks back at the palaeomagnetic evidence of different polar wander paths from Europe and North America published in the mid 1950s as evidence of the opening of the Atlantic, one would nowadays pick the individual data to shreds; few if any would be accepted as adequately confirmed palaeomagnetic directions by current criteria. Yet the correct answer could be seen, and was indeed seen, in the systematic deviation of sets of (internally suspect) data. The same may be so for Onstott and Hargraves' contention of large-scale transcurrent motions. As in the Phanerozoic the confirmation came from elsewhere than continental palaeomagnetism (in dated magnetic anomalies, transform fault interpretation, and the whole range of sea floor spreading data), so for the Proterozoic other disciplines may resolve the problem. The critical lines of inquiry are likely to be careful tectonic analysis of structures in plan, and seismic 'profiling' right through the lithosphere to give structure in cross-section. Mesozoic to present geological experience tells us that there are enough distinctions between major transforms and sites of destruction of major oceans or back arc basins for solutions to this problem to be attainable.

Mongoloid types, Indo-China. King and Queen of Siam.

MONGOLIAN TYPE

from A. H. Keane

We are all familiar with the essential characteristics of the Yellow or Mongolian division of the human family.

They correspond substantially with those we see in the ordinary Malay type, in Java, Bali, Madura, many parts of Sumatra, round the coast of Borneo, and in the peninsula of Malacca. The true aborigines of this region were the Negritos; consequently the Malays, like the pre-Malays or Caucasian Indonesians, are here intruders. Intruders from where? Obviously from where the type exists, the neighbouring Indo-Chinese peninsula. What then becomes of the Malay as a primary division of mankind? As such it can no longer be recognised in anthropology, and must sink to the position of a mere variety of the Mongol type. The so-called true Malay or typical Malay is essentially a Mongolian, and the likeness between the two has not failed to strike all careful observers. "The Malayan race," says Wallace, "as a whole undoubtedly very closely resembles the East Asian populations from Siam to Manchuria. I was much struck with this, when in the Island of Bali I saw Chinese traders who had adopted the costume of that country, and who could then hardly be distinguished from Malays; and on the other hand I have seen natives of Java who, as far as physiognomy was concerned, would pass very well for Chinese." Hence De Quatrefages rightly rejects the claim of the Malays to be regarded as a fundamental type. "All polygenists," he remarks, "have regarded the Malays as one of their *human species;* many monogenists have considered them as one of the principal races. I showed long ago that in reality they are only a mixed race in which white, black, and yellow elements are associated."

The last clause of this sentence gives the true solution of the problem. The inhabitants of Malaysia consist not of one, nor even of three distinct races, but of three races variously intermingled, the yellow or Mongolian, and the white or Caucasian chiefly in the west, these two and the black or Papûan chiefly in the east. As the fusion of yellow, white, and black produces the so-called "Alfuros" in the east, so the fusion of yellow and white produces the so-called Malays in the west. The more the yellow prevails the nearer do the Malays approach the Mongol type; the more the white prevails the nearer do they approach the Causasian type, until in some places they seem to be no longer distinguishable from the Mongols, in others from the Caucasians."

Fallacies of lifestyle cancer theories

Samuel S. Epstein* **& Joel B. Swartz†**

* Professor of Occupational and Environmental Medicine
† Assistant Professor of Occupational and Environmental Medicine,
School of Public Health, University of Illinois at the Medical Center, Chicago, Illinois 60680

Self-interest of the chemical industry apart, the lifestyle theory of cancer causation is held to reflect misinformation and 'inactive conservatism'.

PETO'S article[1], purporting to be a review of the book *The Politics of Cancer*[2], is largely a restatement of the lifestyle theory of cancer causation. This theory postulates that if you get cancer it is essentially your own fault, and that the causal role of past involuntary exposure to environmental and occupational carcinogens is trivial. Not surprisingly, the lifestyle theory has emerged as the major professed basis of the chemical industry's objections to the regulation of its carcinogenic products and processes[3]. As an enthusiastic proponent of this theory, Peto asserts that smoking-derived and fat-associated cancers "collectively account for more than half of all cancer deaths." As a corollary, of Peto's emphasis on lifestyle factors, he denigrates the role of occupational and environmental carcinogens and the need for their effective regulation, claiming that there has been no recent increase in cancer mortality rates other than that due to smoking. We shall demonstrate that there is scant scientific basis for the lifestyle theory, and that it is in fact contradicted by a substantial body of published evidence.

Cancer rate trends

Peto justifies his emphasis on lifestyle factors by dismissing evidence for recently increasing cancer rates, apart from "that due to the massive effects of smoking on lung cancer". However, there is substantial evidence to the contrary. Standardized cancer death rates, adjusted to the 1940 age structure of the total United States population, show a progressive overall increase of about 7% from 1935 to 1970 (ref. 4) despite marked reductions of stomach cancer rates for unexplained reasons and of cervix cancer rates for reasons including the frequency of elective hysterectomy for non-malignant disease and the success of screening programmes. These trends are consistent with standardized mortality data for the United States (Table 1)[5], where they are even more marked in black males, and with crude mortality data for the United Kingdom (Table 2)[6]. The overall rate of increase in US cancer mortality in the 7-year period from 1969 to 1976 (5.5%), adjusted to the 1970 age structure, is substantial and comparable with that for the preceding 35 years, 1935 to 1970 (7%). The overall increase in incidence rates is even more marked than mortality rates in the past decade, involving a wide range of organs besides the lung (Table 3)[5]. Moreover, the increase in incidence for all sites is comparable with that when lung cancer is excluded (Table 4)[7,8].

Reliance on overall age-adjusted incidence or mortality rates alone is simplistic, as such rates can mask steep increases in organ-specific cancers in high risk population subgroups, such as asbestos insulation workers or menopausal women treated with oestrogen replacement therapy. The overall probability, at today's death rates, of a person born now getting cancer by the age of 85 is 27% for both men and women; this is increased from the 19% for men and 22% for women born in 1950 (ref. 9). Furthermore, recent cancer rate trends reflect exposures and events beginning some 20 or 30 years ago, when the production of synthetic organic chemicals was relatively trivial compared with the present levels. The production of synthetic organic compounds in the United States in 1935, 1950 and 1975 was about 1, 30 and 300 billion pounds per annum, respectively[10]; sharp increases have also been observed for a wide range of derived industrial products such as chlorinated hydrocarbon solvents, plastics and resin materials, and of industrial carcinogens, such as vinyl chloride and acrylonitrile. It is reasonable to anticipate that greater production has been paralleled by increased exposure of increasing numbers of both the workforce and the general public, which is likely further to accentuate increasing trends in cancer rates. It must also be recognized that before the 1976 Toxic Substances Act, which the chemical industry so effectively stalled for so long[11], there were no requirements for testing chemicals before their introduction into commerce (with the exception of special-purpose legislation for drugs, pesticides and food additives). Thus, the overwhelming majority of industrial chemicals now in use have never been tested for chronic toxic and carcinogenic effects, let alone for ecological effects.

Role of smoking

As emphasized in *The Politics of Cancer*[1] (p. 178), "Smoking is the single most important cause of lung cancer, as well as of cancer at other sites, chronic bronchitis and emphysema, and cardiovascular diseases". Less well appreciated by lifestyle advocates is that overemphasis on smoking is widely used to divert attention from occupational causes of lung and other cancers. Of the approximately 100,000 annual lung cancer deaths in the United States, at least 20% occur in nonsmokers. It is relevant that lung cancer death rates in nonsmokers approximately doubled[12] from 1958 to 1969, an increase maintained since. Furthermore, the role of occupational exposure to carcinogens was not recognized in most of the classic epidemiological studies which linked lung cancer with smoking. This led to overestimation of the contribution of smoking compared with occupational risks or to their possible interactions.

The 1970 population was used as standard for age-adjustment.

Thus, "we are unable to say how much of the risks attributed to cigarettes is a 'pure' cigarette risk and how much is cigarette times another, possibly on the job hazard"[8]. Moreover, smoking and occupation are confounded variables, smoking among men being more prevalent in 'blue-collar' workers than in professional and managerial classes[13]. Occupational causes of lung cancer include asbestos, radon daughters, nickel ores, chromium, arsenic, beryllium, mustard gas, vinyl chloride and bischloromethyl ether, apart from incompletely identified carcinogens in a wide range of industries such as rubber curing, tanning, steel (coke ovens), foundries, automobile, and petrochemicals. Thus, lung cancer rates in asbestos insulation and topside coke oven workers are as much as 10 times greater than general population rates.

Underestimation of the role of such occupational carcinogens has been assisted by the fact that lung cancer mortality rates, based on the International Classification of Diseases, fail to distinguish pleural mesotheliomas from lung cancers; there is evidence of substantial under-reporting of mesotheliomas (by about 75%) in high risk groups[14], and even more so in occupations, such as automobile mechanics, where asbestos exposure has not been well recognized. There is a further lack of distinction between lung cancers of different histological types, some of which, such as adenocarcinomas, are less likely to be due to smoking than to occupational carcinogens[15,16]. "In several instances where the risk of bronchogenic carcinoma has been shown to be increased among occupationally exposed groups, there has been an accompanying shift in the distribution of histologic types of tumours", away from the small-cell undifferentiated and squamous cell carcinoma of the lung, the principal types whose frequency is increased by smoking, in the direction of other types, particularly adenocarcinoma[16]. "This (shift) has been noted among metal miners, uranium miners, copper smelter workers, vinyl chloride polymerization workers, chloromethyl methyl ether production workers, and mustard gas manufacturers" (ref. 16).

Possible variations of smoking patterns fail to account for the marked excess in US lung cancer rates identified in specific occupational exposures, particularly among ethnic minorities and migrants from southern states[17]. A further challenge to the dominant role ascribed to smoking seems to be provided by observations that the risk of lung cancer in certain occupational groups, such as American Indian uranium miners[18], Swedish zinc–lead miners[19], mustard gas workers[20], copper smelters exposed to arsenic[21], and chloromethyl methyl ether workers[22], is about as high among nonsmokers as smokers, although the latency period is reduced in smokers, suggesting a possible promotional effect of smoking. It appears that the relative risks of lung cancer for smokers as against risks for nonsmokers may have been overestimated, particularly in less than lifetime studies[13]. Variations in smoking do not account for geographic excesses in lung cancer rates in US males and females, which overall reflect proximity of residence to petrochemical and certain other industries[23,24]; there are also data showing associations between levels of atmospheric carcinogens and lung cancer mortality rates[25]. It may be noted that a report[26] from Peto's own institution demonstrates that the correlation coefficient between lung cancer and smoking internationally explains only one-third as much of the variation as does the correlation between lung cancer and solid fuel consumption (0.4 versus 0.7; $r^2 = 0.16$ versus 0.49).

Overemphasis on the carcinogenic effects of smoking, and ignoring or discounting the role of occupational and other exposures, is extended by Peto and others to cancers of the

Table 4 Changes in US cancer incidence rates from 1970 to 1975[7,8]

* 'Liquid energy'.

bladder and pancreas which are variously characterized as related to or caused by smoking[27,28]. However, the relative risks for these cancers are several times less in smokers compared with nonsmokers than is the case for lung cancer. Excess bladder cancer rates have been identified in several occupational categories, including rubber, paint manufacturing and textile dyeing workers[29], and among residents in highly industrialized counties[30], particularly those with large chemical industry complexes[31]. Excess pancreatic cancer rates have also been reported in various occupations including steel and metal workers[32] and organic chemists.

Recognition of the important role of occupational exposures in lung cancers previously ascribed, exclusively or largely, to smoking in no way detracts from the recognition, emphasized in *The Politics of Cancer*, that the impact of smoking constitutes a "national disaster". There is no basis for regarding the smoking/lifestyle and occupational theories as mutually exclusive, particularly as these exposures may operate interactively. Furthermore, lifestyle is a somewhat misleading rubric for smoking as it restrictively implies voluntary personal choice. Placing responsibility for personal choice of an addictive lethal habit on young teenagers, the fastest growing group of new smokers, seems inappropriate. Failure to control smoking reflects a wide range of political and economic constraints, including massive press advertising by the industry which omits the word 'death' from the guarded small print warning of danger, massive revenues to federal, state and local government from tobacco taxes, federal subsidies to the industry and unwillingness of governments to increase tobacco taxation or to develop incentives to tobacco farmers to diversify. It is also important that the industry has moved to open up massive new markets with high-tar cigarettes in less developed countries, where the population is poorly informed on the hazards of smoking.

Role of diet

Lifestyle proponents are on less sure ground when they bracket diet, excess fat and overnutrition with smoking as the causes of the majority of cancer deaths. This claim is based largely on international correlations between consumption of total fat and rates for cancer of the breast and colon[26]; however, such correlations by themselves are not proof of causality. Similar correlations were found, in the same study from Peto's institution, between breast and colon cancers and other variables, such as Gross National Product and consumption of animal protein, which also appear to reflect industrialization[26] (Table 5). Furthermore, "epidemiologically, the case against fat is weak because there are populations that have a high fat intake and little bowel cancer . . ."[33]. Of two case control studies on the association between diet and breast cancer, one found no effect[34] and the other found trivial effects of fat and caloric intake, concluding that ". . . recommendations of major dietary modification as a possible preventive measure for breast cancer are clearly premature"[35].

Equally unconvincing are the studies, cited by Peto as corroborative evidence on the experimental effects of diet, which were largely concerned with the influence of fat on the incidence of tumours induced by chemical carcinogens and ionizing radiation, and the influence of caloric intake on the incidence of spontaneous and induced tumours. Not only were different variables defined in the animal and human studies—per cent fat in the diet and total dietary fat, respectively—but increasing fat levels in the animal experiments were associated with increased incidence of skin, liver and breast cancers, whereas the reported correlations between fat consumption and liver cancer mortality are negative for both men and women (Table 5). Moreover, these experiments often failed to differentiate between variations of total dietary fat and caloric intake in test animals and to adjust caloric intake in controls to reflect dietary fat variations in test animals; the magnitude of the variations in fat and caloric intake required substantially to influence the incidence of induced and spontaneous tumours in experimental animals is generally far in excess of the dietary differences observed among the various human populations studied[33]. These experiments invariably failed to adjust the intake in controls of fat soluble carcinogens, present in fat as accidental environmental contaminants, to reflect variations of fat intake of test animals.

Peto's claim for the causal role of dietary fat in human cancer overstates the conclusions of those cited as the basis for his claims. Armstrong and Doll[26], for instance, merely suggest that dietary fat levels may influence the incidence of colon and breast cancers, without asserting causality. Doll considers that diet may act by modifying the incidence of tumours induced by carcinogens or by acting as a vehicle for exogenous carcinogens[36]—a suggestion also made in *The Politics of Cancer* which Peto dismisses as "implausible". Carrol concludes that "although caloric intake may be a factor in human carcinogenesis, it does not appear to offer a practical approach to the problem"[37]. As recognized by current concepts on the multifactorial aetiology of cancer, there is a substantial probability that a wide range of influences, diet and other lifestyle factors included, modify individual responses to carcinogenic agents. To ascribe causality to any particular modifying factor requires a degree of scientific evidence that has not yet been presented for dietary fat.

Role of occupation

Peto associates himself with the insistence by the chemical industry[2] and other lifestyle proponents that occupational exposures account for about 5% (refs 38–40) or "a very small proportion"[41] of all cancers. This view is based on ascribing given percentages to known or alleged lifestyle factors, including smoking, fatty diet and sunlight, leaving a small unaccounted for residue to which occupational factors are arbitrarily assigned by exclusion. The authors of this simplistic hypothesis compensate for its tenuous basis by reliance on 'educated estimates' and by making circular references to each other, often by 'personal communication', as the responsible authority.

However, there are problems with such 'guesstimates'. First, they fail to consider the multifactorial aetiology of cancer and the role of multiple causal agents, such as asbestos and smoking[42]; thus, the summation of known causes of cancer should properly exceed 100%. As one of the lifestyle authors recently stressed[36], "there is now strong evidence to suggest that the risk of cancer is commonly increased by interaction of two or more factors". Second, current cancer rates reflect exposures 20 to 30 years ago, when production levels of occupational carcinogens were a small fraction of the present; such estimates should thus now be adjusted to reflect increasing numbers of workers exposed. Third, the authors of these guesstimates failed to consider the very limited nature of the data base on exposure to occupational carcinogens. Nor have they at any stage protested or even commented on the persistent refusal of the chemical industry to make such critical data available. In the absence of exposure data, it is even less clear how the 'lifestylers' confidently arrive at their estimate of less than 5%.

Rather than addressing himself to such problems, Peto dismisses recent estimates of the importance of occupational carcinogens in a report by the US Public Health Service[43] as exaggerated, unsound and unreasonable. This report, prepared by nine named and internationally recognized experts in cancer epidemiology, statistics and carcinogenesis from three federal research agencies, is based on a National Occupational Hazard Survey which between 1972 and 1974 surveyed nearly 5,000 workplaces chosen to provide a cross-section of industry in the United States. The report estimated the total number of workers exposed to asbestos, nickel ores, chromium, arsenic, benzene and petroleum fractions, including aromatics. The excess cancers attributable to each of these carcinogens were derived by multiplying the number of exposed workers by known risk ratios and subtracting the "normal incidence" of the cancer.

The report concluded that "as much as 20% or more" of cancers in the near term and future may reflect past exposure to the six carcinogens considered. The uncertainties and limitations in these conclusions, including the possibility that exposures and risk ratios may have been overestimated in some instances, were clearly stated in the report, as were other considerations including the multifactorial aetiology of cancer, and the role of lifestyle factors and their possible interactions with occupational exposures.

The possibility that this government report underestimates rather than overestimates the role of occupational exposures, for several reasons some of which are recognized in the report, has not been considered by its denigrators, including Peto. First, the calculations in the report ignore the role of radiation and of some ten epidemiologically recognized occupational carcinogens, other than the six considered. Second, the risk ratios considered may be artificially low as they were largely derived from less-than-lifetime epidemiological studies, which may thus underestimate the true risk in view of the long latencies commonly involved. Third, the report does not consider the many statistical and methodological constraints common to most occupational epidemiological studies[44] such as relatively small numbers of workers in many locations, changes in exposure patterns over time due to employee turnover, plant shutdown, process and production changes and changes in management, all of which lead to fragmentation of health and exposure records, access to which is often restricted by industry. Fourth, the estimates fail to take account of the many chemicals recognized as carcinogenic in animals for which there are no exposure or epidemiological data. Thus, of 442 chemicals and industrial processes recently evaluated by the International Agency for Research on Cancer (IARC), epidemiological data are available for only 60 (14%), although evidence of experimental carcinogenicity was considered to be sufficient for 143 (32%)[45]. Fifth, the estimates exclude high risk occupations with incompletely defined carcinogens, such as the steel, rubber and tanning industries. Sixth, the estimates do not adequately reflect conditions in small business where exposure levels are likely to be higher than in major chemical companies. Seventh, the report does not reflect major increases in the production of the occupational carcinogens it considered such as benzene, with the likelihood of recently increasing exposures. Eighth, the study examined only a limited number of sites, excluding cancers such as skin and bladder which are known to be occupationally related. Finally, the estimates neglect the possible role of fugitive point-source emissions of industrial carcinogens as causes for the excess of overall and organ-specific cancers, including lung, bladder, colon, pancreas and breast, in residents of certain highly industrialized counties.

This government report has received extensive support from various expert bodies, such as the Toxic Substances Strategy Committee, whose position has been endorsed by 17 federal agencies, and international groups, such as the International Labor Organization, and the US and British trades union. The report has also received additional support in the critique of two consultants to the chemical industry's American Industrial Health Council which concluded that "... the full range (of total cancer attributable to occupational exposure) using multiple classifications may be from 10 to 33% or perhaps higher if we had better information on some other potentially carcinogenic substances.... The annual number of cancer deaths attributable to asbestos is in the range from 29,700 to 54,000, which corresponds to a percentage range of the total cancer of 7 to 14%.... Any argument over these numbers cannot detract from the fact that asbestos exposure was, as the authors (of the Government report) state, a major public health disaster.... We also believe that reduction of exposure to carcinogens in the course of employment can certainly be expected to affect major reductions in the frequencies of occurrence of cancer and is one of the most promising applications of preventive medicine"[47]. The American Industrial Health Council failed to release this critique until the record of the recent Occupational Safety and Health Administration hearings on regulation of occupational carcinogens closed.

Finally, there is no basis whatsoever for recent unsubstantiated allegations by Peto and others that all or most authors of the government report have disowned or rejected it or its conclusions (K. Bridbord, M. Schneiderman and A. Upton, personal communication). It should be further emphasized that this 50-page report was prepared as a government document specifically for inclusion in public hearing records, and not for submission to a scientific journal.

Conclusions

Cancer is a disease of multifactorial aetiology to which occupational exposure and smoking can contribute importantly, sometimes interactively. There have been substantial recent increases in cancer rates which cannot be accounted for by smoking alone. Smoking is the major lifestyle factor of importance in cancer, and evidence for the causal role of other lifestyle factors, particularly diet, is slender. The role of lifestyle factors has been exaggerated, by those with an economic or intellectual investment in this theory, by largely excluding involuntary exposures to carcinogens and minimizing the role of occupational carcinogens. These considerations further illustrate the primary thesis of *The Politics of Cancer*: cancer is essentially a preventable disease which requires intervention and regulation at several levels, particularly the occupational and smoking. Failure to prevent cancer reflects major political and economic constraints which have hitherto been largely unrecognized or discounted.

Proterozoic transcurrent tectonics: palaeomagnetic evidence from Venezuela and Africa

Comparison of palaeomagnetic poles from the Guayana Shield with the published Precambrian palaeomagnetic record for Africa suggests that large-scale (thousands of kilometres) transcurrent motions have occurred along Upper Proterozoic mobile belts in South America and Africa. Displacements of such magnitude are consistent with a transform model for Precambrian mobile belts.

DISCUSSION of the role of plate tectonics in Precambrian crustal evolution has focused on the significance of the mobile belts that partition Precambrian shields (see Fig. 1). They could have been formed by intracratonic vertical movements and crustal thinning induced by mantle upwelling along hotspot tracks or ridge systems[1,2] (ridge-lineament model), or they may be the scars of the subduction zones along which the two adjacent cratons were 'welded' together[3] (suture model). The ridge-lineament (suture) model implies small (large) relative motions among cratonic nuclei.

It is also possible that Precambrian mobile belts are zones of transcurrent movement[4,5]. This hypothesis would predict differential motions of a different type among adjacent cratons. The suture model requires the strike of the mobile belt to fall approximately along a meridian (longitude) passing through the relative rotation pole of the adjacent cratons; whereas in the transcurrent model, the strike of the mobile belt will tend to lie along a latitude line with respect to the relative rotation pole.

With a sufficient amount of reliably dated palaeomagnetic data of the same age from each of the bordering cratons, it is theoretically possible to determine which of the three models best fits the data. We compare here newly obtained Precambrian palaeomagnetic data from the northern part of the Guayana Shield with the published Precambrian palaeomagnetic record for the West African, the Kalahari and the Congo shields. Although the palaeomagnetic data base is still rather small, we believe the data are more consistent with the transcurrent model than the other two models. Our results, however, as in other published intercratonic comparisons of Precambrian palaeomagnetic data[6–11], are not completely unambiguous.

Our palaeomagnetic data (Table 1) are based on a study of 300 samples (47 sites) from five major stratigraphic units of the Venezuelan Guayana Shield: the granulites of the Imataca Complex (2,000–2,050 Myr)[12,13], the Supamo–Pastora granite-greenstone terrain (1,900–2,000 Myr)[14–16], the Cuchivero-Caicara acid metavolcanics (1,600–1,900 Myr)[17–20], the Roraima sandstone and diabases (1.66)[21–23] and the Parguaza rapakivi batholith (1,520–1,590 Myr)[17].

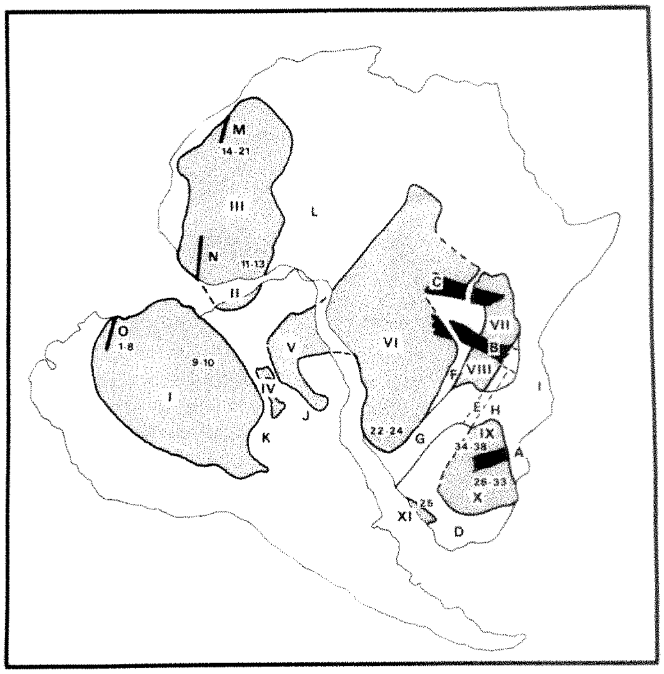

Fig. 1 Stable continental crust since 1,500 Myr BP, and mobile belts in Africa and South America. Plot is on the Bullard *et al.*[36] reconstruction. Stippled areas represent continental crust stable since 1,500 Myr. I, the Guayana Shield. The West African Shield is composed of the West African Craton (III) and the Sao Luis Craton (II). The Congo Shield is composed of the Sao Francisco Craton (V), the Kasai Craton (VI), the Tanzanian Craton (VII) and the Zambian Craton (VIII). The Kalahari Shield is composed of the Rhodesian Craton (IX) and the Kaapvaal Craton (X). XI is the Richtersveld Province, and IV is the Goias Central Massif. The Lower Proterozoic age (2,000 Myr.) mobile belts comprise the Limpopo belt (A), the Ubendian-Rusizian belt (B) and the Kibali-Toro-Bugandian belt (C). The Kibaran age (1,100 Myr) belts consist of the Namaqualand belt (D), the Irumide belt (E) and the Kibaride belt (F). The Pan African age (600 Myr) belts comprise the Damara belt (G), the Zambezi belt (H), the Mozambique belt (I), the Brasilia (Brazilian) belt (J), the Paraguay-Araguaia belt (K) and the Dahomeyan-Pharusian belt (L). M is the Sfariat zone, N is the Sassandra mylonite zone and O is the Guri mylonite zone. Arabic numerals refer to the pole numbers in the first column of Table 1.

Results of the analysis

Two or more components of magnetization were isolated by alternating field demagnetization from most of the sites. Thermal demagnetization of pilot samples of the Imataca Complex and the Roraima Group proved less effective than alternating field demagnetization in separating magnetic components. Examples of alternating field and thermal demagnetization results are given in Fig. 2. In general, the mean site directions of the more stable component as given by minimum dispersion analysis[24] were not significantly different from those given by vector analysis of Zijderveld diagrams[25,26]. The poles reported in Table 1 are averages of site poles based on at least four samples and with values for Fisher's $k > 7$. The mean site poles for the Imataca Complex and the Roraima Intrusive Suite were

* Details on our site locations and on our palaeomagnetic data will be presented elsewhere[27].

† The palaeomagnetic data for the Imataca Complex, the Supamo–Pastora province and the Roraima Group have not been structurally corrected. The Imataca Complex fails the fold test at the 95% level of confidence. Although the between-site *k* values improve after structural corrections for the Supamo–Pastora data (from 6 to 12) and for the Roraima Group data (from 12 to 15), these are not signficant improvements at the 95% confidence level. For the Roraima diabases, the poles given here are the average of the data obtained in this study and previously published results[60–62].

‡ U–Pb ages.

§ K–Ar ages.

∥ Rb–Sr ages, in many cases whole-rock isochrons, $\lambda^{87}\text{Rb} = 1.42 \times 10^{-11}\ \text{yr}^{-1}$.

¶ Number represents total number of samples averaged.

distributed in clusters (separated by at least 120°). The mean and associated fisherian statistics for each cluster are reported (Table 1).

Although the protolith age[12] for the rock units of the Imataca Complex is >3,000 Myr, their stable remanence was probably acquired during regional uplift and cooling following granulite metamorphism, which has been dated at 2,050–2,000 Myr by a Rb–Sr biotite age[13] and detailed Rb–Sr and U–Pb analyses of the granulites[12].

The stable remanence in the Supamo–Pastora rock units was also probably acquired during regional uplift and cooling, which has been dated at 2,000–1,900 Myr based on K–Ar hornblende and biotite ages[15].

The origin of the stable remanence in the Cuchivero–Caicara metavolcanics is uncertain; however, because of their low metamorphic grade (lower greenschist) and lack of multiple components of magnetization, the age of their remanence is probably close to their Rb–Sr whole-rock isochron ages[17–20], which range from 1,960–1,640 Myr. The consistency in the remanence directions from sites separated by >400 km suggest little structural deformation has occurred since the acquisition of their magnetization.

Among the data from the Imataca Complex, the within-site concentration as given by Fisher's *k* varied widely from 6 to 255; the between-site concentrations were fairly high (Table 1). The within-site *k* values for the Supamo–Pastora and Caicara–Cuchivero units ranged from 10 to 165.

The more stable components present in the younger intrusive units, the Roraima diabases and the Parguaza batholith, are probably primary thermoremanent magnetizations acquired at 1,660 and 1,500 Myr. The within-site *k* values for the Roraima diabases were quite high, ranging from 17 to 230; those for the Parguaza were variable, ranging from 3 to 62.

The age and nature of the remanence of the Roraima sandstone are uncertain because hydrothermal alteration is pervasive and the remanence could easily be a chemical overprint.

Many of the less stable secondary directions observed in both the metamorphic and intrusive units represent partial remagnetization during the low-grade Nickorie metamorphic episode[15] dated at 1,200 Myr. Eight of the sites were apparently partially remagnetized during this metamorphic episode. These secondary overprint directions have not been included in Table 1, but will be discussed elsewhere[27].

Palaeomagnetic data

The Precambrian palaeomagnetic poles from the three major African cratons given in Table 1 have been recalculated from the original site–pole distributions. In most cases, the pole obtained is the same as that reported in the original publication. In the data from studies in Algeria[28], Angola[29] and Namibia[30], however, the site–pole distribution showed several distinct clusters. We have calculated poles for each of these clusters rather than a single site-mean pole as originally reported. We believe that the several clusters may be records of the geomagnetic field at different times, and that information is lost by calculating only one mean pole position. Our conclusions, however, do not depend on this operation, and the original published poles could equally well have been used.

All of the African palaeomagnetic data reported in Table 1 and Figs 3, 4 and 5 are based on at least 10 independent samples and have a Fisher's $k \geq 5$ (only three poles have $k < 10$).

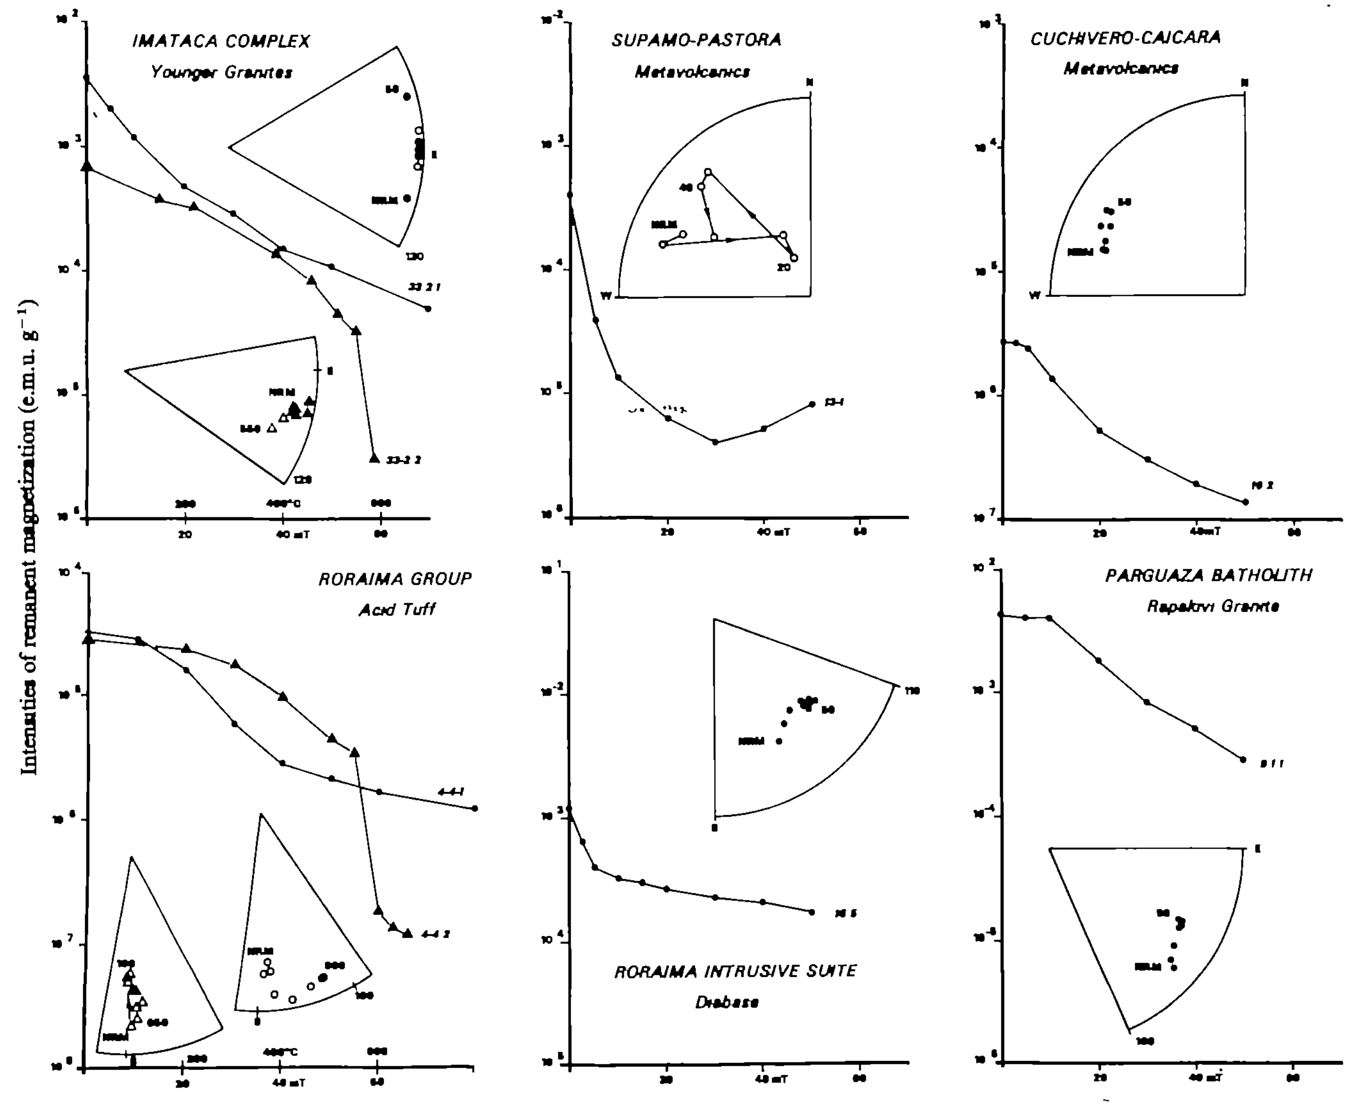

Fig. 2 Progressive demagnetization studies. Representative examples of thermal (▲) and alternating field (●) demagnetization of pairs of specimens from the same oriented samples of the Imataca Complex and the Roraima group, and representative examples of alternating field (●) demagnetization for specimens of the Pastora metavolcanics, Cuchivero metavolcanics, the Roraima diabase and the Parguaza batholith. The directions of remanent magnetization are plotted on equal-area projections, the plane is the present horizontal. Amphibolites and granites intrusive into the Imataca Complex tend to have very stable single-component magnetizations, whereas, mafic granulites, charnockites and biotite gneisses tend to have multicomponent magnetizations. Blocking temperatures indicate that magnetite is the principal carrier of the remanence, in polished sections magnetite is frequently present as very fine rods in pyroxene grains. The remanent magnetization of the greenschist facies rock units of the Pastora tends to be very weak and migrate widely on demagnetization. The remanent magnetization of the very low-grade Cuchivero metavolcanics and the tuffs of the Roraima group tends to be weak, but extremely stable. Blocking temperatures suggest that the magnetization is primarily carried by magnetite, which is present in the groundmass as very fine equant grains. The remanent directions tend to migrate rapidly to a stable, characteristic direction with alternating field demagnetization. The secondary directions seem to be lightning induced. Samples of the Parguaza rapakivi granite exhibited a wide range of demagnetization behaviour, from extremely high coercive single-component magnetization to low coercive multicomponent magnetizations.

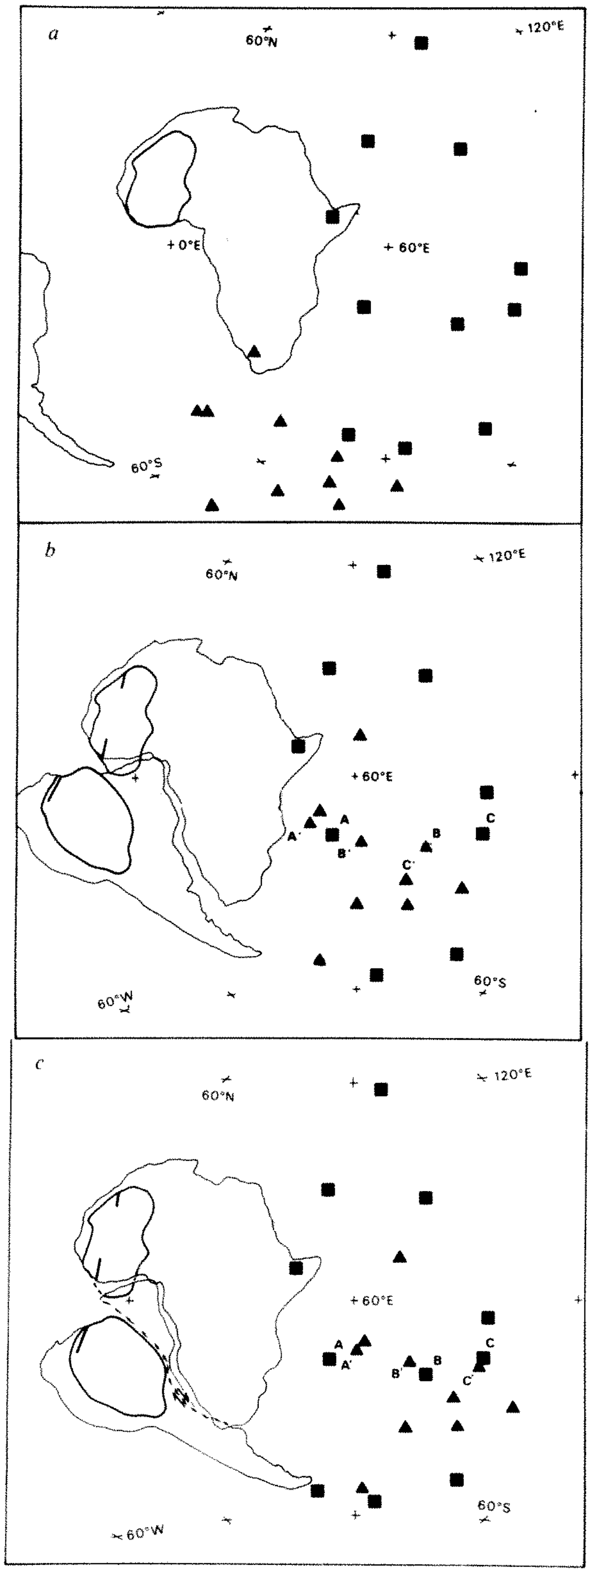

Fig. 3 Palaeomagnetic data from the South American Guayana Shield (▲) and the West African Shield (■) for 1,500–2,100 Myr. Continental crust older than 1,500 Myr and the Guri and Sassandra fault zones are shown (thick lines). *a*, Continents in their present day position. *b*, Reconstruction according to ref. 36, with A, B and C and A', B' and C' indicating the more reliably dated poles from the West African Shield and the Guayana Shield, respectively. *c*, Proposed reconstruction for the period 2,100–1,500 Myr, which brings together the correlatable data points from each shield and also aligns the basement structures between the two shields. Transcurrent fault is shown with direction of displacement indicated by small arrows.

Radiometric ages given in Table 1 are based on data given in refs 15, 16.

The West African data are from a sequence of rock units geologically similar to those in the Guayana shield: a metamorphic basement (1,800–2,000 Myr)[31–33] with intrusive diabases (1,300–1,700 Myr)[28,34]. Comparison of Fig. 2*a* and *b* shows that the South American data (triangles) do agree much better with the West African data (squares) after the South Atlantic has been closed using a Bullard *et al.*[36] fit, in agreement with the hypothesis of the Hurley and Rand[35].

Detailed comparison of one of the Imataca granulites and both of the Roraima diabase poles (numbers 3, 6 and 7 marked A', B' and C' in Fig. 3*b*, *c*) with the most likely correlative poles from the West African Shield, the Aftout diorite pole and the Akilet dyke poles (numbers 17, 20 and 21 marked A, B and C in Fig. 3*b*, *c*) suggests a slight westward offset in the South American data. This offset could be eliminated by rotating the Guayana Shield (Fig. 3*c*) 13° counterclockwise about a pole 70°E, 66°N. Such a rotation would require ~1,500 km displacement along a fault zone postulated to lie in the Brazilian mobile belt (Fig. 1). After this shift, the Sassandra mylonite zone[37] (Fig. 1), which separates the granulite rock units of Ivory Coast from the Birrimian greenstones, becomes continuous with the Guri mylonite zone which separates the Imataca granulites from the Pastora greenstones[38] (Fig. 3*c*). This alignment suggests that the proposed translations may be correct.

In comparing the data from the Guayana Shield and the West African Shield with those from the Congo Shield and the Kalahari Shield (Figs 4, 5), we have shown only those data that fall in the 1,800–2,100-Myr age range, because no palaeomagnetic data in the 1,500–1,800-Myr age range exist for the latter two shields. In Fig. 4 the three poles from Ghana (11–13 in Table 1, Fig. 1) are significantly removed from other contemporaneous West African poles as well as from the poles of the other shields. As observed in Fig. 3*b*, *c*, the Ghana poles do coincide with a pole from Brazil, for which ages of 1,500–1,600 Myr have been reported[39]. This correlation leads us to suspect that the age of the magnetization for the poles from Ghana may be younger than the 2,200-Myr age given for them[40]. For this reason and to clarify the diagram, all the Ghana poles have been omitted from Fig. 5.

The principal observation from Fig. 4 is that the palaeomagnetic data from the Kalahari Shield fall mainly in eastern and northern Africa. In contrast the palaeomagnetic poles from all the other cratons are concentrated in the Indian Ocean. The most recent age determinations[12,41,42] for both data sets strongly suggest that this discrepancy cannot be the result of differences in age.

The Kalahari palaeomagnetic poles exhibit a consistent succession in age from the Lower Ventersdorp Lavas pole (number 26, 2,150 Myr)[43], through the Bushveld Complex pole (number 27, 2,000 Myr)[41,44], to the Mashonaland dolerites pole (number 33, 1,800 Myr)[45,46]. The data from the Cunene Anorthosite Complex (numbers 22–24, 1,800–2,100 Myr[29,47]; diamonds in Figs 4 and 5) of the Congo craton and from the Orange River Lavas (number 25, 2,000 Myr[30,42]; solid hexagon) of the recently recognized Richtersveld Province in Namibia[48] (Fig. 1) are distinct from those of the Kalahari, and compare favourably with poles from the West African and Guayana shields; a temporal distribution pattern for these latter poles is roughly comparable with that displayed by the Kalahari poles (Fig. 4). The best superposition of these two apparent polar wander curves as drawn is obtained by rotating the Guayana, West African and Congo shields and the Richtersveld Province 64° counterclockwise about a pole at 44°E, 28°S (Fig. 5).

As the Richtersveld Province (XI in Fig. 1) also takes part in the rotation, a corresponding zone of right lateral transcurrent displacement must separate it from the Kalahari Shield (IX and X in Fig. 1). The only possible location for this zone is in the 1,100-Myr old Namaqualand mobile belt (D in Fig. 1). Similarly, the Kasai craton (VI in Fig. 1) must be separated from the Kalahari Shield by the northward continuation of this zone of dislocation, which would presumably lie within either the Irumide or the Kibaran mobile belt (E and F, respectively, in Fig. 1), as they are equivalent in age to the Namaqualand belt. If the rotation is attributed solely to transcurrent motion, then a small circle about the rotation pole (P in Fig. 5), passing through the Namaqualand belt, coincides more closely with the Irumide belt than with the Kibaran belt. The rotation would require ~2,000 km of right-lateral displacement within this combined Namaqualand–Irumide mobile belt. As no palaeomagnetic data exist for the Zambian–Tanzanian cratons for this time period, we cannot preclude the possibility that they remained fixed with respect to the Kalahari Shield, and that the displacement occurred along the Kibaran belt. Note, however, that after our postulated rotation, along the Irumide belt, the Limpopo belt (A in Fig. 1) and the Ubendian–Rusizian belt (B in Fig. 1) become continuous (Fig. 5). We consider this result to support primary displacement occurring along the Irumide belt.

Discussion

The geology of Southern Africa is generally consistent with our hypothesis except in the critical area south-east of the Zambian craton where it is extremely complex and much disputed[70]. Ramsay and Ridgway[49] find no evidence for an Irumide belt, and propose that the Pan African Mozambique belt forms the eastern margin of the Zambian (and Tanzanian) cratons. They do admit, however, that older gneisses of Ubendian or Kibaran (Irumide) age may be present within the Mozambique belt. Shackleton[50] recognizes an Irumide belt, but proposes that it terminates south-west of the Ubendian belt, which he concludes can be connected to the eastern end of the Limpopo belt through a trend of granulites in the Mozambique belt. In addition, Key and Sutton[51] propose that the Limpopo belt does not continue westwards completely through the Kalahari shield (Fig. 1), implying that its alignment with the Ubendian belt after rotation (Fig. 5) is fortuitous. Nevertheless, the palaeomagnetic evidence for our hypothesis is compelling, and hopefully any apparent inconsistency with the geology may eventually be resolved.

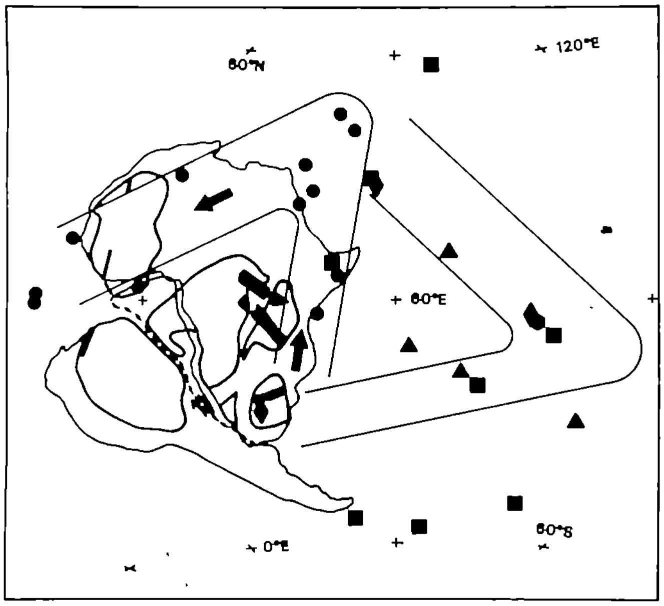

Fig. 4 Palaeomagnetic data for the Kalahari Shield (●), the Congo Shield (◆), the Orange River Lavas (⬢), the West African Shield (■) and the Venezuelan Guayana Shield (▲) for 1,800–2,100 Myr. Suggested apparent polar wander (APW) path for the Kalahari data is outlined and the direction of polar wander indicated (black arrows). Proposed correlative APW for the data from the other shields is outlined. The three solid squares near the bottom of the figure are the data from Ghana[40] and have not been included in the proposed APW path (see text). Continental crust older than 1,500 Myr (enclosed by thick lines), correlative fault zones (thick lines) and correlative mobile belts (solid) are shown. Continents are in the same reconstruction as Fig 3*c*

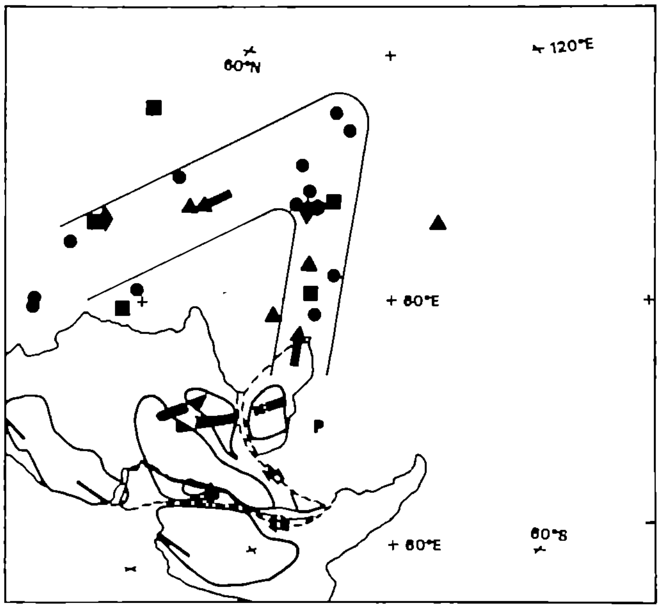

Fig. 5 Palaeomagnetic data same as in Fig. 4, except the data from Ghana have not been included. Continents are in proposed reconstruction, which brings together the two APW paths and aligns the Limpopo belt and the Ubendian–Rusizian belt. P is the pole of rotation, and the transform fault zone is shown with displacement indicated by small arrows. See Fig. 4 for remaining symbols.

Large-scale (thousands of kilometres) transcurrent displacements along Phanerozoic orogenic belts have been documented palaeomagnetically and geologically[52–55]. The above palaeomagnetic analyses suggest that large-scale transcurrent motions have also occurred in Proterozoic mobile belts, particularly those for which intense shearing and smaller-scale transcurrent displacements have been reported[56–59]. Without proper corrections for such movements polar wander paths based on an expanding intercratonic palaeomagnetic data base either will continue to become more complicated and convoluted, or the path widths and the apparent uncertainties in the ages of magnetization will be enlarged when attempts are made to keep the polar wander paths relatively simple.

If palaeomagnetic evidence is found for similar intercratonic movements in other continents then the transcurrent-tectonic model advocated here may signify a tectonic style in the Precambrian similar to that proposed by Sutton and Watson[10], which was characterized more by transcurrent shearing (jostling) of cratonic blocks than by the rifting, spreading and closing of oceans.

This research was supported by the Direccion de Geologia, Ministerio de Energia y Minas. We thank Drs W. J. Morgan, D. Jurdy, F. B. VanHouten and E. Irving for helpful criticisms and also N. Dorety and L. Hollingshead for technical assistance. The laboratory work was supported by the NSF grant EAR 76-22644 AO1.

The *b*-value as an earthquake precursor

Warwick D. Smith

Geophysics Division, Department of Scientific and Industrial Research, Wellington, New Zealand

A systematic study of b*-values in New Zealand has shown that within the vicinity of forthcoming large earthquakes there is initially an increase in* b *and then a return to normal. The Caracas and San Fernando earthquakes show the same phenomenon, which is related to that of seismic gaps.*

IN the recurrence relation of Gutenberg and Richter[1], $\log N = a - bM$, the parameter b measures the relative numbers of small and large earthquakes. Values near unity are common. The value of b is usually calculated by the method of maximum likelihood (see ref. 2) whence

$$b = \frac{\log_{10} e}{\bar{M} - M_0}$$

$\bar{M}$ is the mean magnitude of the sample and M_0 the minimum magnitude considered. The standard error in b is $b/\sqrt{n}$ for a sample of n earthquakes[2] and the 95% confidence limits are twice this value.

Fiedler[3] found that *b*-values increased before the Caracas earthquake of 1967. His estimates were of the 'extreme *b*-value' for each year, and they increased to 1.33 before dropping again before the earthquake. Wyss and Lee[4] considered a sample of many more earthquakes, of much smaller magnitudes, in California. They calculated *b* using the maximum likelihood method and a 50-event window, and claim that it decreased both before and after main events. In their data the decrease before the main events took place over some hundreds of days. But there is also a suggestion of an increase in *b*, followed by a decrease just before the main event, the changes taking place over a few tens of days (for example at Danville, late 1971, where the magnitude of the main shock was 3.4).

Studies of aftershock sequences in New Zealand have also found that the *b*-value is not constant in time. In some cases Gibowicz[5] found an increase after the main event, followed by a decrease before the next large shock. He also found large changes in *b* for large areas of the North Island[6], as did Robinson[7], who found an increase to a peak value of 1.75 in 1971, followed by a decrease.

This paper examines further evidence relevant to Fiedler's suggestion[3] that a period of high *b*-values can occur before an earthquake.

High *b*-values in small regions

A systematic study of the temporal variation of *b*-values throughout New Zealand has now been made, using regions 2° in latitude by 2° in longitude, earthquakes of magnitude 4.0 and greater from 1955 to June 1979, focal depths less than 40 km, and a 50-event window which slides by 10 events. Smaller regions did not contain enough data for adequate resolution of the *b*-values. No attempt has been made to remove swarms and aftershocks from the data. Results for several of the regions are shown in Fig. 1, where the *b*-value is plotted at the time the last event entered the window. All five plots in Fig. 1 begin with low values of *b*, and this implies a lack of detection of small events before the mid 1960s when the New Zealand seismograph network was expanded to reduce the detection threshold to

Table 1 Total precursor times, from the onset of the increase in *b*-values to the occurrence of the earthquake

Earthquake	Magnitude	Precursor time
Tejon Pass, 1961	5.0	3.5 yr
Caracas, 1967	6.7	7 yr
Inangahua, 1968	6.8	6 yr
San Fernando, 1971	6.4	7 yr
Region *E*, 1971	5.9	3.2 yr
Region *C*, 1973	5.7	4 yr
Region *A*, 1977	6.0	7 yr
Pukaki, 1978	3.8	6 months
Pukaki, 1978	4.6	16 months

0028-0836/81/030136—04$01.00

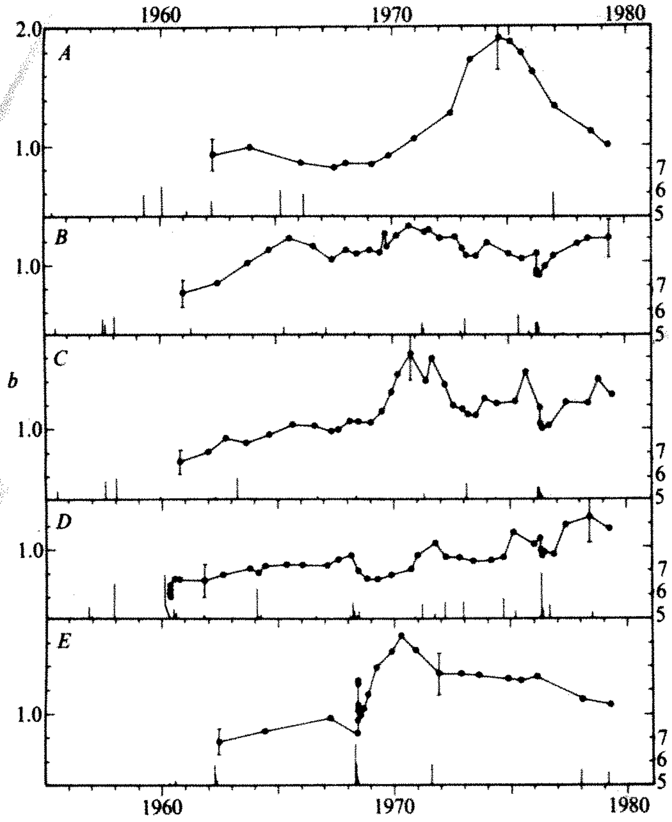

Fig. 1 The variation of parameter *b* from 1955 to 1979, in each of five regions of New Zealand. A location map is given in Fig. 2. Standard errors are proportional to *b* and are shown in a few cases, as are earthquakes of magnitude greater than 5. A 50-event window has been used, sliding by 10 events.

magnitude 4.0 throughout the country. Standard errors, proportional to the ordinate because of the uniform window length, are shown in several cases. Also shown are the earthquakes of magnitude >5 in each area. A location map is shown in Fig. 2.

In region *A* the *b*-value rose to a peak of 1.9 in 1974 and then decreased. During the decrease there was an earthquake of magnitude 6.0. The high *b*-values were accompanied by a paucity of moderate earthquakes. During the period 1969–76, while the *b*-value rose to its peak then began to drop, there were no earthquakes over magnitude 5.0 in the region.

Figure 1*B* shows the *b*-value variation for another area, in the east of the North Island. Little variation is evident, although there was an earthquake of magnitude 5.9 in June 1975. Figure 1*C* plots a region in the north-east, where a high value of *b* (1.6) was followed by an earthquake of magnitude 5.7 in 1973 which occurred near the city of Napier. Figure 1*D* shows a similar plot for the Fiordland area, exhibiting very little variation in *b* in spite of the large earthquake in 1976. This point is taken up again later.

Figure 1*E* shows the Inangahua earthquake of 1968 (magnitude 6.8), and a marked increase in *b* which followed it. It is clear that high values of *b*, while they may be associated with imminent earthquakes, may also relate to previous activity. If Fig. 1*E* is any indication, however, the previous event should be easily identified, and in this case the period of high *b*-values could also be associated with the magnitude 5.9 event in 1971.

Figure 3 shows data obtained from the Lake Pukaki microearthquake network, situated in the South Island of New Zealand near 44°S, 170°E. This network of nine stations was installed in 1975 to monitor seismicity there during the raising of the lake level for hydroelectricity generation. *b*-Values have been calculated for magnitudes 1.5 and greater, using a 50-event window which slides by 10 events. In December 1978 an earthquake of magnitude 4.6 occurred close to the centre of the network[8]. This event was preceded by a period of high *b*-values. There may also be another occurrence of the same phenomenon before the magnitude 3.8 shock of August 1978, superimposed on the larger trend.

Further evidence concerning whether or not periods of high *b*-value are followed by large earthquakes must be sought in other seismic regions, by systematic studies such as has been done in New Zealand. But the converse—whether or not large earthquakes are preceded by periods of high *b*-value—is examined in Fig. 4. The region 34–35°N, 118–119°W includes the San Fernando earthquake of 1971. Data selected from the Southern California catalogue[9] are shown in Fig. 4*A*. The magnitude threshold is 2.5 and the window length is 20 events, sliding by five events. Decreasing the window length was necessary because of the small area chosen and the generally low level of seismicity, even at the magnitude 2.5 level, but, of course, the standard error increases. Two periods of high *b*-value are evident (approximately double the background level), one before the earthquakes of 1961 and 1963 in the Tejon Pass quadrangle, and the other before the San Fernando earthquake of 1971. The data set did not include the San Fernando earthquake itself.

Figure 4*B* shows a reexamination of the data for area *e* (see Figs 1 and 2). The window length has been reduced to 20 events, sliding by five events. The *b*-value increased to 2.2 before the Inangahua earthquake of 1968. This is an alternative expression of the precursory gap which Evison[10] found for that earthquake. The area is of only moderate seismicity, and detection may not have been complete to magnitude 4.0 in the early 1960s. Both of these reasons demanded the short window. There is no clear decrease in *b* before the earthquake, but note that the final value of 2.2 at the beginning of 1968 represents an average back to 1963. There is clearly insufficient data to resolve any decrease which may have occurred before the major event. Extending the data sets to include the San Fernando and Inangahua earthquakes returns the *b*-value to its background level in each case.

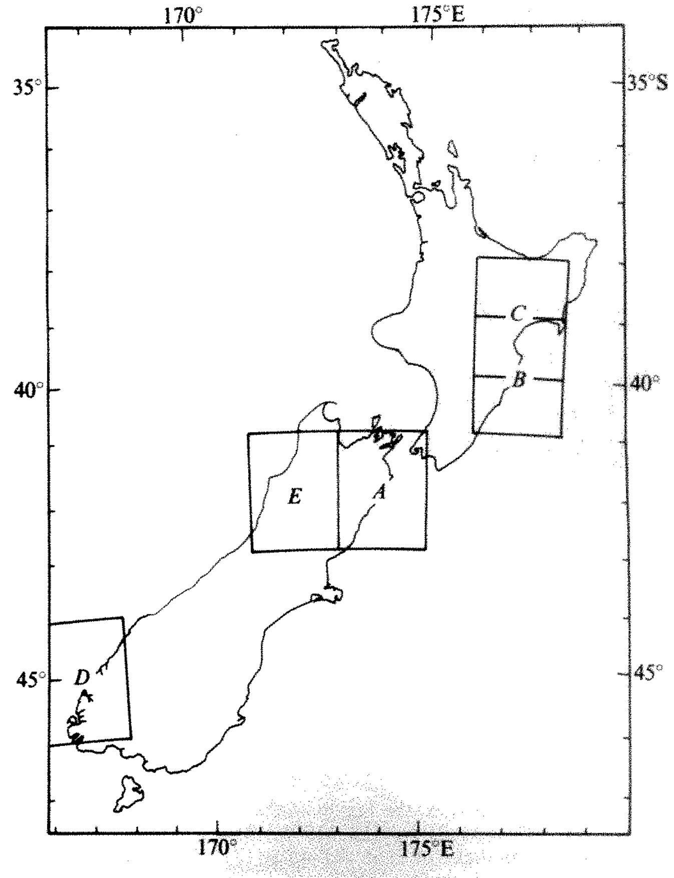

Fig. 2 Location map for the regions of Fig. 1.

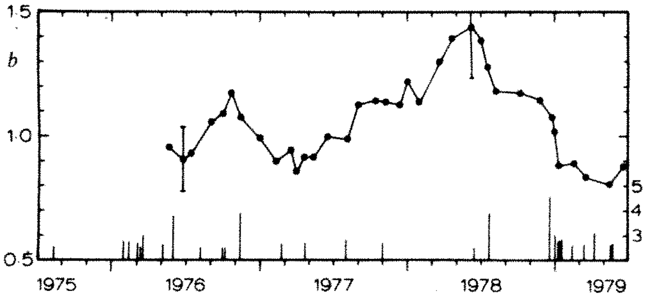

Fig. 3 b-Values for the Lake Pukaki seismic network. Magnitude threshold 1.5, window length 50 events, sliding by 10 events. Earthquakes of magnitude 3.5 and greater are also shown.

The Fiordland area (Fig. 1*D*) is very active, and if there are precursory changes in b for the large events shown, it will be necessary to decrease the search area to isolate them. Precursory changes for individual earthquakes, if they occur, are obscured by the high level of activity. The same problem is also likely to occur in Japan or any highly active area. It may be intensified in Fiordland where the source regions of earthquakes are generally small.

It is interesting to simulate these windowed b-value calculations using a synthetic data set with an exponential frequency distribution. The b-value so calculated does, of course, fluctuate. In fact the probability that the observed changes in b with real data occurred by chance is significant (if the earthquake population does actually have a random exponential distribution), but this is not the point. The proper question is: 'Are periods of high b-value followed by large earthquakes?'. The evidence presented here suggests that they are.

Note also that b-values have been calculated only as a statistical parameter of the small samples. No extrapolation to large samples is implied. The b-value is directly related to the mean magnitude, which may be a more useful parameter, but the terminology has been retained in favour of the well-known parameter b. A high b-value implies a low mean magnitude.

The *b*-value as an earthquake predictor

The evidence presented, that a period of high b-values is followed by a large event, is alternately expressed in the gap hypothesis. Mogi's[11] "seismic gap of the second kind", defined as a region deficient in moderate earthquakes before the occurrence of a large earthquake, may find expression in a high b-value. Evison's[12] suggestion of a precursory swarm followed by a gap may also be accommodated by identifying the swarm with the initial low value of b.

The b-values in each frame of Fig. 1 are calculated for an area rather larger than the precursory gap area for any of the earthquakes. This is encouraging for a surveillance scheme, if the b-value does indeed prove to be a predictor, because a routine procedure to examine the whole country for changes in b-value need not use search areas coincident with the aseismic area related to the forthcoming shocks it is endeavouring to detect. Provided that the search areas overlap the precursory area, but are not too much larger than it, the anomaly in b-values will be detected. The maximum b-value reached is not very significant, because of the mixed population it represents. What is apparently important is the temporal behaviour.

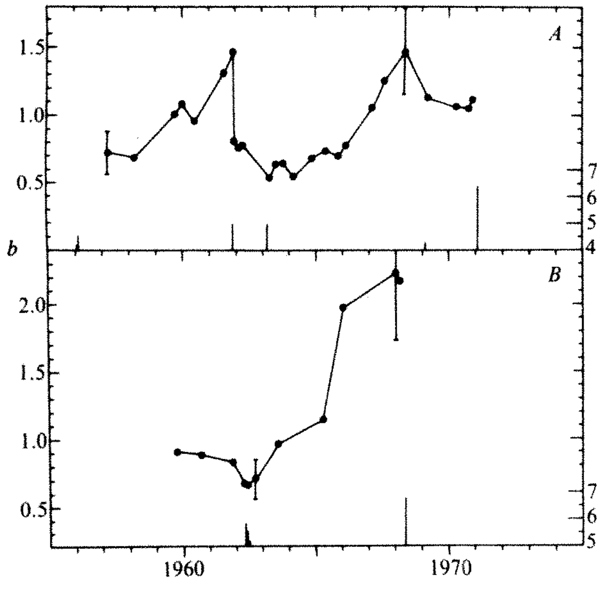

Fig. 4 b-Values for: *A*, the region of the San Fernando earthquake of 1971 (34–35°N, 118–119°W; $M \geq 2.5$) and *B*, the Inangahua earthquake of 1968 (41–43°S, 171–173°E; $M \geq 4.0$). Window length 20 events, sliding by 5 events. Earthquakes of magnitude greater than 4.0 (*A*) and 5.0 (*B*) are also shown.

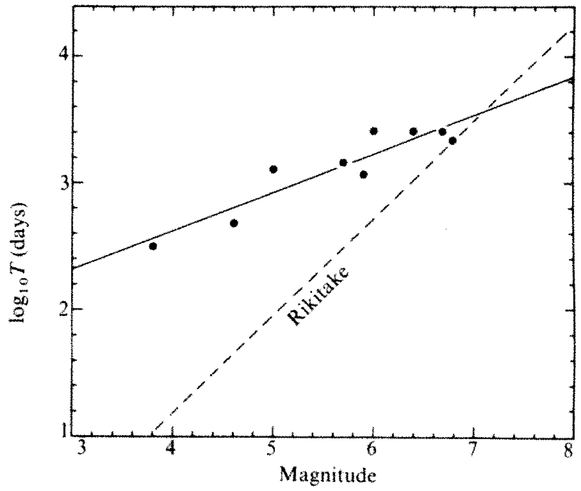

Fig. 5 Total precursor time T as a function of magnitude, for the earthquakes listed in Table 1.

Precursor time and magnitude

Total precursor times for the nine events identified are shown in Table 1, and in Fig. 5 as a function of magnitude, with the least squares regression:

$$\log T = 1.42 + 0.30M$$

For the Caracas event a magnitude of 6.7 has been used, as quoted by Rial[13], although the ISC value of m_b was only 5.7. The regression is admittedly poor, and heavily dependent on the two Pukaki earthquakes of magnitude 3.8 and 4.6. But clearly the b-value does not fall into the class of phenomena which obey Rikitake's relationship[14], also shown. The windowing technique can only reduce the observed precursor time, never increase it. This means that the ordinates plotted may be systematically small, except for the Caracas precursor which was determined from annual values. There seems to be no clear rule for the elapsed time from the b-value peak to the major earthquake, but this may be due to the windowing technique and the variety of seismicity levels in the data presented. The occurrence of foreshocks would tend to depress the b-value before a large event[15], but this is a phenomenon on a much shorter time scale than that presented here.

Conclusions

The occurrence of a period of high b-values before a large earthquake has been observed in New Zealand, California and Venezuela. Only one case is known where it may have been associated with a previous event, the occasion when high b-values followed the Inangahua earthquake of 1968, but there was also a subsequent earthquake of magnitude 5.9 with which the high b-values could be associated. There may be a decrease in b towards normal levels before the earthquake actually occurs, but it is difficult to resolve this in areas of low seismicity. The regression between magnitude and precursor time is poor, but the b-value clearly does not fall into the general class of phenomena which obey Rikitake's well known relationship.

I thank Drs E. G. C. Smith, R. Robinson and T. Hatherton for their helpful comments, and analysis staff at the Seismological Observatory for painstakingly locating many thousands of small earthquakes. Dr Smith also performed the calculations on the synthetic data sets.

Note added in proof: Ma[16] has also found evidence for high b-values before large earthquakes in China, including the Tangshan and Haicheng events.

Actin-containing matrix associated with the plasma membrane of murine tumour and lymphoid cells

Matthew F. Mescher, Mimi J. L. Jose & Steven P. Balk

Department of Pathology, Harvard Medical School, Boston, Massachusetts 02115

A detergent-insoluble matrix has been isolated from murine tumour cell and lymphocyte plasma membranes. The major components of this matrix include actin and four additional proteins not previously identified as cytoskeletal proteins. Labelling studies indicate that the matrix is located on the inner face of the plasma membrane. A cell-surface glycoprotein, 5′-nucleotidase, remains associated with the isolated matrix.

THE cytoplasmic face of the plasma membrane appears to be the meeting place for two sets of cellular structures intimately involved in determining the response of a cell to its environment. It is here that the transmembrane cell-surface proteins may interact with components of the cytoskeletal system. The red cell membrane has served as an extremely useful model for understanding many aspects of the plasma membrane of more complex cells[1], but whether the similarity of red cell membranes and the plasma membranes of nucleated cells extends to one of the most striking features of the red cell membrane, the 'membrane skeleton', has remained unclear. Recent studies have revealed that the red cell membrane is not composed simply of a lipid bilayer with individual proteins interacting with it. Instead, spectrin and a group of associated proteins form an extensive network at the cytoplasmic face of the bilayer and function as a membrane skeleton to stabilize the membrane. This skeletal network controls the shape and elasticity of the membrane[2,3] and the distribution of transmembrane glycoproteins[4] and intramembrane particles[5]. The network can be readily isolated by extracting membranes with the non-ionic detergent Triton X-100. Spectrin, the major skeletal protein, along with the other network proteins and some of the membrane lipids, remains insoluble[6]. The results of numerous recent studies have led to an increasingly clear picture of how these proteins are organized to form the skeletal network[7].

Spectrin is present in all mammalian and avian red cells but is not found in other cell types and a membrane skeleton similar to the spectrin network has not been demonstrated in nucleated cells. These cells have extensive filamentous cytoskeletal networks within the cytoplasm[1,8,9] and it has been proposed that there are associations between transmembrane surface proteins and components of this cytoskeletal network at the inner surface of the membrane[8,10]. These interactions may be involved in such phenomena as capping of surface molecules on lymphocytes[11,12], control of cell motility[13] and attachment to surfaces[14]. Some direct evidence for interactions between transmembrane proteins and components of the cytoskeletal system has been presented[15–17]. Whether such interactions, primarily implicated in dynamic processes such as receptor redistribution or cell motility, might also serve to stabilize the membrane is unclear. It is also unclear whether a distinct structure exists on the cytoplasmic face of the membrane, analogous to the red cell membrane skeleton. The results reported here demonstrate that a detergent-insoluble component can be isolated from the plasma membranes of murine tumour and lymphoid cells which may function as a membrane skeletal network. The network is apparently located on the inner surface of the membrane and has five major protein components. Only one of these proteins, actin, has previously been shown to be a component of cytoskeletal structures.

Plasma membrane isolation and Nonidet P-40 solubilization

Plasma membranes were isolated as described previously for P815 ascites cells[18] with only minor modifications (see Fig. 1 legend). This procedure results in a 40–50-fold purification, as assessed by 5′-nucleotidase activity, and a yield of 40–60%. Co-purification of the cell-surface H-2 antigens with the plasma membrane fraction (ref. 18 and unpublished data) confirmed the results obtained by assaying 5′-nucleotidase. Membranes have been purified from P815, EL4, RDM-4 and CH1 murine tumour cells and normal murine spleen cells with essentially identical results. Examination of the purified membranes by electron microscopy shows them to be in the form of vesicles of relatively heterogeneous size, ~0.1–1.2 μm in diameter[18]. Small amounts of endoplasmic reticulum are also apparent, as indicated by the presence of some membrane vesicles with bound ribosomes. Based on yields obtained, the plasma membrane accounts for 1–3% of the total cell protein, in good agreement with values reported by others[19].

0028-0836/81/030139—06$01.00

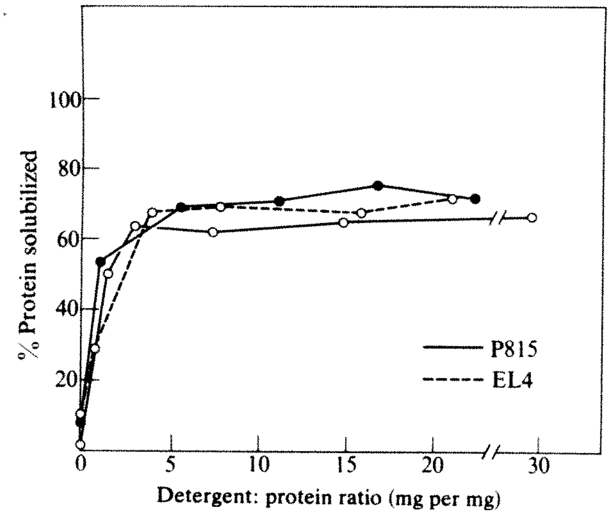

Fig. 1 Solubilization of P815 and EL4 plasma membrane protein with Nonidet P40. Plasma membranes were purified as described previously with minor modifications[18]. The cells were lysed by nitrogen cavitation in Earle's salts buffered at *p*H 7.2 with 10 mM sodium phosphate (PBES) containing 1 mM PMSF and 10 mM iodoacetamide. Following differential centrifugation, the membrane pellet containing predominantly plasma membrane and endoplasmic reticulum was dispersed in buffer by brief sonication in a bath sonicator (10 × 10 s in a Branson model B-12) and loaded on a sucrose step gradient. The purified plasma membrane fraction was resuspended in PBES at 2–5 mg ml^{-1} and stored frozen (−20 °C) until use. Detergent solubilization was done by resuspending membranes in PBES with vigorous vortexing and adding 1% NP-40 in PBES to give the desired detergent to protein ratio. Protein concentration was held constant at 0.5 mg ml^{-1}. The samples were incubated on ice for 20 min with frequent vortexing and then centrifuged for 45 min at 100,000*g*. After centrifugation, the supernatants were removed and the insoluble pellets resuspended in PBES. Protein content of the supernatant and pellets was assayed by the method of Lowry *et al.*[33] in the presence of 1% SDS using bovine serum albumin as the standard. Values shown are averages of duplicate determinations. -●—●- and -○—○-, results obtained using two separate P815 membrane preparations. --○--○--, EL4 membrane solubilization.

Treatment of lymphocyte plasma membranes with the non-ionic detergent Nonidet P-40 (NP-40) solubilizes much of the membrane protein, including histocompatibility antigens and surface immunoglobulins, but leaves an insoluble residue which can be pelleted by centrifugation at 100,000*g*. When solubilization of P815 (a mastocytoma) and EL4 (a thymoma) membranes was examined in more detail, it was found that the amount of protein solubilized increased with increasing detergent up to a detergent to protein ratio of approximately 4 : 1, which gave 70–80% solubilization (Fig. 1). The remaining 20–30% of the protein remained insoluble at detergent to protein ratios of up to 30 : 1. The amount of protein remaining was constant above a detergent to protein ratio of 4 : 1 regardless of the concentration of detergent (from 2–20 mg ml^{-1}). Re-extraction of the insoluble residue with NP-40 resulted in no additional solubilization. Identical results were obtained using Triton X-100 (TX-100) in these experiments and those described below. The detergent-insoluble material formed a tight, translucent pellet on centrifugation at 100,000*g*. In comparison, the unextracted membranes formed a white, opaque pellet.

Protein composition of the detergent-insoluble fraction

Relative to red cell membranes, the plasma membranes of nucleated cells contain a larger number of proteins. At least 50 membrane polypeptide chains can be resolved by SDS-polyacrylamide gel electrophoresis of P815 plasma membranes (Fig. 2*a*, lane 1). Examination of the NP-40-soluble and -insoluble fractions of P815 membranes revealed that most of the proteins were completely solubilized while a small number remained selectively insoluble (Fig. 2). The major components of the insoluble fraction were polypeptides having apparent molecular weights (MWs) of 70,000 (70K), 69,000 (69K), 42,000 (42K), 38,000 (38K), and 36,000 (36K). The p70, p69, p38 and p36 proteins were found only in the detergent-insoluble fraction. Proteins at 42K were present in both the soluble and insoluble fractions. The occurrence of the minor bands seen in the detergent-insoluble fraction, particularly the low-molecular weight proteins near the dye front, varies between membrane preparations. Some of these may be products of proteolysis, although phenylmethylsulphonyl fluoride (PMSF, 1 mM) and iodoacetamide (10 mM) are present during membrane purification and solubilization.

Comparison of membranes and whole cells labelled with ^{125}I by lactoperoxidase-catalysed iodination suggested that most of the detergent-insoluble proteins are not exposed in intact cells. p70, p69, p38 and p36 are prominently labelled proteins on isolated membranes (Fig. 2*b*, lane 4). In contrast, they are not detected when proteins from labelled intact cells, containing comparable amounts of radioactivity, are examined (Fig. 2*b*, lane 5). p42 is also a major labelled protein on membranes but proteins in the same molecular weight range are labelled on intact cells; therefore, these results do not exclude the possibility that some of the p42 is present at the cell surface. The efficient labelling of p70, p69, p38 and p36 by lactoperoxidase on

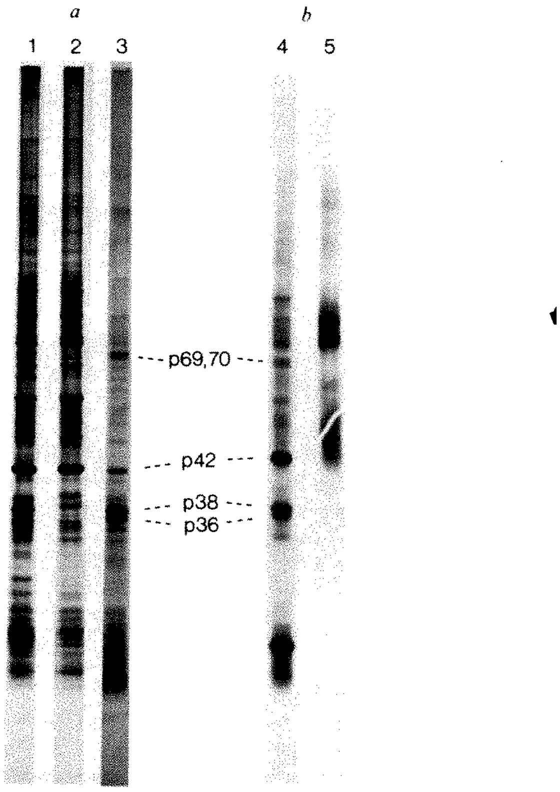

Fig. 2 *a*, The protein composition of membranes and detergent-soluble and -insoluble fractions. P815 tumour cell membranes were prepared as described in the Fig. 1 legend. Membranes were solubilized in 0.5% NP-40 (also as described in Fig. 1 legend) at a detergent to protein ratio of 5 : 1 (w/w). The samples were then analysed by SDS-polyacrylamide slab gel electrophoresis following reduction with 5% β-mercaptoethanol. Electrophoresis was done using the buffer system of Laemmli[34] on a running gel consisting of a 5–15% polyacrylamide gradient. Gels were stained with Coomassie Brilliant blue following electrophoresis. Lane 1, intact membranes; lane 2, proteins solubilized by 0.5% NP-40 (100,000*g* supernatant); lane 3, detergent-insoluble fraction (100,000*g* pellet). *b*, ^{125}I-labelled membranes and intact cells. Cells were labelled by lactoperoxidase-catalysed iodination as previously described[35]. After labelling and washing to remove free iodine, cells were solublized in SDS gel application buffer, reduced with 5% β-mercaptoethanol and electrophoresed as described above. Isolated membranes were labelled by the same procedure, washed and prepared for electrophoresis in the same way. Following electrophoresis, the gel was dried and ^{125}I-labelled proteins visualized by autoradiography. Lane 4, ^{125}I-labelled membranes; lane 5, ^{125}I-labelled whole cells. Stained samples (lanes 1–3) and iodinated samples (lanes 4, 5) were run on separate SDS gels. MWs are based on standard proteins run on each gel.

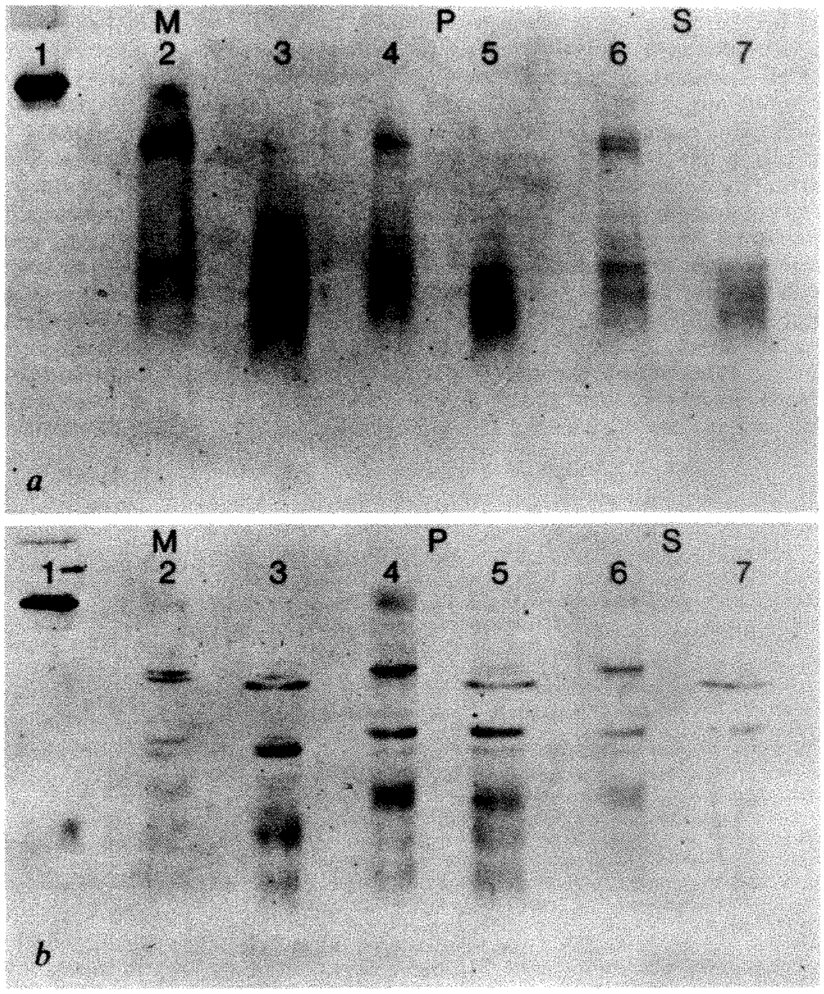

Fig. 3 Limited proteolysis peptide mapping of p42 from the NP-40-soluble and -insoluble fractions of P815 tumour cell membranes. Mapping was done by the procedure of Cleveland *et al.*[22]. Plasma membranes were solubilized with NP-40, the soluble and insoluble fractions electrophoresed on 7.5% polyacrylamide gels and the gels lightly stained. The p42 bands of each fraction were sliced out and soaked for 30 min in a solution containing 0.125 M Tris-HCl, *p*H 6.8, 0.1% SDS and 1 mM EDTA. The slices were then placed in the sample wells of a 15% polyacrylamide gel and the same buffer containing 10% glycerol and a given amount of protease layered on top. Electrophoresis was then done in the usual manner with the exception that the current was turned off for 30 min just before the bromophenol blue tracking dye entered the running gel. Gels were stained for protein with Coomassie Brilliant blue. Proteolytic enzymes used were: *a*, *Streptomyces* protease, type VI (Sigma); *b*, V8 protease (Miles) from *Staphylococcus aureus*. Protein samples for mapping were: M, rabbit muscle actin with: no protease (lane 1), 0.05 μg protease (lane 2) and 0.25 μg protease (lane 3). P, p42 from the detergent-insoluble fraction (100,000*g* pellet) with 0.05 μg (lane 4) and 0.25 μg (lane 5) protease. S, p42 from the detergent-soluble fraction (100,000*g* supernatant) with 0.05 (lane 6) and 0.25 μg (lane 7) protease.

isolated membranes and not on intact cells suggests that these proteins are located on the inner face of the membrane.

Actin has been demonstrated to be present in plasma membranes from a variety of cell types[20], including lymphocytes[21], and the 42K MW protein present in P815 membranes co-migrates with rabbit skeletal muscle actin. When the p42s of the NP-40-soluble and -insoluble fractions were compared by limited proteolysis peptide mapping[22], it was found that both gave peptide patterns which confirmed their identity as actin (Fig. 3). Fragments obtained using *Streptomyces* protease (Fig. 3*a*) were very similar for rabbit muscle actin and p42 and those obtained using V8 protease (Fig. 3*b*) showed only small differences between the two. Small differences in peptide patterns are expected for the same protein from different species. No significant differences with either protease could be seen for the soluble and insoluble forms of p42. It thus seems that P815 membranes have two forms of actin, one soluble in NP-40 and the other making up a major component of the detergent-insoluble fraction. As mentioned above, re-treating the insoluble fraction with detergent results in no further solubilization of the actin.

Results of limited proteolysis peptide mapping of p38 and p36 ruled out the possibility that one or both of these proteins might be actin degradation products (results not shown). Although p70, p69, p38 and p36 have not been identified, we should point out that they do not have the same molecular weights as any of the proteins which have been shown to interact with actin or to be components of cytoskeletal structures. α-actinin, 100,000 MW, has been suggested to be involved in the attachment of microfilaments to the plasma membrane[23,24] and Hoessli *et al.*[25] have shown that murine lymphocytes synthesize a protein having the expected properties of α-actinin. A protein of 100,000 MW is present in intact membranes from P815 cells but is completely solubilized by NP-40 (Fig. 2).

A detergent-insoluble component comprising the same major proteins has been found in membranes of all the tumour cell lines examined and in normal murine lymphocytes. Such cells include EL4 (a thymoma), RDM-4 (a lymphoma), CH1 (a B-cell lymphoma) and normal murine spleen lymphocytes. In all cases, NP-40 solubilization at detergent to protein ratios of >4:1 leaves 20–30% of the protein insoluble and the major protein components of the insoluble fraction have MWs of 70K, 69K, 42K, 38K and 36K.

The cell-surface enzyme 5′-nucleotidase[26,27] was also found to be a component of the detergent-insoluble fraction. When P815 membranes were solubilized as shown in Fig. 1, 90–98% of the 5′-nucleotidase activity was recovered in the detergent-insoluble fraction at all detergent to protein ratios tested. This was also true for EL4, CH1 and normal spleen cell membranes. 5′-Nucleotidase purified from pig lymphocytes has been reported to have a MW of 130,000 (ref. 28). It is unlikely, therefore, that any of the major proteins seen in the insoluble fraction is 5′-nucleotidase; the enzyme is probably present in too low an amount to be visualized by Coomassie blue staining.

5′-nucleotidase is present on a wide variety of cell types including most lymphocytes, and cytochemical studies have demonstrated that it is localized predominantly on the cell surface[26,27]. Experiments were done to confirm the surface location of the 5′-nucleotidase activity of P815 cells. The cells were incubated for 1 h at 4 °C in the presence or absence of 5 mg ml^{-1} concanavalin A (Con A), an inhibitor of 5′-nucleotidase. They were then washed to remove unbound lectin, lysed by freeze–thaw, centrifuged at 100,000*g* to pellet membranes and the 5′-nucleotidase activity of the pellets measured. Cells which had been exposed to Con A had about 70% less activity than untreated cells. Control experiments demonstrated that free Con A, which could cause inhibition of internal 5′-nucleotidase, was not available at the time of cell lysis. Following washing to remove unbound Con A, treated and untreated cells were mixed and lysed by freeze–thaw. The 5′-nucleotidase activity of the membranes was the sum of that obtained for each type of cell lysed separately, indicating that no free Con A was available to inhibit the activity of the untreated cell membranes. Similarly, when both types of membrane were mixed and assayed, no further inhibition was obtained. These results indicate that at least 70% of the membrane-bound 5′-nucleotidase activity of P815 cells is located at the cell surface. This probably represents a minimum estimate as cell aggregation during the incubation with Con A may result in some of the surface enzyme becoming inaccessible to the lectin.

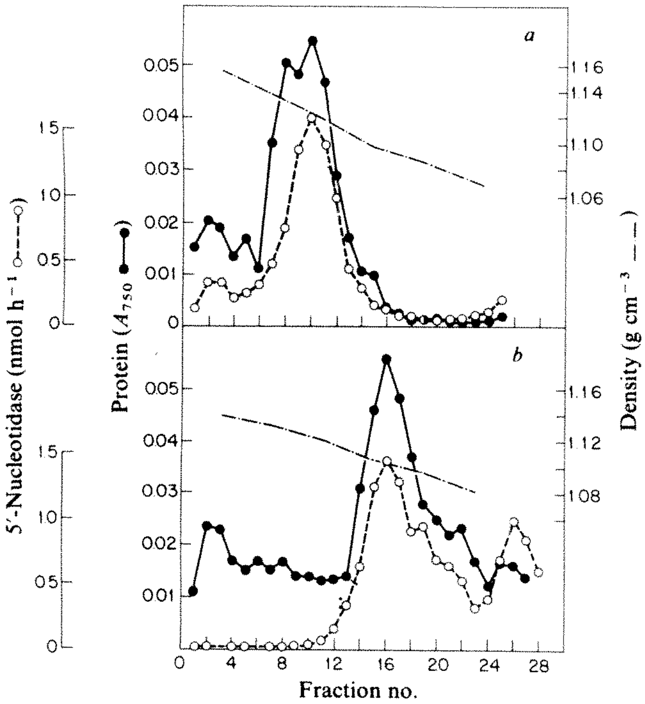

Fig. 4 Sucrose density gradient profiles of P815 plasma membranes and the detergent-insoluble fraction. Detergent-insoluble material was prepared as described in Fig. 1 legend using Triton X-100 in PBES at a detergent to protein ratio of 5:1 and washed once in PBES. Membranes or detergent-insoluble material were resuspended in PBES at a concentration of 2 mg ml^{-1} and layered on top of a 20–40% sucrose gradient (in 10 mM Tris-HCl, pH 7.2) with a 50% cushion at the bottom. The gradients were centrifuged for 18 h at 18,000 r.p.m. in a Beckman SW-27 rotor. Fractions were then collected from the bottom of the tubes and assayed for protein (A_{750}) and 5′-nucleotidase activity[16]. *a*, Density gradient profile obtained with 500 μg of P815 membranes; *b*, profile obtained with 400 μg of detergent insoluble material.

Density gradient centrifugation of the detergent-insoluble fraction

The occurrence of a specific set of proteins, including part of the membrane actin, in the NP-40-insoluble fraction suggested that this material might consist of a membrane skeletal network structure and not simply membrane proteins insoluble in NP-40 in aqueous buffer. We therefore examined the insoluble fraction by equilibrium density gradient centrifugation to determine if it behaved as a discrete structure and as an integral part of the membrane and not a contaminant in the membrane preparation.

P815 plasma membranes were found at a density of 1.125 ± 0.001 g cm^{-3} (average of three experiments ± s.d.) on overnight centrifugation in a 20–40% sucrose gradient (see Fig. 4). When the TX-100-insoluble fraction from P815 membranes was examined in the same way, the protein and 5′-nucleotidase peak had shifted to a density of 1.107 ± 0.005 g cm^{-3} (average of three experiments ± s.d.). Most (>70%) of the 5′-nucleotidase activity remained associated with the protein peak. The TX-100-insoluble fraction has a somewhat lower density than intact membranes. Experiments using ^{3}H-labelled TX-100 demonstrated that the lower density was not due to residual detergent bound to the protein. Less than 0.02 mg of detergent per mg of protein could be detected in the washed, detergent-insoluble material. Some of the membrane lipid remains bound to the red cell cytoskeleton on isolation using TX-100[6] and this is also the case for the detergent-insoluble material from P815 cells. This fraction contains 1.0–1.4 μmol phospholipid per mg of protein (chloroform/methanol extractable organic phosphate). Preliminary examination of this lipid by TLC indicates that some of the membrane lipids remain selectively associated with the insoluble fraction. Studies are in progress to identify these lipids.

The protein composition of fractions across the TX-100-insoluble peak from a density gradient was examined by SDS-gel electrophoresis (not shown). No indication of any separation of one protein species from another could be detected. Examination of fractions across the intact membrane peak from a density gradient in the same way also gave no indication of any separation of the major insoluble proteins from other membrane components. These results strongly suggest that the proteins of the detergent-insoluble fraction are components of the plasma membrane and form a structure which remains intact after solubilization of the other membrane proteins and much of the lipid. Examination of the insoluble fraction by electron microscopy further supports this suggestion.

The detergent-insoluble plasma membrane matrix

The results described above strongly suggested that plasma membranes have a matrix of protein at their cytoplasmic face which can be isolated on the basis of its insolubility in non-ionic detergent. The detergent-insoluble preparations were examined by electron microscopy to determine if their appearance was consistent with this conclusion. Plasma membranes from P815 cells isolated by the procedure used here are predominantly in the form of closed vesicles[18]. They are heterogeneous in size, ranging from ~0.1 to 1.2 μm in diameter, and have a typical unit membrane appearance. No filamentous material associated with the membranes is apparent in the preparations[18]. The detergent-insoluble fraction from these membranes also seems to be largely in the form of closed structures (Fig. 5) also having a heterogeneous size distribution. A unit membrane structure does not seem to be present.

The appearance of the detergent-insoluble fraction in thin section supports the suggestion that this material consists of a skeletal matrix structure isolated from the inner surface of the membrane and not simply of aggregates of insoluble protein. No protein layer adjacent to the bilayer is apparent in thin sections of intact membranes, suggesting that the skeletal network is very closely associated with the lipid bilayer. The spectrin network of red blood cells is similarly not apparent in thin sections of intact red cell membranes[6].

Further evidence for the presence of a matrix associated with the plasma membrane was provided by experiments done with whole cells. Treatment of intact lymphoid cells with NP-40 (or TX-100) lyses the cells and solubilizes the membrane and cytoplasmic proteins while leaving the nuclei intact. This procedure is frequently used for solubilizing cell-surface antigens before immunoprecipitation. If the detergent-insoluble proteins form a continuous matrix on the inner surface of the plasma membrane, it might be expected that this matrix would be trapped around the nucleus and sedimented by low speed centrifugation along with the intact nuclei following cell solubilization. The 5′-nucleotidase activity associated with the detergent-insoluble matrix provides a convenient marker for determining if this is the case. When P815 cells were solubilized with 0.5% NP-40 (at 5 × 10^{6} cells ml^{-1}) and centrifuged for

10 min at 1,000g, ~60% of the 5′-nucleotidase activity was found in the nuclear pellet. In these same conditions, >95% of ^{125}I-labelled cell-surface proteins were found in the supernatant. Of the 40% of 5′-nucleotidase present in the low speed supernatant, approximately half (19%) could be sedimented by centrifugation at 100,000g. When the same experiment was done using normal murine spleen cells, essentially identical results were obtained.

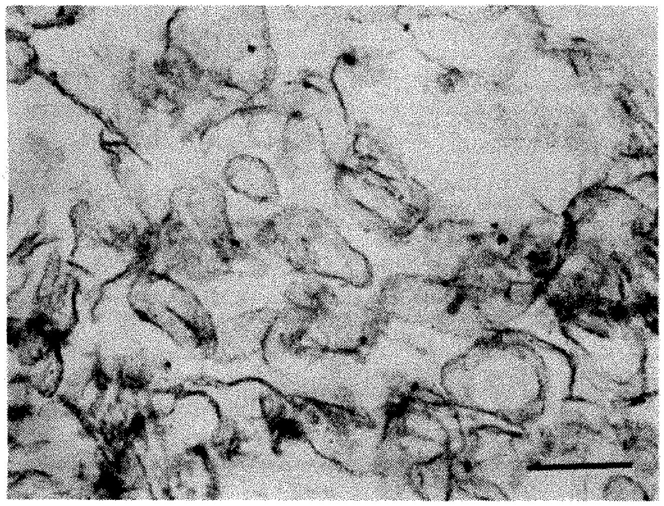

Fig. 5 Electron micrograph of thin section of the detergent-insoluble fraction (100,000g pellet from P815 plasma membrane). Scale bar, 0.2 μm.

Discussion

The results described here strongly suggest that actin and a small, discrete set of additional proteins form a matrix associated with the plasma membrane of murine tumour and lymphoid cells. Labelling studies using lactoperoxidase indicate that the matrix is probably localized at the inner face of the membrane, although further studies will be necessary to confirm this. The matrix is in some respects similar to the spectrin matrix of red blood cells in that it remains selectively insoluble in non-ionic detergents and some of the membrane lipid remains associated with it. Not surprisingly, the protein components are different from those of the spectrin matrix, with the exception of actin.

Unlike erythrocytes, nucleated cells have extensive internal membrane systems and it is therefore more difficult to obtain pure plasma membranes. Although the plasma membranes used in these experiments are highly purified, it is clear that some contaminants are present, including small amounts of endoplasmic reticulum and some small, electron-dense material[18]. Several of the observations reported here argue strongly, however, that the detergent-insoluble matrix is derived from the plasma membrane and not from contaminants in the preparation. The detergent-insoluble matrix proteins account for a relatively large fraction (~20%) of the total protein in the preparations and these proteins co-purify with the plasma membranes on density gradient centrifugation. Although some contaminants are apparent in electron micrographs of the purified membranes, none has the appearance of the isolated matrix. The large size and closed structure of the isolated matrix make it very likely that they are derived from the plasma membrane vesicles. The association of 5′-nucleotidase with the detergent-insoluble matrix also provides strong evidence for the plasma membrane origin of this material. The majority of this enzyme is localized on the plasma membrane of P815 (see results) and other cells[26,27].

The functional role of the plasma membrane matrix described here is not known. It may have a structural role, serving to stabilize the membrane bilayer. The location of the matrix also makes these proteins likely candidates for mediating interactions between transmembrane proteins and the filament systems of the cytoskeleton. The matrix proteins may serve as anchorage points on the inner membrane surface for components of the cytoskeletal system.

In other work being done in this laboratory[29] it was found that reconstituted vesicles containing lipid, purified H–2 antigen and the isolated matrix proteins could be formed by mixing the components in deoxycholate-containing buffer and dialysing to remove the detergent. The H–2 antigen present in these vesicles was much more effective in stimulating generation of an *in vitro* cytolytic T-lymphocyte response than vesicles having only H–2 and lipid. Whether this greater effectiveness of the vesicles containing matrix proteins results from interaction of the H–2 with the matrix is now being investigated.

Evidence for the interaction of at least one cell-surface glycoprotein with the matrix is provided by the observation that 5′-nucleotidase remains associated with the detergent-insoluble fraction. This association may occur through interaction of the enzyme with either a matrix protein(s) or with the lipid which remains associated with the matrix. It is difficult to speculate about the functional role for this association, as the role of the cell-surface 5′-nucleotidase activity is not well understood. It is interesting, however, that the cell-surface 5′-nucleotidase displays an unusual property with respect to inhibition by Con A which may be related to its association with the matrix. Carraway *et al.*[30] have shown that the 5′-nucleotidase activity of MAT-A and MAT-C1 cells is inhibited in a non-cooperative manner by Con A. Cooperative inhibition was observed, however, if the cells were first treated with colchicine, cytochalasin B or D, or dibucaine. No direct correlation could be found between the induction of cooperativity and changes in Con A receptor redistribution or cell morphology.

The association of 5′-nucleotidase with the matrix and the resulting lack of solubilization when whole cells are lysed with NP-40 suggest a potential problem in attempting to identify cell-surface proteins by immunoprecipitation. Solubilization with non-ionic detergent, centrifugation and immunoprecipitation from the soluble supernatant, has become a standard procedure for determining the cell-surface proteins recognized by antisera and for studying cell-surface antigens. A cell-surface antigen which interacts with the matrix as the 5′-nucleotidase does would be difficult, if not impossible, to isolate by this procedure.

Actin occurs in two forms in the plasma membranes examined here, one soluble in detergent and the other associated with the insoluble matrix. Gruenstein *et al.*[31] have previously shown that membranes from 3T3 mouse fibroblasts and HeLa cells have two forms of actin. Treatment of the membranes in conditions which favour actin filament depolymerization resulted in removal of 80% (3T3) and 60% (HeLa) of the actin while the rest remained associated with the membrane. This actin fraction may be a component of a membrane matrix similar to that described here. We have noted that the soluble and insoluble forms of actin described here usually have a slight difference in mobility on SDS gels and we are now investigating the possibility that the two forms differ structurally.

With the exception of actin, the protein components of the matrix do not have molecular weights consistent with their being previously described components of the cytoskeletal network. Moore *et al.*[32] have examined the TX-100-insoluble fraction from sarcoma 180 ascites cell membranes. The membranes were isolated from cells which had been treated with Zn^{2+}, a procedure which seems to stabilize the interaction of cytoskeletal elements with the membrane. The TX-100-insoluble fraction of these membranes included proteins which the authors tentatively identified as actin-binding protein, α-actinin and actin. Several other polypeptides were also present in these preparations. Our failure to observe components of the cytoskeletal network associated with the membrane matrix may be due to failure to preserve these associations during membrane isolation and/or solubilization. It seems that actin and the other components observed in our studies are sufficient to form a stable, detergent-insoluble matrix.

Preliminary experiments have suggested that human peripheral lymphocytes have a plasma membrane matrix similar to that found for murine cells. The major protein components had the same mobilities on SDS gels as those found for the matrix components of murine cells. It will be of interest to determine whether a matrix is associated with the plasma membranes of other cell types (for example fibroblasts) which have more extensive cytoskeletal networks than lymphocytes and, if so, whether the same major protein components constitute the matrix.

Intrachromosomal gene conversion in yeast

Hannah L. Klein & Thomas D. Petes

Department of Microbiology, The University of Chicago, 920 East 58th street, Chicago, Illinois 60637

We have shown that the yeast Saccharomyces cerevisiae *has a mechanism by which information from one gene can be transferred non-reciprocally to a repeated copy of the gene on the same chromosome. This intrachromosomal gene conversion may be important in maintaining sequence homogeneity within families of repeated eukaryotic genes.*

GENETIC exchange is usually thought to be an interchromosomal event occurring between homologous chromosomes in a diploid cell. This exchange of genetic information between two chromosomes may be either a reciprocal or a non-reciprocal (gene-conversion) event. A second type of genetic exchange is intrachromosomal recombination (or conversion). This term has been used to describe both recombination between chromatids attached to the same centromere (sister-strand recombination) and recombination between repeated genes within a single chromatid (intrachromatid recombination). Experimental evidence for both types of intrachromosomal recombination has been obtained. Using a selectable marker inserted into the tandemly repeated ribosomal DNA genes of yeast, T.D.P.[1] and Szostak and Wu[2] have shown that unequal sister chromatid exchange occurs in meiosis and mitosis. Sister chromatid exchange has also been observed in *Drosophila*[3] and in cultured mammalian cells[4]. Reciprocal recombination between repeated elements within a single DNA strand (intrachromatid recombination) has been seen within the 2-μm plasmid of yeast[5–9], as a rare recombination event of yeast chromosome III associated with a mating-type switch[10] and as a mitotic excision of a duplicated *LEU*2 gene from chromosome III (ref. 11). No clear example of non-reciprocal intrachromosomal exchange has been reported although mating-type switching in yeast can be interpreted as a unidirectional gene-conversion event[12,13].

The technique of yeast transformation provides an opportunity for examining the more general occurrence of intrachromosomal gene exchange. Hinnen *et al.*[11] showed that a transforming recombinant plasmid containing an insertion of yeast DNA usually integrates into the yeast chromosome by a homologous recombination event. As shown in Fig. 1 (after Fig. 2 of Hinnen *et al.*[11]), the result of this integration is a chromosome that contains a non-tandem duplication of a portion of yeast genome with the duplicated segments separated by bacterial plasmid sequences. In the experiments of Hinnen *et al.*[11], a recombinant plasmid containing the yeast *LEU*2$^+$ gene was integrated into a chromosome containing a *leu*2 mutation on chromosome III. We have shown that the mutation in the mutant copy can be transferred to the wild-type *LEU*2 gene by an *in vivo* meiotic intrachromosomal gene conversion. We do not know whether the transfer of information occurs as the result of an intrachromatid interaction or an unequal association between sister chromatids. Whatever the details of the interaction, the existence of such a mechanism may have important consequences for the evolution of repeated genes.

Isolation of a strain containing a duplicated *LEU*2 gene

The haploid yeast strain AH22[11] contains two frameshift mutations, *leu*2-3 and *leu*2-112, in the *LEU*2 gene on chromosome

III. This strain was transformed with the plasmid CV9 (obtained from J. Hicks). The CV9 plasmid contains a wild-type *LEU*2 yeast gene on a *Pst* restriction fragment that is inserted into the *Pst* site of pBR322[14]. Forty-nine independent Leu$^+$ transformants were obtained and one of these, AH22/CV9-12, was analysed in detail.

In the first experiment, AH22/CV9-12 was crossed to a haploid of opposite mating type (strain 2262; ref. 1) that carried a *leu*2 mutation. When the resulting diploid was sporulated and tetrad analysis performed[15], 41 of 42 tetrads examined segregated $2^+{:}2^-$ for the Leu2 phenotype. This segregation pattern indicates that the *LEU*2$^+$ transforming DNA had integrated at a single site in the host genome[11]. To determine the site of integration, we crossed AH22/CV9-12 to a *LEU*2$^+$ haploid strain HK-3A to form the diploid HK-12. Tetrad analysis of HK-12 showed segregation patterns of 4 Leu$^+$ to 0 leu$^-$ spores in more than 90% of the tetrads. This result indicates that the transforming *LEU*2$^+$ gene is closely linked to the normal *LEU*2 locus on chromosome III. The presumed arrangement of the *LEU*2 genes in AH22/CV9-12 is shown in Fig. 1 and the arrangement of markers in the diploid HK-12 (after meiotic DNA synthesis) is given in Fig. 2*a*. Additional evidence confirming these arrangements will be given below.

Of 306 tetrads analysed from the diploid HK-12, 294 tetrads segregated 4 Leu$^+$ to 0 leu$^-$ spores and 12 segregated 3 *LEU*$^+$ to 1 *leu*$^-$ spores. As described below, a detailed genetic analysis of tetrads showing the aberrant $3^+{:}1^-$ pattern provided evidence for intrachromosomal gene conversion.

Genetic analysis of aberrant tetrads

The diploid strain HK-12 had the genotype:

$$\frac{\text{a}\ \ leu2\text{-}3\ \ leu2\text{-}112\ \text{plus CV9 insertion}}{\alpha \qquad\qquad LEU2^+}$$

$$\frac{his4}{HIS4^+}\ \ \frac{TRP1^+}{trp1}\ \ \frac{ADE6^+}{ade6}\ \ \frac{MET13^+}{met13}\ \ \frac{TYR7^+}{tyr7}.$$

For purposes of our analysis, the most important genetic markers other than the *LEU*2 genes were the *HIS*4 gene, located on chromosome III centromere-distal to *LEU*2, and *TRP*1, a tightly centromere-linked marker on chromosome IV. These markers were used to monitor gene–gene or gene–centromere recombination on chromosome III by standard tetrad analysis[15].

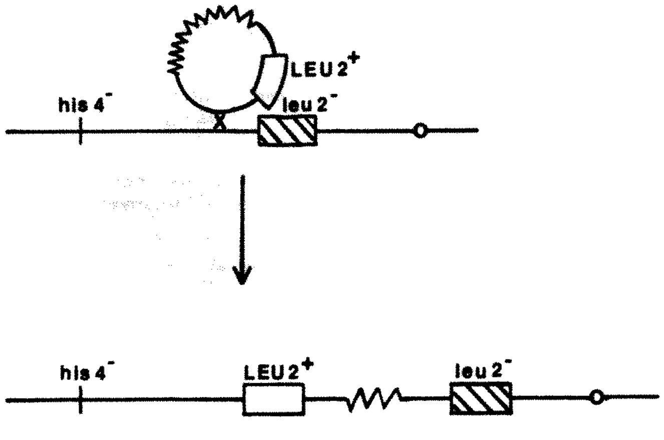

Fig. 1 Derivation of AH22/CV9-12 (after Hinnen *et al.*[11]). The recombinant plasmid CV9, consisting of a *Pst* fragment carrying the yeast *LEU*2$^+$ gene inserted into pBR322, is shown to integrate into the yeast chromosome III during transformation by homologous recombination. The exchange event is shown here to occur in flanking sequences that are centromere-distal to the *LEU*2 coding region. The resulting transformant contains duplicated *LEU*2 genes separated by pBR322 sequences. The thin line represents yeast sequences, the open boxes the yeast *LEU*2$^+$ gene, the lined boxes the yeast *leu*2$^-$ gene and the wavy line pBR322 sequences.

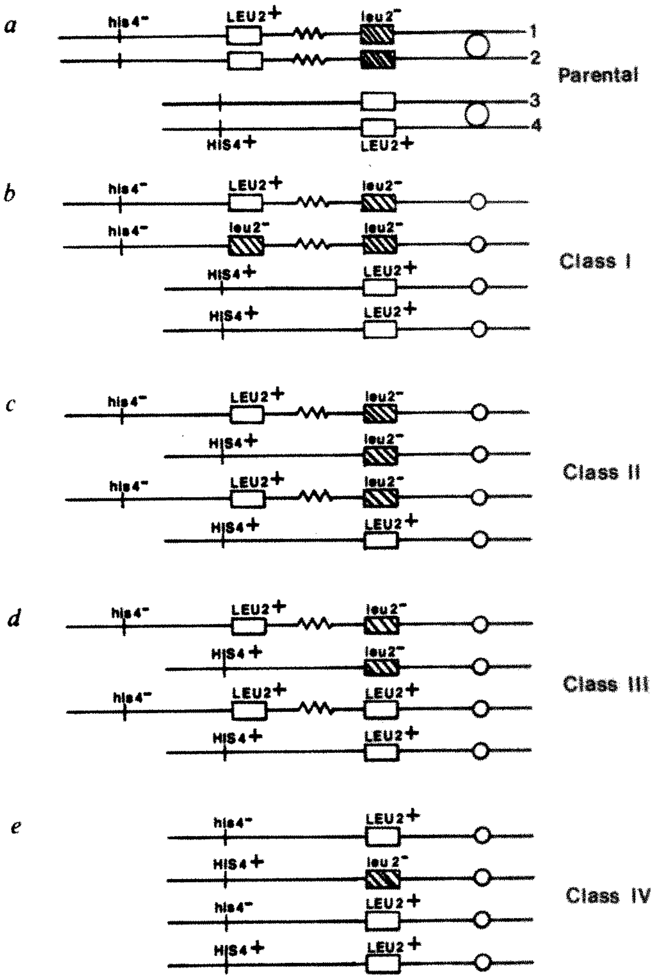

Fig. 2 Arrangement of *LEU*2 genes on chromosome III following transformation. The arrangement of *LEU*2 genes and the *HIS*4 gene on chromosome III in the diploid HK-12 is shown. Also shown are the order of these genes in tetrads from classes I, II, III and IV. *a* Shows the parental configuration of chromosome III in HK-12 following premeiotic DNA synthesis. The chromatids are labelled 1–4. *b* Shows an example of the chromosome III configuration in a class I tetrad. In some tetrads, reciprocal recombination events along chromosome III (noted in Table 1) have also occurred. *c* Shows an example of the chromosome III configuration in the class II tetrads. *d* Shows the chromosome III configuration in the class III tetrad. *e* Shows the chromosome III configuration in the class IV tetrad. The thin line represents yeast sequences, the open boxes the *LEU*2$^+$ gene, the lined boxes the *leu*2$^-$ gene and the wavy line pBR322 sequences.

Each spore clone from the aberrant tetrads was analysed in several ways. First, each strain was checked by standard procedures for auxotrophic requirements. Second, we examined each strain for the presence or absence of pBR322 sequences by using the colony hybridization technique[11]. Third, DNA from each strain was examined using the Southern blotting technique[16] to determine whether the spore had one or two copies of the *LEU*2 gene per chromosome. The details of the Southern analysis are described in Fig. 3 legend.

The procedures described above were done with all the spores from the aberrant tetrads. For some spores, additional tests were done. For those spores that were phenotypically leu$^-$, we did standard allelism tests[17] to determine whether they contained the *leu*2-3 allele, the *leu*2-112 allele, both mutant alleles or a new mutation in the *LEU*2 gene.

Some of the spores derived from the aberrant tetrads contained two copies of the *LEU*2 gene and were phenotypically Leu$^+$. In such spores, there could be either two *LEU*2$^+$ genes or one *LEU*2$^+$ gene and one mutant *leu*2 gene. To distinguish between these possibilities, we did a mutability test of the spores. The rationale for the test is that it should be more difficult to isolate a *leu*2-3 or *leu*2-112 mutation from a strain that has two wild-type *LEU2* genes than from a strain that has one wild-type *LEU2* gene and one *leu2*-3 *leu2*-112 mutant gene. As will be described in more detail below, by comparing the frequency of induced *leu2*-3 and *leu2*-113 mutations with the frequency of other *leu*$^-$ mutations, we could distinguish between two copies of the wild-type *LEU2* gene and one copy each of the wild-type and mutant *LEU2* genes.

Table 1 summarizes the genetic analysis of the aberrant tetrads of HK-12. On the basis of these data, we concluded that there were several mechanisms by which aberrant tetrads could be produced: class I (intrachromosomal gene conversion), class II (interchromosomal gene conversion), class III (reciprocal interchromosomal exchange) and class IV (multiple genetic events).

The four classes of aberrant tetrads

Class I tetrads were the most common aberrant segregation; 6 of the 12 aberrant tetrads were in this group. As described below, our analysis indicates that this class is the result of intrachromosomal gene conversion. The diagnostic feature of class I tetrads is the presence of two mutant copies of the *LEU2* gene (and associated pBR322 plasmid) in the leu$^-$ mutant spore (Table 1, Figs 2*b*, 3). Thus, a chromosome which originally had one mutant *leu2* gene and one wild-type *LEU2* gene has been changed to one which has two mutant genes. Allelism tests showed that the *leu2* mutations present in the leu$^-$ spores are derived from the *leu2* mutation of the untransformed parent AH22 and do not result from new *leu2*$^-$ alleles (Table 1). Both mutant alleles *leu2*-3 and *leu2*-112 (class IA) or one mutant allele *leu2*-3 (class IB) occur in the converted *leu2* gene. The mutational changes during intrachromosomal gene conversion do not involve deletions of any significant size, as no differences in the size of *LEU2*-specific restriction fragments are observed by Southern analysis (Fig. 3). Also, the *leu2*$^-$ mutants obtained in class IB can be reverted to the Leu$^+$ phenotype (H.K., data not shown).

The tetrads of HK-12 that have not undergone a conversion event (Fig. 2*a*) should have four wild-type *LEU2* genes and two mutant *leu2* genes within the four haploid spores. If class I tetrads represent a gene conversion event of a wild-type *LEU2* gene to a mutant *leu2* gene, they would be expected to have three *LEU*$^+$ genes and three mutant *leu2* genes. As previously

Table 1 Genetic analysis and segregation of aberrant tetrads

* The *leu2* alleles present in the leu$^-$ spores were determined by standard allelism tests. These involved mating each leu$^-$ spore with *leu2*-3 and *leu2*-112 testers of the appropriate mating type. Following growth of the diploids, the crosses were irradiated with UV rays, grown overnight in the dark and replica-plated to synthetic medium lacking leucine. The appearance of papillations due to mitotic recombination induced by the UV-ray treatment was taken as an indication of non-allelism. When only one *leu2* allele was observed in the leu$^-$ spore, it is assumed that the second copy of the *LEU2* gene contains the original double mutation *leu2*-3 *leu2*-112, although it is possible that the *leu2*-112 allele may have been lost by intrachromosomal gene conversion.

† This column shows the phenotype of the *LEU2* genes present in each spore. Minus signifies a mutant *leu2* gene. Plus signifies a wild-type *LEU2* gene. This interpretation is based on the data shown in Table 2.

discussed, the only ambiguous spore class in terms of the number of wild-type *LEU*2 alleles is that in which the spore is phenotypically Leu$^+$ and has two copies of the *LEU*2 gene. Such spores could contain either two wild-type *LEU*2 alleles or one mutant and one wild-type allele. As discussed previously, these two alternatives should be distinguished by testing the frequency with which *leu*2-3 and *leu*2-112 mutations can be recovered. To do this test, we grew a suspension of the cells being tested in rich medium. The cells were then treated with UV-ray irradiation (75% survival) and grown up overnight in the dark. The culture was then plated for single colonies on rich medium and replica-plated to synthetic medium lacking leucine. Complementation tests and allelism tests were done on the leucine-requiring mutants that were isolated.

The data for spores of class I as well as the original parental strains are shown in Table 2. Two results indicate that all the tested spores from class I tetrads contain one wild-type *LEU*2 gene and one mutant *leu*2 gene. First, in all cases it was easy to recover mutations at the *LEU*2 locus. For each class I strain tested, mutations at the *LEU*2 locus accounted for more than half of the total *leu*$^-$ mutations. In addition, the spectrum of mutant alleles recovered from the class I spores was similar to those recovered from the parental strain AH22/CV9-12. Second, at least half of the *leu*2 mutations produced by UV light are *leu*2-3, *leu*2-112 or both *leu*2-3 and *leu*2-112. We assume that the UV-ray treatment is not specifically inducing mutations at these loci, but is 'uncovering' the pre-existing mutations. The effect of the radiation is likely to be a stimulation of excision of the wild-type *LEU*2 gene or stimulation of gene conversion. The mutant *leu*2 genes remaining in the spore after UV-ray treatment are unlikely to be deletion mutants because several of the mutants are revertible (H.K., unpublished data). Also, the *leu*2-3 *leu*2-112 mutants derived from spore HK-121D show recombination with a different *leu*2 allele (*leu*2-1).

In summary, the mutability analysis indicates that the class I Leu$^+$ spores that contain two *LEU*2 genes have one wild-type gene and one mutant gene. Within the class I tetrads, therefore, there are a total of three wild-type *LEU*2 genes and three mutant *leu*2 genes (Fig. 2*b*). These results strongly support intrachromosomal gene conversion as the mechanism that generates class I tetrads. We do not know whether the intrachromosomal conversion event occurs as the result of an interaction within one chromatid or an unequal interaction between sister chromatids. For either type of interaction, we assume that the conversion event involves heteroduplex formation followed by mismatch repair[18], as for classical gene conversion.

Class II tetrads result from interchromosomal gene-conversion events. They are distinguished from class I tetrads by the segregation pattern of pBR322 sequences with the leu$^-$ spore. In class I tetrads the leu$^-$ spore contains pBR322 sequences, whereas the class II leu$^-$ spore does not (Table 1). Analysis of the types of leu$^-$ clones generated by UV-ray irradiation of the Leu$^+$ spores containing pBR322 sequences in the class II tetrads shows that both of these spores in each tetrad contain a mutant *leu*2 gene in addition to the wild-type *LEU*2 gene (Table 2). Thus, the class II tetrads have three mutant *leu*2 genes and three wild-type *LEU*2 genes. In contrast to the class I tetrads, the mutant *leu*2 genes are distributed over three chromosomes rather than two (Fig. 2*c*). This pattern of segregation requires the same interchromosomal interaction between homologues as occurs in 'classical' gene conversions[15].

Class III represents a reciprocal recombination event; only one such tetrad was found. In this tetrad, the mutability test of the spore HK12-11A (which is Leu$^+$ and has two copies of the *LEU*2 genes) yields a different result from similar tests of class I and II spores. The low frequency of *leu*2 mutations in this strain (Table 2) suggests that the spore HK12-11A has two wild-type *LEU*2 genes. Within the four spores, therefore, this class III tetrad has two mutant *leu*2 genes and four wild-type *LEU*2 genes (as shown in Fig. 2*d*). The simplest explanation of this segregation pattern is that a reciprocal recombination event occurred between the homologous chromosomes (chromatids 2 and 3 in Fig. 2*a*). This event occurred in the yeast sequences flanked by pBR322 and the mutant *leu*2 gene on strand 2 and homologous sequences centromere-distal to the wild-type *LEU*2 gene on strand 3 (see also Table 1).

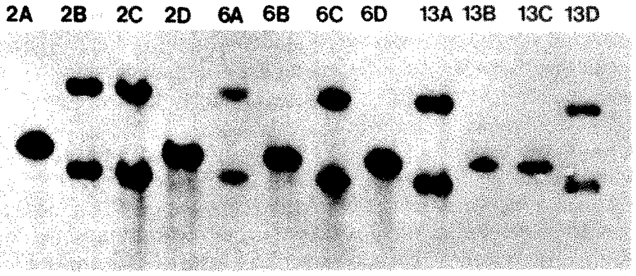

Fig. 3 Quantification of *LEU*2 genes. An autoradiogram of two class I tetrads and one control tetrad is shown. Nuclear DNA was isolated[29] from class I tetrads 2 and 6 and a control tetrad called tetrad 13 that showed 4$^+$: 0$^-$ segregation for the *LEU*2 gene. DNA was digested with *Bam*HI endonuclease. There is no *Bam*HI site within the yeast DNA inserted into plasmid pBR322 in the CV9 vector. The pBR322 plasmid contains one *Bam*HI site. Thus, a yeast strain with one *LEU*2 gene should have one *Bam*HI fragment containing the *LEU*2 gene. A yeast strain carrying two *LEU*2 genes separated by pBR322 sequences will have two *Bam*HI fragments, each containing one *LEU*2 gene. Following digestion of nuclear DNA with *Bam*HI, the fragments were separated by agarose gel electrophoresis on a horizontal 0.7% agarose slab gel run at 1 V cm^{-1} for 36 h. DNA was transferred to nitrocellulose[16]. The filters were hybridized to a DNA probe labelled with ^{32}P by nick translation[30]. The probe used was the large *Eco*RI fragment of the CV9 recombinant plasmid. The fragment contains approximately one-half of the yeast fragment inserted into pBR322 and half of the pBR322 plasmid.

The segregation pattern of this tetrad provides preliminary evidence that the orientation of genes in the AH22/CV9-12 parent is (*his*4)-(*LEU*2$^+$ gene)-(pBR322 sequences)-(*leu*2 mutant gene)-(centromere). If the order of the wild-type *LEU*2 gene and mutant gene were reversed, one should not obtain a spore with one mutant *leu*2 gene and no pBR322 sequences as the result of a single recombination event.

The most difficult segregation pattern (class IV) to explain is that found for tetrad 12. In this tetrad, no pBR322 sequences are present in any of the spores. In addition, only four copies of the *LEU*2 gene are present instead of the expected six copies. As both of the pBR322 sequences are missing from the tetrad, it is possible that two independent meiotic excisions of the plasmid

Table 2 Number of UV ray-induced leu$^-$ segregants

Strain	*leu*2-3 2-112	*leu*2-3	*leu*2-112	*leu*2 mutant alleles different from *leu*2-3 and *leu*2-112	*leu*$^-$ complementation groups other than *LEU*2

HK-3A	0	0	0	0	2

Selected spores from Table 1 that were Leu$^+$, but contained two copies of the *LEU*2 gene were grown overnight in rich medium. Approximately 10^6 cells were irradiated with UV rays to give 75% survival. Cells were grown overnight in the dark, plated for single colonies on rich medium and replica-plated to synthetic medium lacking leucine. Leucine-requiring mutants were picked and retested for the leucine requirement. The *leu*2 alleles were determined by the allelism test used in Table 1.

occurred (one associated with a conversion). Alternatively, if the excision of the plasmid was associated with heteroduplex formation between the duplicated *LEU*2 genes during G_1 of meiosis, replication of the resulting chromosome could produce a class IV tetrad.

Our discussion of classes I–IV aberrant tetrads has emphasized the number and types of *LEU*2 genes in each spore. By examining the segregation of the *HIS*4 and *TRP*1 genes, we could also determine the position of other recombination events along chromosome III (between *HIS*4 and *LEU*2 and *LEU*2 and the centromere). This information is also summarized in Table 1.

In conclusion, a non-tandem duplication consisting of a mutant *leu*2 gene and a wild-type *LEU*2 gene can be altered by a number of genetic mechanisms. The most common alteration is an intrachromosomal gene conversion. Interchromosomal gene-conversion events and other alterations are also found. As will be discussed below, we believe intrachromosomal gene conversion may have important consequences in the evolution of repeated genes.

Discussion

Repeated cycles of unequal sister chromatid exchange have been suggested as a mechanism for maintaining homogeneity among highly repeated sequences such as the ribosomal DNA sequences, satellite DNA, histone and the immunoglobulin genes[3,19,20]. Recently, this mechanism has been extended to the globin genes following the observation that the restriction enzyme maps of the duplicated α-globin genes in humans and primates are highly conserved within a species[21,22]. Although unequal sister-strand recombination undoubtedly occurs in some systems[1,2,22–24], it is not clear that such exchanges are the mechanism by which sequence homogeneity is maintained. There are at least two inherent disadvantages in maintaining sequence homogeneity among repeated genes by unequal sister-strand exchange. First, unequal sister-strand exchange involves a change in gene dosage. For some classes of repeated genes, therefore, one would expect selection against the products of the exchange. Second, if the repeated genes on a chromosome are not arranged in tandem, but are separated by unique DNA, unequal sister chromatid exchange will result in the deletion of these unique sequences from one chromatid.

We believe that certain experimental results can be most easily explained by an intrachromosomal event. For example, in certain individuals, the γ-globin genes contain a restriction endonuclease pattern which is different from that found in most humans[25]. Both copies of the γ gene on a single chromosome contain this change. Jeffreys[25] has proposed that some type of intrachromosomal recombination event maintains this polymorphism. DNA sequencing of γ-globin genes suggests the possibility of a gene-conversion event[26].

Although intrachromosomal gene conversion has the advantage that a mutation can be duplicated or deleted in a single generation without changing gene dosage, it is still possible, of course, that unequal sister-strand recombination is also important in maintaining sequence homogeneity, as these events can be quite frequent[1,2]. In the present study six tetrads contained an intrachromosomal gene conversion and there were no examples of an unequal sister-strand exchange. We do not know whether the lack of unequal exchanges is the result of the small sample size, the small size of the duplicated segment or some other factor. We suggest that in some systems, unequal sister-strand exchange may be more important as a mechanism for changing gene dosage than as a mechanism for maintaining sequence homogeneity. The relative importance of intrachromosomal gene conversion and unequal sister-strand exchange in maintaining sequence homogeneity may depend on many factors, for example, whether the duplicated genes are in tandem or separated by unique DNA sequences, the number of repeated units in the family or the DNA sequence within the repeated unit.

In the data reported here, intrachromosomal gene conversion, resulting in two mutant *leu*2 genes, was observed in 6/306 unselected tetrads, a frequency of 2%. If the conversion of a mutant *leu*2 allele to a wild-type *LEU*2 allele is assumed to occur at the same rate, the overall frequency of intrachromosomal gene conversion is estimated to be 4%. This frequency is clearly much higher than the frequency of mutation. Consequently, this mechanism should be suffcient to maintain the homogeneity of certain classes of repeated genes (such as those genes that code for ribosomal RNA) within the yeast genome. Note also that for some classes of repeated genes, intrachromosomal gene conversion may not function often enough to remove all sequence diversity. The conversion frequencies may depend on such factors as the specific base sequence, the size of the repeated gene or the distance between repeated units.

Finally, there is the question of whether the intrachromosomal gene conversion that we have observed occurs naturally in yeast or is induced by the insertion of the recombinant plasmid CV9. Although we cannot entirely rule out the latter possibility, we believe that it is unlikely. Using different recombinant plasmids and different selectable yeast genes, Jackson and Fink (personal communication) and Falco and Botstein (personal communication) have found similar results. In the experiments of Jackson and Fink, both meiotic and mitotic conversion events were observed. In addition, Munz and Leupold[27], in reversion studies of suppressor mutations in the yeast *Schizosaccharomyces pombe*, have obtained evidence that is consistent with the occurrence of interchromosomal gene-conversion events among repeated tRNA genes. Scherer and Davis[28] have recently demonstrated that similar non-homologous interchromosomal gene-conversion events occur in *Saccharomyces cerevisiae*.

We thank Dorothy Stamenkovitch and Tuula Vuorio for technical assistance, Drs R. Esposito, S. Klapholtz, S. Lindquist and R. Farber for comments and criticism concerning the manuscript, and Drs Fink and Botstein for communicating to us unpublished results. Ordering of mouse immunoglobulin heavy chain genes by molecular cloning

Akira Shimizu, Naoki Takahashi, Yuriko Yamawaki-Kataoka, Yasuyoshi Nishida, Tohru Kataoka & Tasuku Honjo

Department of Genetics, Osaka University Medical School, Kita-ku, Osaka 530, Japan

We have determined the order of the mouse immunoglobulin $\gamma 1$, $\gamma 2b$, $\gamma 2a$ and ε genes by molecular cloning of overlapping chromosomal segments. The results clearly demonstrate that the order is 5′–$\gamma 1$–(21 kilobases)–$\gamma 2b$–(15 kilobases)–$\gamma 2a$–(15 kilobases)–ε–3′. There seem to be no J regions at the 5′ side of each constant region gene so far obtained except for the μ gene and these constant region genes seem to have repetitive sequences characteristic of switch (S) regions at their 5′ side.

IMMUNOGLOBULIN heavy (H) chain genes comprise a family of variable region (V) genes and several constant region (C) genes which are classified, in mouse, into five major classes: μ, γ, α, δ and ε. Genetic studies using allotype markers have clearly demonstrated that the V_H and C_H genes of a single chromosome are coordinately expressed—this is called *cis* expression[1-3]. During differentiation, a given lymphocyte seems to be able to associate a single V region sequentially with two or more different classes of H chain C region[4-11]. In this H chain class switch, the direction of the switch is always from μ to γ or α.

Using cDNA–mRNA hybridization kinetics, we have shown that specific C_H genes are deleted in mouse myelomas depending on which C_H genes are expressed[12], and have proposed that a chromosomal segment which intervenes recombining V_H and C_H genes is deleted to bring the V_H and C_H genes close together. Based on the deletion profiles of C_H genes in various myeloma tumours producing different C_H genes, a linear arrangement of C_H genes has been proposed as 5′–μ–$\gamma 3$–$\gamma 1$–$\gamma 2b$–$\gamma 2a$–α–3′. Subsequently, more direct evidence has been presented that deletion of the intervening DNA segment accompanies the H chain class switch[13-18]. Such studies using Southern blot[19] hybridization experiments also support the proposed order of C_H genes.

Comparative studies of rearranged and germ-line H chain genes have led to proposals[20-26] for a molecular mechanism of H chain class switch. According to this model, a complete H chain gene is formed by at least two types of the recombination event. The first type of recombination takes place between a given V_H, a J_H and a D gene segment, completing a V region gene[23-25]. The second type of recombination is required to switch a C_H gene and occurs between S_μ and S_γ (or S_α) regions which are located at the 5′ flanking regions of respective C_H genes. This model postulates two important structural features in the H chain gene organization: (1) the presence of only one set of J_H region genes in the 5′ side to the μ gene and (2) the presence of the S region before each C_H gene.

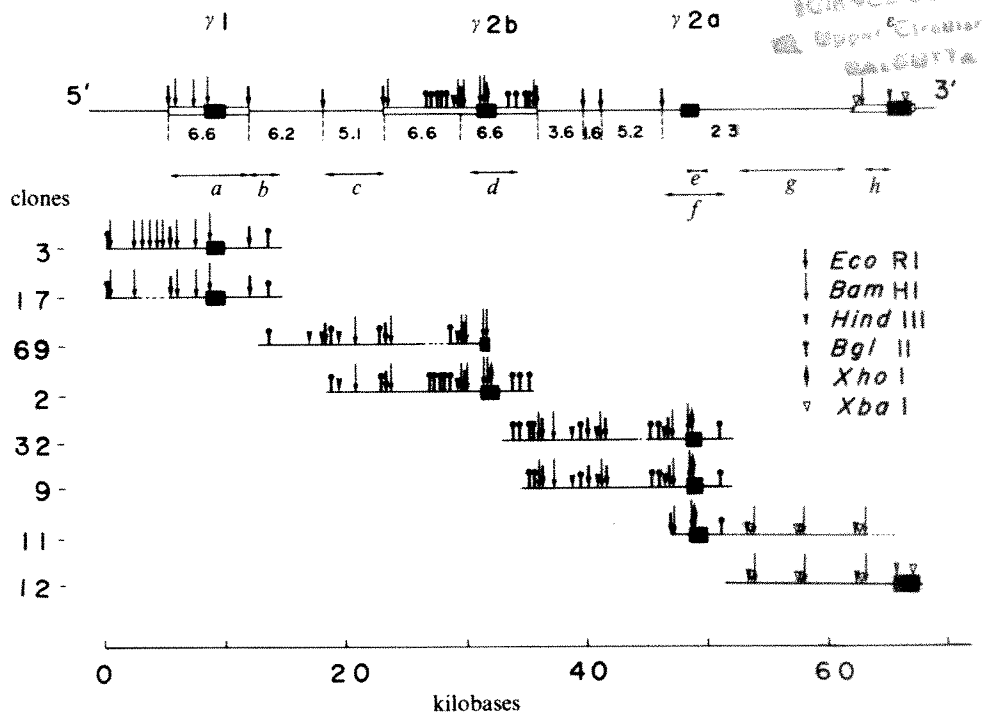

Fig. 1 Restriction endonuclease cleavage maps of overlapping cloned fragments between $\gamma 1$ and ε genes. We used a recombinant phage library[42] for cloning DNA segments that contain immunoglobulin genes or their flanking regions, except for clone 11. The Charon 4A phage[43] library of BALB/c mouse embryo DNA (provided by Dr P. Leder) contained partial *Hae*III digests of embryonic mouse DNA with average length 18 kilobases. These fragments were ligated with *Eco*RI linkers and incorporated into phage DNA. The 20-kilobase insert of clone 11 was partially purified from *Eco*RI digests of RPC5 myeloma DNA by RPC5 column chromatography and agarose gel electrophoresis as described previously[27]. The partially purified DNA fragments were ligated with the outer fragments of Charon 4A phage DNA. Screening was done on 230×230 mm tryptone broth plates containing 5–20×10⁴ plaques by an *in situ* hybridization method[44]. Appropriate restriction endonuclease fragments of immunoglobulin genes were labelled with ^{32}P by nick translation[45] to a specific activity of 30–200 c.p.m. per pg and used as hybridization probes. Nitrocellulose filters were washed as described elsewhere[17]. A plaque containing an immunoglobulin gene or its flanking region was picked up and the phages were grown in liquid cultures to prepare DNA as described[46]. At the top is a schematic representation of the chromosomal segment containing the $\gamma 1$, $\gamma 2b$, $\gamma 2a$ and ε genes. Open bars indicate DNA segments cloned previously: the $\gamma 1$ gene (IgH2)[27], the $\gamma 2b$ gene (IgH22, Igγ2b-26)[28,30,33] and the ε gene (Igε – 1)[34]. Structural genes are shown as solid boxes with direction of transcription from left to right, determined by nucleotide sequence determination. Numbers under the top line indicate sizes of *Eco*RI fragments in the germ-line gene. Horizontal arrows indicate fragments used as probes for screening or Southern hybridization. The insert of each clone is shown by a horizontal line with restriction sites. Clones were aligned by restriction endonuclease cleavage mapping and Southern hybridization analysis (see text and Figs 2, 4). Restriction digests were examined by electrophoresis in 0.5–0.7% agarose gels. It is possible that very small fragments (for example, 100 base pairs) may have been missed. *Bgl*II and *Xho*I sites at the 3′ side of the $\gamma 2a$ gene and *Xba*I sites at the 5′ side of the $\gamma 2a$ gene were not determined. Broken lines in clones 11, 17, 32 and 69 indicate deletions.

0028-0836/81/030149—05$01.00

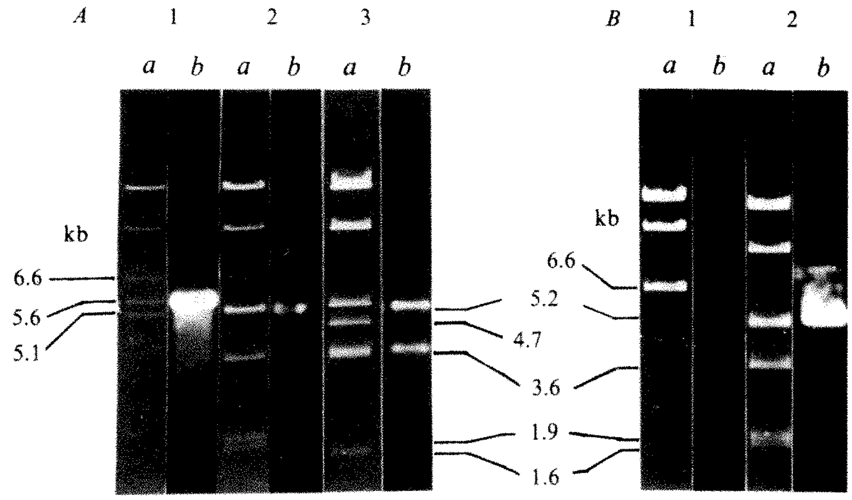

Fig. 2 Southern hybridization of isolated clones linking between the γ2b and γ2a genes. DNAs from isolated clones (0.1–0.3 μg each) were digested with *Eco*RI and electrophoresed in 0.5% agarose gels. The fragments were transferred to nitrocellulose filters[19] and hybridized with ^{32}P-labelled probes as described elsewhere[17]. Ethidium bromide stains (*a*) and autoradiograms (*b*) of Southern blots are shown. In *A*, 4.0-kilobase (kb) *Xba*I–*Hha*I fragment of γ2b gene (Fig. 1*d*) was used as a probe. Lanes 1, 2 and 3 contain DNAs of clones 2, 9 and 32, respectively. In *B*, γ2a cDNA clone (pG2a-14) (probe *e* in Fig. 1) was used as a probe. Lanes 1 and 2 contain DNAs of the 6.6-kilobase γ2b gene clone (IgH22)[28,30] and clone 9, respectively.

To determine directly the order of C$_H$ genes and test the proposed C$_H$ gene organization, we and others cloned mouse immunoglobulin genes, and have determined the complete nucleotide sequences of the γ1, γ2b and μ genes[27–31]. Liu *et al.*[32] isolated a clone which contains both μ and δ genes, and demonstrated that the μ gene is located ~4.5 kilobases 5′ to the δ gene. The linkage of 5′–γ1–γ2b–3′ was shown by cloning overlapping chromosomal segments[20]. We have recently cloned the γ3 and ε genes[33,34], and using these cloned DNA segments as probe, cloned overlapping chromosomal segments from embryonic mouse DNA. Characterization of these clones unequivocally demonstrates that the mouse immunoglobulin γ chain genes are aligned as proposed[12] (that is, 5′–γ1–γ2b–γ2a–ε–3′) on a chromosome. The linkage of 5′–ε–α–3′ is described elsewhere[34].

The γ2b gene is located 5′ to the γ2a gene

When we screened a Charon 4A library containing partial *Hae*III digests of embryonic mouse DNA with the 4-kilobase *Xba*I–*Hha*I fragment (probe *d* in Fig. 1) of the γ2b gene clone[28,30] as a probe, we isolated three clones which were designated Ch · M · Igγ2b–2 (clone 2), Ch · M · Igγ2a–9 (clone 9) and Ch · M · Igγ2a–32 (clone 32). These were characterized by restriction enzyme cleavage mapping and Southern blot hybridization (Figs 1, 2). Clone 2 contains an *Eco*RI fragment (5.6 kilobases) that hybridizes with probe *d* (Fig. 2*A*, lane 1) and shares common restriction sites with the 6.6-kilobase *Eco*RI fragment of the γ2b gene, the nucleotide sequence of which has already been determined[30]. Comparison of restriction maps of clone 2 and the γ2b clone indicates that clone 2 contains the γ2b gene at the 3′ end (Fig. 1).

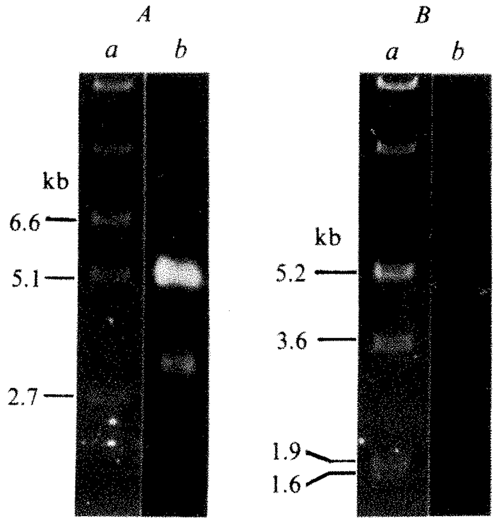

Fig. 3 Cross-hybridization between S$_{\gamma 1}$ and S$_{\gamma 2a}$ regions. Experiments were done as described in Fig. 2 legend. DNA was digested with *Eco*RI and Southern blot hybridized with ^{32}P-labelled 5′ *Eco*RI fragment (5.1 kilobases) of clone 3. Ethidium bromide stains(*a*) and autoradiograms(*b*) of Southern blots are shown. *A*, clone 3 DNA. *B*, clone 9 DNA. A faint band of 3.1 kilobases in lane *A*(*b*) is due to deletion of the 5.1-kilobase fragment of clone 3 during propagation.

However, restriction cleavage site mapping indicates that clone 9 does not contain any region corresponding to the γ2b structural gene (Fig. 1), but has one *Eco*RI fragment (5.2 kilobase) that hybridizes with the γ2b gene fragment (probe *d*) as shown in Fig. 2*A*, lane 2. Because the γ2b and γ2a genes are known to share extensive homology and cross-hybridize[30,35,36], we thought that clones 9 and 32 could contain the γ2a gene.

To test this we used as probe a γ2a cDNA clone pG2a-14 (probe *e* in Fig. 1) which does not hybridize with the γ2b gene in the stringent conditions used[17]. As shown in Fig. 2*B*, clone 9 was shown to contain an *Eco*RI fragment (5.2 kilobases) that hybridized to the γ2a gene probe (probe *e*). This *Eco*RI fragment is located at the 3′ end of the clone 9 insert and is cleaved by *Xho*I (data not shown). We have determined a partial nucleotide sequence of the 5.2-kilobase *Eco*RI fragment of clone 9. The nucleotide sequence from the *Bam*HI site towards the *Xho*I site of the γ2a coding region is

GGATCCCTGTCCAGTGGTGTG
CACACCTTCCCAGCTGTCCTGCAG,

which coincides with that reported for the CH1 domain of the γ2a cDNA clone[36]. The amino acid sequence

Gly-Ser-Leu-Ser-Ser-Gly-Val-His-
Thr-Phe-Pro-Ala-Val-Leu-Gln

predicted from the nucleotide sequence agrees well with that previously determined for the CH1 domain of the γ2a chain of MOPC173 (ref. 37). The sequence determines the direction of transcription of the γ2a gene and unequivocally demonstrates that clone 9 contains the γ2a gene at the 3′ side.

The restriction map analysis indicates that clones 9 and 32 are almost identical to each other except that clone 32 extends 1.7 kilobases further in the 5′ direction and has a small deletion (0.5 kilobases) in the middle (Fig. 1). It is clear that clone 32 has a γ2a gene fragment at the 3′ end identical to that of clone 9. In addition, clone 32 contains, at the 5′ end, a 3.6-kilobase *Eco*RI fragment which hybridizes with the γ2b gene probe (Fig. 2*A*, lane 3). The restriction map of the 5′-terminal portion (~2.6 kilobases) of clone 32 is indistinguishable from that of the 3′ end of clone 2 (Fig. 1). These results indicate that clone 32 shares overlapped regions at the 5′ end with clone 2 and at the 3′ end with clone 9. The linear alignment of clones 2, 32 and 9 clearly demonstrates that the γ2b gene is located 5′ to the γ2a gene and the two genes are 15 kilobases apart (Fig. 1).

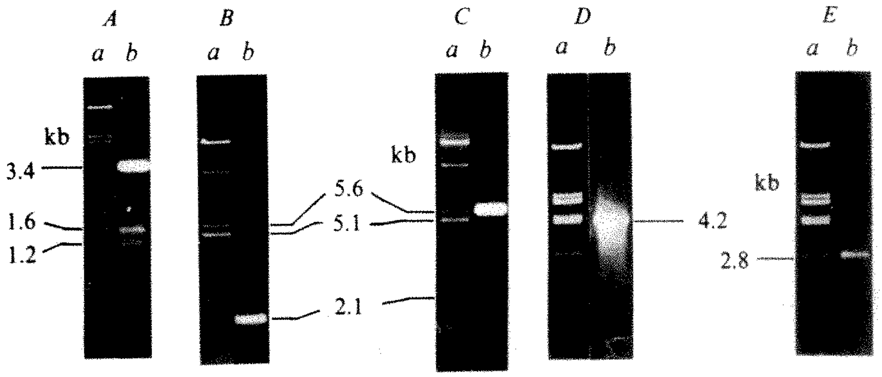

Fig. 4 Southern hybridization of isolated clones linking between the $\gamma1$ and $\gamma2b$ genes and between the $\gamma2a$ and ε genes. Experiments were done as described in Fig. 2 legend. Ethidium bromide stains(*a*) and autoradiograms(*b*) of Southern blots are shown. In *A*, clone 3 DNA was digested with *Eco*RI and *Bam*HI, and the 6.6-kilobase *Eco*RI fragment of the $\gamma1$ gene (Fig. 1*a*) was used as a probe. In *B*, clone 69 DNA was digested with *Eco*RI and 4.0-kilobase *XbaI–HhaI* fragment of the $\gamma2b$ gene (Fig. 1*d*) was used as a probe. In *C*, clone 69 DNA was digested with *Eco*RI and 2.7-kilobase 3′ *Eco*RI fragment of clone 3 (Fig. 1*b*) was used as a probe. In *D*, clone 12 DNA was digested with *Eco*RI and *Bam*HI, and the probe was 2.2-kilobase *Bam*HI–*Hin*dIII fragment of the ε gene (Fig. 1*h*). *E*, clone 12 DNA was digested with *Eco*RI and *Bam*HI and the probe was the 5.2-kilobase *Eco*RI fragment of clone 9 (Fig. 1*f*).

The $\gamma1$ gene is located 5′ to the $\gamma2b$ gene

The embryonic mouse DNA library was screened with a 6.6-kilobase $\gamma1$ gene fragment (IgH2) cloned previously[27] as a probe (probe *a* in Fig. 1) and two different clones were obtained: Ch · M · Igγ1 – 3 (clone 3) and Ch · M · Igγ1 – 17 (clone 17). Restriction maps of these are shown in Fig. 1.

Comparison of the restriction maps of clones 3 and 17, and the $\gamma1$ gene clone (IgH2) indicates that both clones 3 and 17 contain the 6.6-kilobase *Eco*RI fragment of the $\gamma1$ gene. The comparison also allows determination of the orientation of the two clones. The insert of clone 17 is $\sim$2 kilobases shorter than that of clone 3 and the deletion is located in the 5′-terminal *Eco*RI fragment. These two clones may be derived from a common ancestral phage and the deletion may have occurred during propagation of phages, because the directions of the inserts within these phages and the ends of the inserts in these clones are identical to each other. Furthermore, clone 3 underwent deletion during propagation, producing a phage similar to clone 17 (see Fig. 3*A*). Southern blot experiments (Fig. 4*A*) provide additional evidence that clone 3 contains the $\gamma1$ gene. When clone 3 DNA was digested with *Eco*RI and *Bam*HI simultaneously, clone 3 DNA produced 3.4-, 1.6- and 1.2-kilobase fragments which hybridize to the $\gamma1$ gene (probe *a*), as expected from the restriction map.

Because $\gamma1$ gene clones (3 and 17) and $\gamma2b$ gene clone (2) do not share a common region, we screened the embryonic mouse DNA library with a 3′ fragment of clone 3 (Fig. 1, probe *b*) and a 5′ fragment of clone 2 (Fig. 1, probe *c*) as probes. We isolated a new clone designated Ch · M · Igγ2b–69 (clone 69)—the restriction map of this is shown in Fig. 1.

The 3′ part of clone 69 is indistinguishable from that of clone 2 except that the former has an $\sim$1.5-kilobase deletion at the 5′ side of the $\gamma2b$ gene. Comparison of restriction maps of clones 69 and 2 indicates that clone 69 contains the $\gamma2b$ gene at the 3′ end. Southern blot hybridization experiments show that a 2.1-kilobase *Eco*RI fragment of clone 69 hybridizes with the $\gamma2b$ gene probe (Fig. 4*B*). Clone 69 also contains a 5.6-kilobase *Eco*RI fragment that hybridizes with the 3′-terminal fragment of clone 3 (Fig. 1, probe *b*) as shown in Fig. 4*C*. From these results it is clear that the 3′ region (2.1 kilobases) of clone 3 and the 5′ region (2.1 kilobases) of clone 69 are identical. The linear alignment of clones 3, 17, 69 and 2 clearly demonstrates that the $\gamma1$ gene is located 5′ to the $\gamma2b$ gene and the two genes are 21 kilobases apart. These results are consistent with those of Maki *et al.*[20].

The ε gene is located 3′ to the $\gamma2a$ gene

We recently cloned a $\gamma2a$ gene fragment from *Eco*RI digests of RPC5 myeloma DNA designated Ch · M · Igγ2a–11 (clone 11). Southern blot hybridization and R-loop mapping show that the $\gamma2a$ gene is located at the 5′ end of the 20-kilobase cloned fragment (data not shown). The restriction map of clone 11 is shown in Fig. 1. The 5′ region of the RPC5 $\gamma2a$ gene fragment shares common restriction sites with the 3′ region of clones 32 and 9.

The 8.5-kilobase *Hin*dIII fragment (probe *g*) of clone 11 was recloned into pBR322 and used as a probe to screen the mouse embryonic DNA library. We obtained a germ-line $\gamma2a$ gene fragment designated Ch · M · Igε–12 (clone 12)—the restriction map of this is also shown in Fig. 1. The 16.5-kilobase insert of clone 12 has restriction sites almost identical to those of the 3′ portion of clone 11 except that the latter has a deletion at the 3′ part.

Cloning of an expressed ε gene from an ε chain-producing hybridoma has been reported elsewhere[34]. Partial nucleotide sequence determination indicates that our ε gene clone Ch · M · Igε–1 encodes an amino acid sequence similar to that of human ε chain. The expressed ε gene (Ch · M · Igε–1) contains, as do other expressed H chain genes[20–26], at least three germ-line gene segments: a V gene, a J gene (including S_μ region that flanks the 5′ end of the μ gene) and the ε gene. The restriction map of the region encoding the ε gene of Ch · M · Igε–1, shown at the top of Fig. 1, seems to be identical to that of the 3′ region of clone 12.

To test whether or not clone 12 contains the ε gene, Southern blot hybridization experiments were done using a *Bam*HI–*Hin*dIII fragment (probe *h*) of the ε gene as a probe. Figure 4*D* shows that probe ε hybridizes a 4.2-kilobase *Bam*HI + *Eco*RI fragment at the 3′ part of clone 12. We also confirmed (Fig. 4*E*) that the 5′ segment of clone 12 has a region identical to the 3′ segment (probe *f*) of clone 9 which contains the germ-line $\gamma2a$ gene. Taken together, these results indicate that the ε gene is located 3′ to the $\gamma2a$ gene and the two genes are about 15 kilobases apart.

We have recently isolated three clones[38] which link the $\gamma1$ gene (clone 3) and the $\gamma3$ gene (Igγ3–30)[33]. Our data indicate that the $\gamma3$ gene is located 34 kilobases 5′ to the $\gamma1$ gene, and we

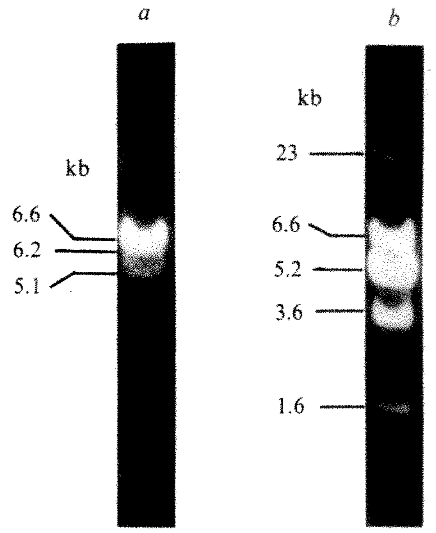

Fig. 5 Distance between the $\gamma1$, $\gamma2b$ and $\gamma2a$ genes. BALB/c newborn mouse DNA (3 μg) was digested with *Eco*RI to completion and run on 0.5% agarose gel electrophoresis. DNA was transferred to a nitrocellulose filter[19] and hybridized with ^{32}P-labelled probes as described elsewhere[17]. Total DNAs of clones 69 and 9, respectively, were used as probes in *a* and *b*.

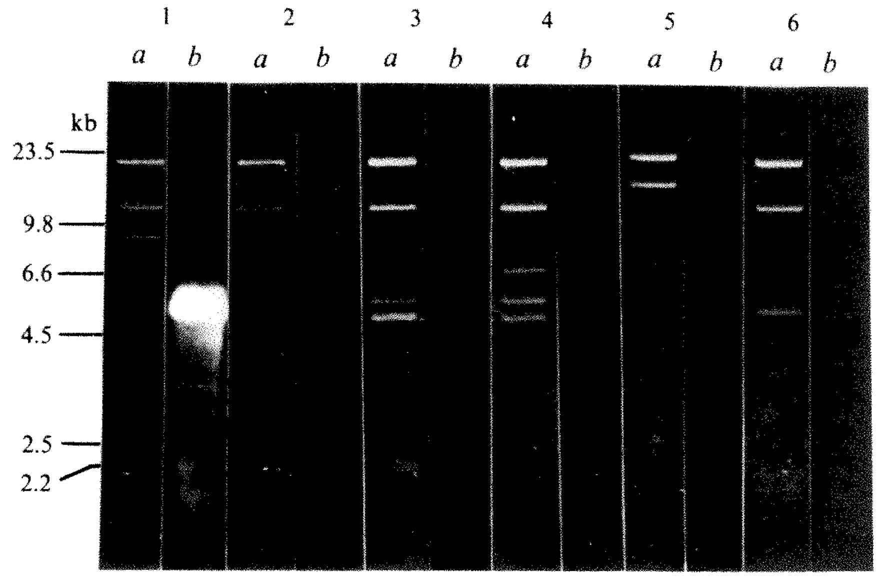

Fig. 6 Hybridization analysis with J-region probe. DNAs from isolated clones covering the region between the $\gamma1$ and $\gamma2a$ genes were digested with *Eco*RI and run on 0.7% agarose gel electrophoresis. DNAs were transferred to a nitrocellulose filter[19] and hybridized with the 1.5-kilobase *Hin*dIII–*Eco*RI fragment that is located 6.5 kilobases 5′ to the μ gene. This fragment contains the J_{H4} region[24]. Ethidium bromide stains(*a*) and autoradiograms(*b*) of Southern blots are shown. DNA in each lane is as follows: (1) the expressed $\gamma1$ gene of MC101 myeloma (Igγ1–706)[25,47,48] that contains V, D, J_3, J_4, S_μ and $C_{\gamma1}$ gene segments; (2) clone 3; (3) clone 69; (4) clone 2; (5) the 6.6-kilobase $\gamma2b$ gene clone (IgH22)[28,30]; (6) clone 9.

have demonstrated[34] that the ε gene is present 12.5 kilobases upstream of the α gene. The linkage of J_H–μ–δ has been shown elsewhere[24,32]. Thus it is now clear that the organization of the mouse C_H gene is 5′–J_H–(6.5 kilobases)–μ–(4.5 kilobases)–δ–(unknown distance)–$\gamma3$–(34 kilobases)–$\gamma1$–(21 kilobases)–$\gamma2b$–(15 kilobases)–$\gamma2a$–(14.5 kilobases)–ε–(12.5 kilobases)–α–3′. Note that all the C_H genes ordered have the same orientation and thus are transcribed from the same strand of DNA.

Distance between C_H genes in germ-line DNA

Comparison of the restriction maps of the clones isolated indicate that some have deletions which probably occurred during propagation of phages. This was also reported for globin gene clones[39]. We therefore compared the sizes of *Eco*RI fragments obtained from cloned γ genes and from Southern blot hybridization of newborn mouse DNA. When the total insert of clone 69 was used as a probe, *Eco*RI digests of newborn mouse DNA produced 6.6(doublet)-, 6.2- and 5.1-kilobase bands which coincide with the *Eco*RI fragments deduced from the cloned DNAs (Fig. 5). When the total insert of clone 9 was used as a probe, *Eco*RI digests of newborn mouse DNA produced 23-, 6.6-, 5.2-, 3.6- and 1.6-kilobase bands which coincide with the *Eco*RI fragments deduced from the cloned DNAs.

Furthermore, consideration of the maximum size of the insert (21 kilobases) that can be taken by Charon 4A phage makes it unlikely that there is a deletion >2 kilobases in the clones obtained. Because the insert sizes of clones 69 and 32 are 19.3 and 19.2 kilobases, respectively, the original inserts cannot be more than 2 kilobases greater than those of the present clones. We therefore conclude that the distances between the $\gamma1$ and $\gamma2b$ genes and between the $\gamma2b$ and $\gamma2a$ genes in the germ-line chromosome are 21.2 and 15.5 kilobases, respectively. Similar experiments using the ε gene as a probe[34] indicate that the distance between the $\gamma2a$ and ε gene is 14.5 kilobases in newborn mouse DNA.

Absence of J region sequences in the entire region encompassing γ and ε genes

We determined whether or not each γ gene clone contains a sequence homologous to a J region. We used a J segment (J_4) as a probe and hybridized it with restricted DNA fragments of all the γ gene clones shown in Fig. 1. There were no J or J-like sequences between 8 kilobases 5′ to the $\gamma1$ gene and 3 kilobases 3′ to the $\gamma2a$ gene (Fig. 6). The J_4 sequence was actually expressed in the $\gamma2b$ chain produced by MOPC141 myeloma[24]. It can be argued that other completely different J sequences may be present in the γ gene-flanking regions. If this is the case, V region sequences formed by the use of J_μ and J_γ are different. This is unlikely because the same idiotype (a V region sequence) can be expressed as either μ or γ chain. It is possible that a γ gene has completely different J-flanking regions and an identical J_4 sequence of 51 base pairs which was not detected by our probe. This also seems unlikely because the precise joining between the same V gene and J_γ probably requires a nucleotide sequence similar to that of the J_μ-flanking region[23,24]. A similar experiment was done on the ε gene clone (clone 12) and a $\gamma3$ gene clone[33], in which we did not find a J region or J-like sequences (data not shown).

The S region before each C_H gene may comprise repetitive sequences

The class-switch recombination takes place at the region 5′ to each C_H gene. Such regions responsible for the class switch have been functionally defined as S regions[21]. We have recently demonstrated that the $S_{\gamma1}$, $S_{\gamma2b}$ and $S_{\gamma3}$ regions comprise tandem repetitive conserved sequences of 49 base pairs[25,33]. The 5′-flanking region of the $\gamma2b$ gene which contains the repetitive sequence is deleted from clone 69. Such tandem repetitive sequences of conserved 49-base pair units can be easily deleted when propagated in bacteria[40]. Deletions of short segments (0.5–2.0 kilobases) found in several clones are always located in the 5′-flanking region of each γ gene. The distance from the 5′ end of each γ gene to a deleted region is almost constant (~3 kilobases). During propagation of clone 9, we also found a deletion of ~1.5 kilobases at ~3 kilobases 5′ of the $\gamma2a$ gene, about the same place where deletion occurred in clone 32. The deletions in these clones may indicate the positions of repetitive sequences.

Although we have not determined the nucleotide sequence of the $S_{\gamma2a}$ region, the deletion in clone 32 may suggest a similar repetitive sequence in the 5′-flanking region of the $\gamma2a$ gene. We found that the 5′-flanking region of the $\gamma2a$ gene cross-hybridizes with the $S_{\gamma1}$ region (Fig. 3). The S_μ and S_α regions also contain repetitive sequences[22,31,41] and these are often deleted during cloning. Thus it is likely that each C_H gene, except for the δ gene which is probably expressed by RNA splicing[32], has its own S region for class-switch recombination and that all the S regions comprise repetitive sequences.

We thank Dr P. Leder for an embryonic mouse DNA library, Dr K. Matsubara for critical reading of the manuscript, Mrs S. Nishida for technical assistance, and Miss T. Wada for preparation of the manuscript. Research was supported in part by grants from the Ministry of Education, Science and Culture of Japan and from Asahi Scientific Research Fund.

Variability of the double quasar 0957+561 A, B

Joseph S. Miller, Robert R. J. Antonucci & William C. Keel

Lick Observatory, Board of Studies in Astronomy and Astrophysics,
University of California, Santa Cruz 95064

Evidence suggests that the double nature of the quasar 0957+561 A, B results from the influence of an intervening gravitational lens on the light from a more distant, single quasar. The nearly identical spectral characteristics of the two objects have been established[1-3] and have been the incentive for interpreting the two apparent objects as images of a single one. We report here spectroscopic and photometric observations which show that the images of the double quasar 0957+561 A, B are variable. Brightness changes were observed to be accompanied by corresponding spectral variations. These data suggest that the quasar itself is an intrinsically variable object.

Photographs by one of us (W.C.K.) taken with the 0.9-m Lick Observatory Crossley reflector on 18 and 19 May 1980 (all dates are given in UT) showed that ratio of brightness in the blue of B to A was 0.95, considerably different from the value of about 0.75 given earlier[1,4] (A is taken as northern image) and it seemed more likely that B brightened than that A faded[5]. To investigate further the nature of the variability, we obtained additional Crossley photographs and made spectrophotometric observations with the Lick Observatory 3-m Cassegrain image-tube scanner on 9 June 1980. We also obtained spectrophotometric data for the pair on 12, 13 and 14 March 1980 using a similar observing set-up. The instrument and observing procedures have been described elsewhere[6].

Plates were obtained with the Crossley reflector on 19 May and 7 and 21 June 1980. The plate-filter combination, 103a-0 plus GG 13, corresponds approximately to the B bandpass. We also have a plate taken on 20 March with the Lick Observatory 20-inch astrograph for the proper motion program which recorded the double quasar by chance; this plate had roughly the same spectral response as the Crossley plates. Lacking the extension of a photoelectrically calibrated sequence of stars to magnitudes comparable with those of the quasar images, we present here only flux ratios. The ratios, given in Table 1, were determined from IRIS photometry of the plates. We extrapolated the slope of the IRIS photometry calibration to the brightness of the double quasar, which was ~2 mag fainter than our faintest calibrated star. Only a small additional error is introduced by this procedure when measuring ratios close to unity, and this is included in the errors quoted in Table 1. These ratios refer almost entirely to the continuum fluxes, because the only strong line included, C III] λ 1,909, has a small equivalent width compared with the total bandpass of the plate-filter combination. Also, these measures are only very slightly affected by the presence of the lens galaxy near component B. All measures used comparable IRIS openings corresponding to ~3 arc s diameter, thus including much of the galaxy light with the southern quasar image. This introduced a constant additional contribution, which, from the red magnitude given by Young *et al.*[4] and an approximate *K*-correction, we estimate to be ~3% of the image B flux; this small correction is not

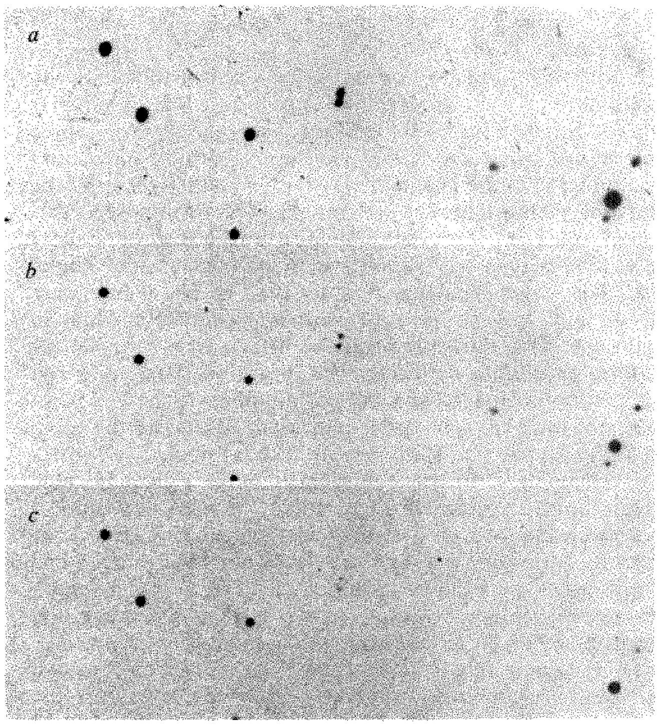

Fig. 1 Three photographs of the double quasar taken with the Lick Observatory Crossley reflector. *a*, 22 January 1915: the images are slightly comatic because the double was not centred on the original plate. *b*, 18 May 1980. *c*, 21 June 1980: this plate was underexposed because of poorer observing conditions, but shows B brighter than A. In all pictures north is at the top and east is at the left, so that image A is the upper of the double; the double is close to the centre of each of the three.

0028-0836/81/030153—03$01.00

Table 1 0957+561 A, B brightness ratios (B/A)

Date (UT)	Ratio
20 March 1980	0.84±.07
19 May 1980	0.95±.05
7 June 1980	1.15±.07
21 June 1980	1.09±.07

important for the results in Table 1 and has not been included. All exposures were well below the level at which saturation and growth of the galaxy image could affect the measured magnitudes. Figure 1 reproduces two of the 1980 Crossley plates. Observing conditions were less satisfactory on 7 June, resulting in a plate which reproduced poorly, but the images contain sufficient information to provide a reliable flux ratio.

Lick Observatory files contain Crossley plates taken in 1902, 1903 and 1915 which recorded the double quasar, with the plates centred on the galaxy NGC3079. Figure 1 reproduces the plate taken on 22 January 1915 which shows the brightness ratio of the double near that given previously[1,3,4]. The other archival Crossley plates exhibit a similar flux ratio for the pair, but preliminary analysis indicates that both images were systematically brighter in the past. A detailed analysis of the past history of the images on the archival plates is in progress and will be presented elsewhere.

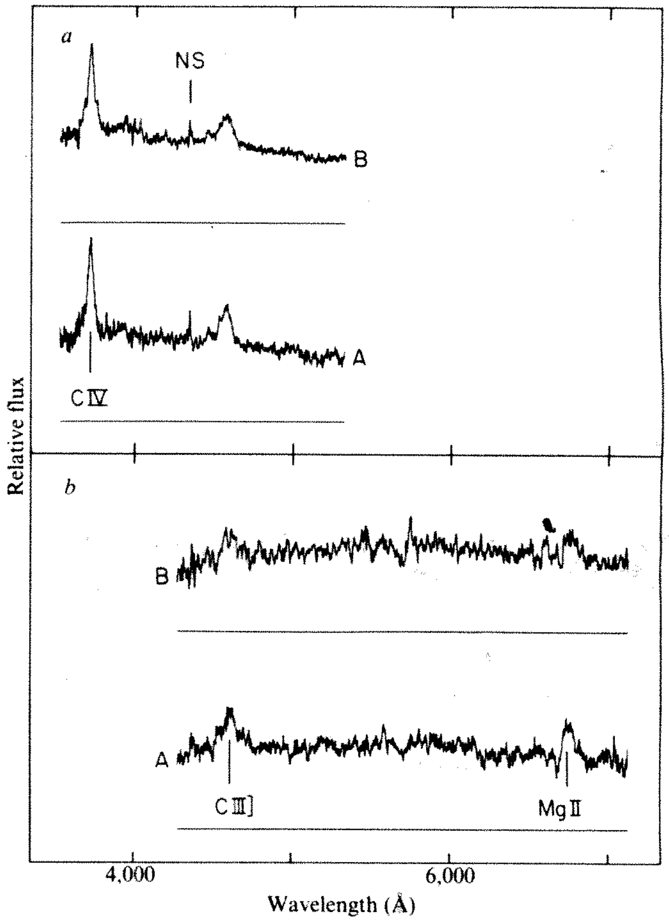

Fig. 2 Spectra of the double quasar. *a*, 12–14 March 1980; *b*, 9 June 1980. The total observing time for each of the March spectra was ~2.5 h, but observing time limitations allowed only 32 min for each in June, resulting in noisier spectra from the June data. A and B had very similar spectra in March, but in the June spectra the equivalent widths of the emission lines are smaller for B than for A. NS marks the position of a partially uncancelled strong night sky emission line.

Additional information on the variability is available in the spectrophotometry. Because we used a 2.8 arc s circular entrance aperture for both the March and June spectrographic observations to reduce the sky contribution and avoid contamination of the image being observed with light from the other image, the data are not reliable for absolute spectrophotometry. The March data show that image B was definitely fainter than image A and are consistent with the result of Young *et al.*[4] that A was ~0.3 mag brighter than B. The 9 June data indicate that the two images were approximately equal in brightness. The data obtained in March are suitable for measurements of the equivalent widths of the C IV λ1,549 and C III] λ1,909 emission lines. We did not observe the UV spectrum on 9 June but can derive equivalent widths for the C III] and Mg II λ2,800 emission lines from those data. The spectra are shown in Fig. 2, and the equivalent widths are given in Table 2. To produce an internally consistent set of equivalent widths for a given line, we used an identical wavelength interval to define the extent of the line profile on all of the individual spectra. Each spectrum is actually derived from two independent spectra. The spectrograph has two entrance apertures, and an object under observation is switched between them, ultimately spending equal time in both. The data from the two apertures are reduced separately. Comparisons of the equivalent widths determined from the independent spectra and similar data for other objects indicate that the errors in the equivalent widths are unlikely to exceed 5Å. Although we include values from earlier workers, we have not compared their values with ours because of the possibility of systematic differences between groups in methods of evaluating equivalent widths in data of only moderate signal-to-noise ratio. In our March data, the equivalent widths of C IV and C III] in images A and B agreed to within the measuring errors, as the earlier workers found. However, the June data show a marked change, as C III] and Mg II have significantly smaller equivalent widths in B than they do in A. Also, for both objects, the June equivalent widths of C III] differ from those measured from the March data, though the change for image A is only of marginal significance given the estimated errors. A simple interpretation of these data is that between March and June, the continuum of A faded slightly, the continuum of B brightened substantially, and all emission lines remained constant in flux. This spectroscopically motivated conclusion is in complete accord with the photographic photometry mentioned above. Because no change in the properties of the gravitational lens would be expected to produce changes in the equivalent widths of various lines, we conclude that 0957+561 is an intrinsically variable quasar, and the spectral differences between the two images in June result from different light-travel times for the rays responsible for each image. Other studies of variable QSOs (see for example, refs 7, 8) indicate that, at least on short time scales (≤1–10 yr), only continua have been observed to vary while line fluxes remained

Table 2 Equivalent widths (Å) in the observed frame

	0957+561 A			0957+561 B		
	C IV λ1,549	C III] λ1,909	Mg II λ2,800	C IV λ1,549	C III] λ1,909	Mg II λ2,800
12, 13 March	60	47	—	55	48	—
9 June	—	58	41	—	32	28
WCW[1]	68	54	28:	70	55	Present
WW[3]	—	58	61	—	58	62
Young *et al.*[4]	77	62	58	74	58	45

constant. Furthermore, the ratio of equivalent widths derived from the June data of C III] for the two images is different in size from that of Mg II, but this difference is consistent with a considerably greater galaxy contribution to the continuum of B in the spectral region of Mg II than in the region of C III], as was pointed out by Young *et al.*[4]

The double quasar 0957+561 A, B is, therefore, variable in both brightness and spectrum. The light variations were accompanied by corresponding changes in the equivalent widths of emission lines, and we conclude that the quasar is an intrinsic variable with behaviour similar to that observed in other variable quasars. Establishing a value for a constant time-difference between variations of the two images would not only confirm the gravitational lens hypothesis, but would add an additional parameter to models for the lens. As Young *et al.*[4] have pointed out, it is not even clear which image is formed by the path of shortest light-travel time.

We thank G. D. Schmidt for assistance in the observations. This research was supported in part by NSF grant AST 76-20843. This is Lick Observatory Bulletin no. 824.

Periodic comet Tempel-2, first discovered in 1873, is a possible target of a spacecraft flyby in the 1980s. Accurate physical measurements of this comet have only recently been attempted. Few spectrophotometric data exist for any faint comet, but we present here such data for Tempel-2 at a heliocentric distance of 2.97 AU. The data were obtained during an outburst in which the comet exhibited heightened CN and C_3 emission over a quiescent phase. Comet flares of such magnitude are exceptional, and are particularly surprising for a periodic comet at such a large heliocentric distance.

We observed Tempel-2 on 22.2 December 1978 UT using the Oke multichannel spectrometer[1] and 200-inch telescope. Fluxes of the comet and the sky 40 arc-s away were measured simultaneously in 30 channels in the wavelength range 3,200–10,500 Å. The bandwidth was 160Å below 5,720 Å and 360 Å above (in rectangular bandpasses). All measurements were made using a 14-arc s aperture. The air mass of the comet was 1.1 during the observations.

Tempel-2 was post-perihelion at a heliocentric distance of 2.97 AU with a phase angle of 8.61° and a magnitude at 5,600 Å of ~18.5. Identification at the telescope was confirmed by motion of the comet on the television monitor with the expected rate and direction. No coma was evident on the monitor, but the seeing was poor.

The sky background was removed by differencing the count rates in the spectrometer apertures on the comet and the sky. The relative sensitivity of the apertures was determined by observing the same object in each aperture. The spectral reflectance was obtained by taking the ratio, in each channel, of the flux due to the comet and that of HD28992, a G1V star in the Hyades observed at nearly the same air mass. (A Hyades star was chosen because it would be expected to have a nearly solar metal abundance and thus provide the closest possible spectral match to the Sun.)

The accuracy of this method was confirmed by applying it to measurements of the bright asteroid 14 Irene. An excellent match with the data of Chapman and Gaffey[2] was obtained within the confidence limits of their data (±3%). The spectral reflectance data for the comet are listed in Table 1 and plotted in Fig. 1, including channels from 3,480 Å to 8,160 Å. Channels at longer and shorter wavelengths are very noisy and are not shown.

Comparison of our data with the photometry of other observers (ref. 3 and R. L. Millis, personal communication) shows that our observations were made during an outburst in which the continuum brightness of this comet temporarily increased by about one visual magnitude. This suggests that the reflectance spectrum is produced principally by scattering of sunlight off particles around the nucleus and is not diagnostic of the nucleus itself. An additional outburst of ~1.5 mag was observed by Zellner *et al.*[4] a month later with broadband photometry. Although one flare[5] of Tempel-2 was reported during its 1946 apparition, to our knowledge these are the first confirmed outbursts of Tempel-2.

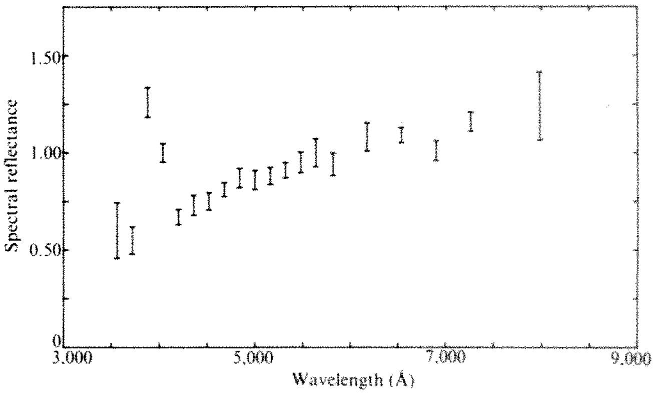

Fig. 1 The spectral reflectance of Tempel-2, normalized to unity at 5,640 Å. These measurements were made on 22.2 December 1978 UT when the comet was post-perihelion at a heliocentric distance of 2.97 AU. The data are indicated with ± 1σ confidence intervals.

The occurrence of a series of outbursts at such a large heliocentric distance is surprising. Only one other short-period comet, Schwassman–Wachmann 1 (the heliocentric distance of which varies between 5.5 and 7.3 AU), has been reported to exhibit high-amplitude outbursts at heliocentric distances ≳3 AU. Note that Schwassman–Wachmann 1 is not a typical short-period comet for several reasons[6]. First, this comet undergoes frequent non-periodic variations in its brightness by a factor of 100. Second, there has been no confirmed measurement of molecular emission from Schwassman–Wachmann 1 other than a weak CO^+ feature[7,8]. Observations of a 1–2 mag flare in any comet are quite rare, even near perihelion where such effects would be expected to be observed most readily, due to both the increased brightness and expected increase in activity of comets at perihelion. Richter[9] has looked for anomalous outbursts of every comet observed photometrically between 1880 and 1947. Of these 358 comets, only 12 had observed flare-ups in total light of a magnitude comparable with that which we measured for Tempel-2 (~1 mag).

With the measured spectral reflectance of Tempel-2, we can estimate the abundance of gas and dust in the coma and the albedo of the dust. The emission bands in the channels at 3,880 Å and 4,040 Å are due to the $\Delta\nu = 0$ band of CN at 3,883 Å and the 4,050 Å C_3 group and permit a determination of the CN and C_3 production rates. The CN flux is taken to be the excess flux, in the channel centred at 3,880 Å, above the continuum represented by a linear interpolation between the spectral reflectances in the adjacent channels at 3,720 Å and 4,200 Å. Using the flux (J. B. Oke, personal communication) of the standard star HD84937, we find that this excess represents a flux in the CN band of 8.8×10^{-18} W m^{-2}. This flux is next converted to a number abundance of CN molecules using the relation between the flux per unit column-number density and the heliocentric Doppler velocity as reported by Tatum and Gillespie[10]. For the geocentric distance of 2.062 AU and an $\dot{r}$ of 9.8 km s^{-1}, the CN abundance in the field of view is 1.6×10^{27} molecules.

In the Haser model[11,12], observed molecular column densities in the steady state case can be related to production rates by

$$D(R) = C[\exp(-R/l_d) - \exp(-R/l_p)]/R^2 \qquad (1)$$

where $D(R)$ is the number density of a given molecule at a distance R from the nucleus, l_p is the scale length for the decomposition of the parent molecule, l_d is the scale length for the destruction of the observed species, and C is a constant of proportionality. Using the scale lengths given for CN by Delsemme[13] and the CN abundance derived above, we find a production rate of 5×10^{23} CN molecules s^{-1}. It is ~100 times greater than the upper limit of 6×10^{21} CN molecules s^{-1} found by Spinrad *et al.*[3] during a post-perihelion quiescent phase two months earlier at a heliocentric distance of 2.66 AU. Similarly we find a C_3 production rate[12] of ~10^{24} C_3 molecules s^{-1}. Note that although the region of sampled sky was less than l_d from the comet nucleus, the R^2 term in equation (1) limits the amount of emission to be expected in the sky channel to ≤10% of the emission in the object aperture, if the Haser model is applicable.

Table 1 Spectral reflectance of Tempel-2

Wavelength (Å)	Bandwidth (Å)	Normalized reflectance
3,560	160	0.60
3,720	160	0.55
3,880	160	1.26
4,040	160	1.00
4,200	160	0.67

* Unreliable channel.

Next we investigate the role of dust in contributing to the brightness of the comet through reflection. Following Spinrad *et al.*[3] we assume a CN/H_2O number ratio of 1 : 200 and a dust/gas mass ratio near unity. We then have a dust production rate of 3,000 g s^{-1}. Delsemme and Miller[14] derive a relationship between the total gas vaporization rate of a comet and its dust expansion velocity. Arbitrarily assuming dust expansion in a 60° cone, one finds a dust expansion velocity ~10 m s^{-1} (ref. 3). With a dust particle size distribution characterized by a geometric cross-section of 3.17×10^{-7} km^2 g^{-1} (ref. 15) and the dust production rate given above, we derive a total cross-section of 1.6×10^3 km^2 for the dust situated within the projected boundary of our aperture.

Finally, we can estimate the albedo of the dust by assuming that all the continuum flux is produced by scattering of sunlight off of the dust. Using the cross-section obtained above and a nominal phase coefficient of 0.03 mag deg^{-1} (ref. 3), a geometric albedo of ~6×10^{-4} would be required at 5,600 Å. This contrasts with the geometric albedo of 0.10–0.15 suggested by Spinrad *et al.*[3] for the nucleus. The albedo we derive is actually a lower limit. Assuming a 'burst' model, where all of the molecules and dust contributing to the comet brightness are located inside the projected object aperture, the CN abundance, as before, is 1.6×10^{27} molecules. Again assuming a CN/H_2O number ratio of 1 : 200 and a dust/gas mass ratio near unity, we find 9.2×10^6 g, or 2.9 km^2, of dust within the field of view. This leads us to a geometric albedo ~0.3, in closer agreement to the value obtained by Spinrad *et al.*, and nearer to what one would expect for ice grains.

The burst model requires that the time, t, elapsed since the outburst of matter from the nucleus is less than r/v, where r is the maximum radial distance from the nucleus still within the aperture and v is the thermal velocity of the parent molecule of CN. With a v of 0.71 km s^{-1} (ref. 16) and an r of 1.05×10^4 km, we find that $t \leq 10^4$ s. Since the albedo of 0.3 derived from this model certainly seems to agree within a factor of 10 with what one would expect, these results suggest that this observed outburst of Tempel-2 was of relatively short duration, ≤ 1 day. Such rapid outbursts have in fact been observed in Schwassman–Wachmann 1 and seem to occur in the other comets which have exhibited large brightness fluctuations[9].

The present results suggest rapid variability of Tempel-2. More quantitative results on faint comets are hampered by the extreme paucity of data. In particular, more spectrophotometry of faint comets is needed to constrain comet modelling.

We thank Dr R. L. Newburn Jr for supporting this research (via JPL contract BT-708801) and Professor B. Zellner, Professor E. Barker and Dr J. Degewij for helpful discussions. We thank the staff of Hale Observatories for observing time and help with measurements. This work was supported by NASA under contracts NAS7-100 and NGR 49-002-142. Stability of zeolites under electron irradiation and imaging of heavy cations in silicates

L. A. Bursill*, J. M. Thomas‡ & K. J. Rao†

Department of Physical Chemistry, University of Cambridge,
Lensfield Road, Cambridge CB2 1EP, UK

The aluminosilicate framework of synthetic 'zeolites' of type A (Na^+-form) and ZSM-5, as well as the Na^+-forms of faujasite (Fig. 1) in their so-called X- and Y-variants (fuller structural descriptions are given in refs 1 and 2) have recently been imaged at near-atomic scale by high-resolution electron microscopy (HREM)[3–5]. However, the as-prepared synthetic and naturally occurring zeolites, all of which contain alkali metal and alkaline-earth exhangeable cations and much constitutional, intracrystallite water, are converted within minutes into an amorphous state on examination in an electron beam of the intensity required to yield high-resolution images. The specimen has to withstand 10^6 electrons $Å^{-2}$ bombardment within a few minutes. To extract further information from HREM about the local atomic structure, and, in particular, to identify the siting of the various cations that may be accomodated in these catalytically important and shape-selective materials, methods have to be developed which retain the structural integrity of the zeolite for a reasonable time under electron irradiation *in vacuo*. It has been shown[3] that dehydration of the zeolite before observation significantly increases its lifetime in an electron beam. Here we show that the commercially important[4] zeolite-Y may be chemically stabilized against electron irradiation damage by the simple expedient of incorporating uranyl (UO_2^{2+}) ions into the structure beforehand. Beam sensitivities are decreased by factors of 10–100 in this way, but appropriate heat-treatment of the UO_2-exchanged zeolite is required to achieve this stability and hence to locate these heavy cations.

For the present study the UO_2^{2+} ion has two advantages. First, its propensity to form strong links with surrounding oxygen ligands: this along with the space-filling nature of this bulky ion should strengthen and rigidify the relatively fragile aluminosilicate framework of the zeolite. Second, the U atom ($Z = 92$) is a strong scatterer of electrons which should make it relatively easy to locate the centres of the linear UO_2^{2+} ions in high-resolution images.

Low-dose electron diffraction studies showed that straightforward cation-exchange of Na^+ by UO_2^{2+} in Na-Y and drying at ~90 °C does not significantly change the lifetime of the zeolite. Subsequent high-magnification imaging results in rather rapid amorphisation, as found previously for Na-A, -X and -Y. Simultaneously with this transformation to a zeolitic glass we observe (Fig. 2) growth of a thin surface film. Both the image, which was recorded for the optimum objective lens defocus condition ($\Delta f = -652$ Å) for a lens having spherical aberration coefficient $C_s = 1.2$ mm, and the corresponding optical transform (inset Fig. 2) show that interatomic spacings of 2.5–2.7 Å predominate. A survey of the various phases of uranium oxide and of uranium metal reveals that U–U separations, when projected normal to common low-index zone axes, should cluster around 3.5 Å for phases of the crystalline UO_3-type, around 2.2–3.3 Å for UO_2 and 2.5–2.9 Å for α-uranium metal. Clearly the surface film, the identity of which has not yet been fully characterized, shows a microcrystalline texture with short-range order extending over only 9–15 Å.

If, instead of the drying at ~90 °C, the UO_2^{2+}-exchanged zeolite is heated for extended periods *in vacuo* (typically 15 h at 410 °C), the beam resistance of the Y-zeolite is greatly enhanced. Thus the micrograph shown in Fig. 3 was obtained after the specimen had been subjected to at least 100 times the exposure previously required to amorphise Na–Y. The pseudo-hexagonal array of dark spots in Fig. 3*a* (spacings 17 and 16 Å) shows an essentially one-to-one correspondence with the positions of the 'decorated' super-cages in the [110] projection of zeolite-Y (that is faujasite—see Fig. 3*b*). Because the image was obtained using the condition of optimum objective lens defocus for structure imagining at ~5 Å resolution[6] we interpret the dark spots as representing the projected charge density of UO_2^{2+} ions occupying the zeolite cages.

This specimen, the IR spectrum[7,8] of which indicated that the UO_2^{2+} ions were still intact and that the OH frequencies were greatly reduced in intensity after heating to 410 °C, could be given short bursts of extremely high electron irradiation (by

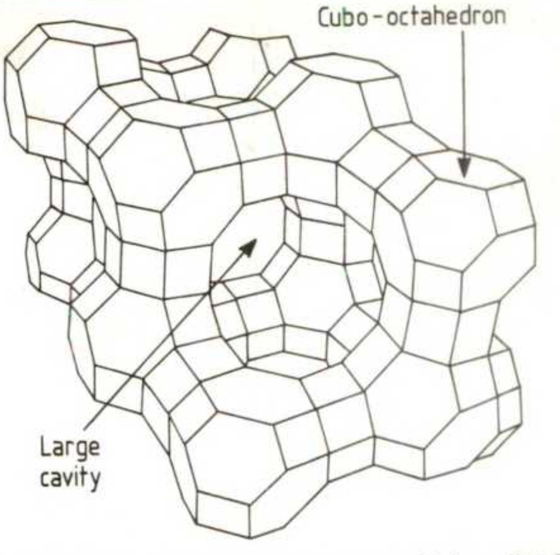

Fig. 1 Faujasite, the parent structure on which zeolites-X and -Y are based (Si:Al ratios differ in X and Y and they differ also from the ratio of 2.48 in idealized faujasite).

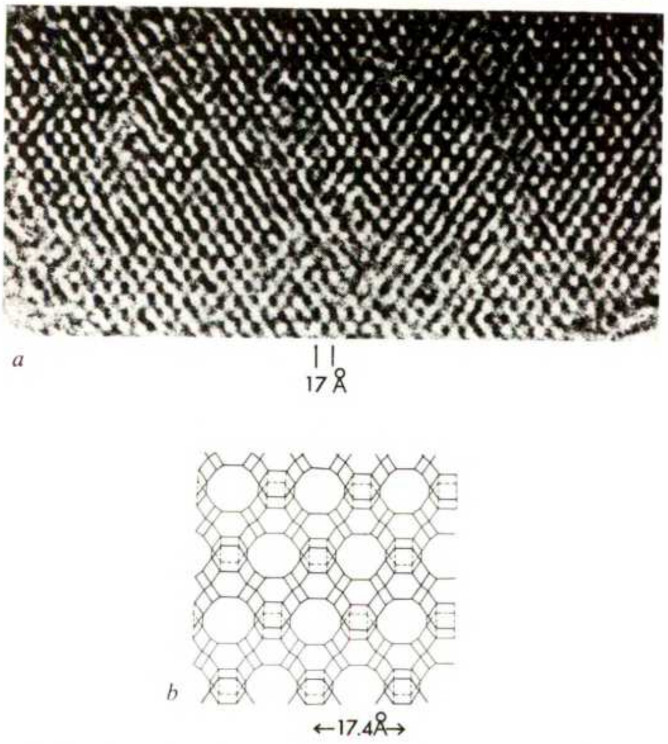

Fig. 3 *a*, High-resolution image along [110] showing location of uranyl ions inside a dehydrated uranyl-exchanged zeolite-Y. This crystal survived a dose of ≈100 times that experienced by the specimen shown in Fig. 2. *b*, Schematized projection, along [110], of faujasite (zeolite-Y) showing that the large cavities are 17.4 and 15.1 Å apart. The dark spots in *a* are, therefore, identified as the cavities decorated with UO_2^{2+} ions (see text).

removing condenser apertures and focusing the illumination) without any apparent change in structural integrity. Excessive beam currents did, however, lead to the growth of electron-opaque spherical crystallites (~300 Å diameter) within a matrix of amorphized zeolite. This confirms that the Y-zeolite contained, as suggested by Fig. 3*a*, an initially homogeneous distribution of incorporated UO_2^{2+} ions. The mobility of the specimen, when subjected to excessive beam currents, suggests that the temperatures reach well beyond 1,000 °C.

Although the precise environment of the UO_2^{2+} ion after high-temperature treatment (410 °C) and hence the detailed reasons for the enhanced beam stability are not yet fully identified, it is plausible to suppose that residual water has a key role (see also ref. 1). If water molecules are present in appreciable quantities (either as hydration shells or bound to cage walls) a ready mechanism exists for the exsolution of the UO_2^{2+} ions. Thus, at ~90 °C, the substitution of $2H_3O^+$ for UO_2^{2+} would be possible. At 410 °C, as the IR results reveal, this substitution cannot occur: the UO_2^{2+} ions are firmly chemically bound to, and thereby strengthen, the aluminosilicate framework.

The possibility of using UO_2^{2+} ions to decorate or label cages, cavities, tunnels and interlamellar spaces in other crystalline or non-crystalline aluminosilicates, as well as of charting the connectivity of the voids in, and the diffusion of heavy ions through, such materials is being investigated.

There is considerable technological interest in the stability and environment adopted by uranium in various host matrices. This stems from the need to sequester actinide waste products effectively in environments that prevent migration of the radioactive ions into the biosphere. During this work, we have incidentallly discovered that both uranium glasses and uranyl ions embedded in 'dehydrated' zeolites are remarkably stable to quite intense 200 keV electron bombardment.

We thank the SRC, and the University of Melbourne for support, and Drs S. Vasudevan, G. R. Millward and D. A. Jefferson for cooperation.

Photochemical cleavage of water by photocatalysis

Enrico Borgarello*, John Kiwi*, Ezio Pelizzetti†, Mario Visca‡ & Michael Grätzel*

A bifunctional redox catalyst, composed of Pt and RuO_2 co-deposited on a colloidal TiO_2 carrier, is a highly potent mediator for water decomposition by visible light[1]. The system contains apart from the sensitizer ($Ru(bipy)_3^{2+}$) an electron relay—methylviologen. The latter is reduced on light excitation, and the photoreaction is coupled with catalytic steps[2] generating H_2 and O_2 from water. To rationalize the surprisingly high efficiency of this photoredox system, we proposed a mechanism involving species adsorbed at the TiO_2 surface. This led us to explore sensitizers which through suitable functionalization show an enhanced affinity for adsorption at the particle–water interface. We describe here the performance of electron relay-free systems capable of efficiently decomposing water into H_2 and O_2 under visible light illumination. A bifunctional redox catalyst composed of RuO_2 and Pt co-supported on colloidal TiO_2 particles is used. The only other component present is a sensitizer. Amphiphilic surfactant derivatives of $Ru(bipy)_3^{2+}$ exhibit extremely high activity in promoting the water cleavage process. Adsorption of the sensitizer at the TiO_2 particle–water interface and electron ejection into the TiO_2 conduction band are evoked to explain the observations. Exposure to UV radiation leads to efficient water cleavage in the absence of sensitizer.

The successful operation of this device depends on the proper preparation of the catalyst. In our experiments 100 mg of H_2PtCl_6 was added to 250 ml of water and stirred for 30 min without heating. 85 ml of a 1% sodium citrate solution was added and the mixture refluxed for several hours until the colour changed from yellow to brown. At this time the characteristic absorption of $PtCl_6^{2-}$ has disappeared, the spectral features in the visible and UV being typical of those of an ultrafine Pt sol[3]. The absorbance at 450 nm is 0.55 (pathlength 1 cm). After cooling, the solution was stirred with Amberlite MB 3 exchange resin to remove excess citrate until the conductivity decreased below 5 μs cm^{-1}. The solution was filtered through a 0.45 μm Millipore filter and a clear liquid was obtained with an absorbance of 0.50 at 450 nm. 12 mg of TiO_2 was added to 12 ml of this solution and exposed for several minutes to ultrasound in a water bath.

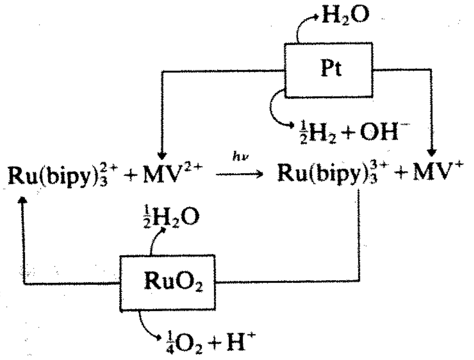
The TiO_2 particles have an anatase structure and were prepared from $TiOSO_4$ by acid hydrolysis. The surface area is 200–240 m^2 per g and the hydrodynamic radius of the particles 470 Å. They are also doped by 0.1% RuO_2 and by 0.4% Nb_2O_5.

Illuminations were carried out with an XBO-450 W Xe lamp fitted with a water jacket to remove IR irradiation. The gas produced was analysed by gas chromatography. A Gow Mac system, carbosieve column (35 °C) and Ar (for H_2) or He (for O_2) carrier gas was used. The volume of the solution was invariably 24 ml and contained 500 mg l^{-1} TiO_2 as well as 40 mg l^{-1} Pt; it was contained in a Pyrex flask fitted with a septum. The solution was deaerated before illumination by flushing with Ar or He.

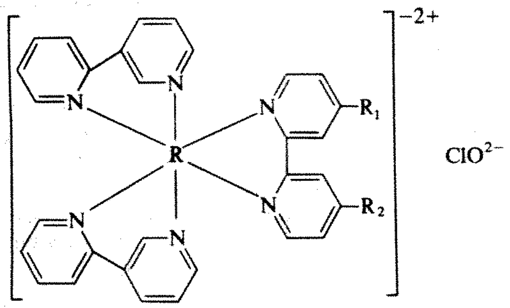
0028–0836/81/030158—03$01.00

The colloidal $Pt/TiO_2/RuO_2$ particles were first irradiated without the sensitizer. If no cutoff filter is used to remove UV irradiation (in this case transmission is restricted by the Pyrex flask) production of H_2 and O_2 is observed through direct band gap excitation of the semiconductor particles. After 10 h exposure to light 3.4 ml of H_2 was evolved. Oxygen was formed in stoichiometric proportions. Stirring of the solution in the dark for 10–20 h results in H_2/O_2 recombination. This reaction can be avoided by removing the gas mixture after photolysis with a stream of N_2. On renewed exposure to light, the water splitting continues at the initial rate, 0.34 ml H_2 h^{-1}. This cycle can be repeated many times. H_2 and O_2 generation is completely suppressed if a 400-nm cutoff filter is placed in the light beam. These results show that the particles can split water into hydrogen and oxygen after band gap excitation. The yields are surprisingly high showing efficient electron–hole separation. Water splitting on TiO_2 and $SrTiO_3$ powders has been observed before[4–9], but with much lower efficiency.

The $Pt/TiO_2/RuO_2$ particles can also be used as catalysts for water splitting by visible light in the presence of a suitable sensitizer and methylviologen as an electron relay[1],



The present study shows that this system can be made operative even in the absence of the electron relay. The sensitizers used were ruthenium trisbipyridyl complexes of the structure:



where

$R_1 = R_2 = H$: $Ru(bipy)_3^{2+}$
$R_1 = R_2 = n$-hexadecyl: $Ru(bipy)_3^{2+} \cdot 2C_{16}$
$R_1 = CH_3$, $R_2 = n$-octadecyl: $Ru(bipy)_3^{2+} \cdot C_{18}$
$R_1 = CH_3$, $R_2 = n$-doceyl: $Ru(bipy)_3^{2+} \cdot C_{12}$

Data from visible light illumination of solutions containing the sensitizer and the bifunctional redox catalyst are displayed in Fig. 1. The amount of hydrogen generated is compared for the four different sensitizers. Oxygen remained in stochiometric ratio to the H_2 produced. These solutions contained no buffer and were adjusted to a pH of 4.5 by addition of HCl. No pH changes could be detected even after prolonged irradiation. In Fig. 1 the lowest H_2 production rate is observed with the simple $Ru(bipy)_3^{2+}$ complex. Introduction of a long alkyl chain leads to a drastic improvement in the H_2 yields. Of the surfactant derivatives available[10], the mono C-12 substituted complex exhibits optimal efficiency. After a short induction period, the H_2 generation rate was established at 1.5 ml h^{-1}. In view of the small concentration of sensitizer ($\sim 5 \times 10^{-5}$ M), this rate is surprisingly high. At this concentration, light absorption is incomplete even at λ_{max} of the sensitizer. As the solutions are slightly turbid scattering of light cannot be neglected making the determination of quantum yield difficult. However, from a comparison with a non-regenerating H_2-producing system[11] ($\phi(H_2) = 0.13$) used in identical conditions, the quantum yield of the H_2 production with the C-12 substituted Ru-complex is derived as ~5%. This may be further improved by optimization of the sensitizer, catalyst and pH condition.

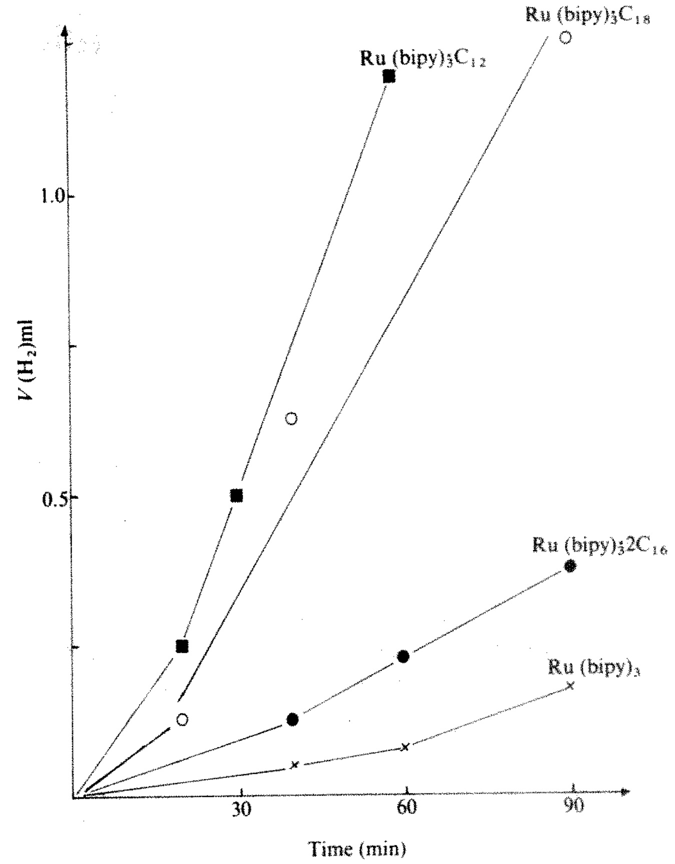


Fig. 1 Hydrogen yields from visible light (>400 nm) photolysis of solutions containing 500 mg per l TiO_2/RuO_2 (0.1%) doped with 40 mg per l Pt, $pH = 4.5$ adjusted with HCl. Sensitizer concentration:

$Ru(bipy)_3^{2+} = 2 \times 10^{-4}$ M;

$$\left.\begin{array}{l} Ru(bipy)_3^{2+} \cdot 2C_{16} \\ Ru(bipy)_3^{2+} \cdot C_{18} \end{array}\right\} = 7 \times 10^{-5}\ M;$$

$Ru(bipy)_3^{2+} \cdot C_{12} = 5 \times 10^{-5}$ M.

The H_2 production rate does not decrease even after 50 h of irradiation time, the turnover for the Ru complex being >1,000.

These observations may be rationalized in terms of the scheme shown in Fig. 2. The effect of functionalization of the $Ru(bipy)_3^{2+}$ on the H_2 yields confirms that the photoredox processes involve adsorbed species. Excitation of the sensitizer is followed by charge injection into the conduction band of TiO_2. The electron is readily channelled to Pt sites where H_2 evolution occurs. A small Schottky potential barrier at the Pt/TiO_2 junction may assist the electron movement. The back conversion of oxidized sensitizer into its original form is coupled to oxygen formation through RuO_2 which is an excellent electrocatalyst for water oxidation.

The effects observed when the TiO_2 particles are directly excited by band gap irradiation have been well understood since Honda's[12] work on the cleavage of water by UV-ray irradiation of TiO_2 macroelectrodes. The surprisingly high quantum yields of the UV process show that electron–hole separation in the particles is efficient and probably assisted by local fields.

Cleavage of water is possible by four quanta of visible light in an electron relay-free system containing simply a sensitizer and colloidal redox catalyst. A key to achieve high efficiencies is the

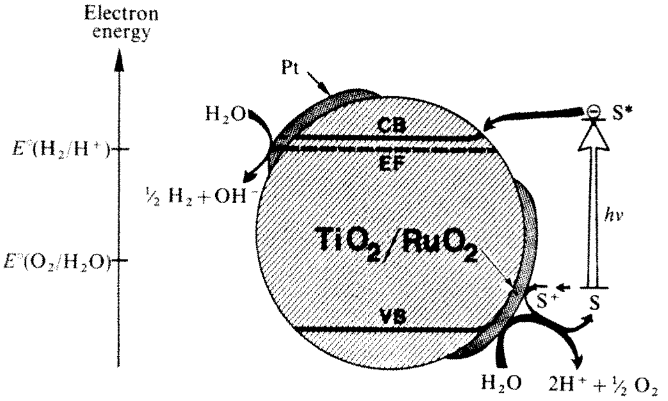

Fig. 2 Processes involved in the photodecomposition of water.

use of surfactant redox chromophores[13–15] which are adsorbed at the surface of the catalytic particles. The water cleavage on such functional microspheres can thus occur without participation of diffusional processes. These results should encourage research into photochemical conversion of solar energy[16–20].

We thank Sir George Porter for discussions on electron relay-free systems and Dr W. F. Sasse for samples of the surfactant ruthenium complexes. This work was supported by the Swiss NSF, Engelhard Industries, and CIBA-GEIGY, Basel.

Crustal influence in the generation of continental flood basalts

R. W. Carlson*, G. W. Lugmair & J. D. Macdougall

Scripps Institution of Oceanography A-020, University of California, San Diego, La Jolla, California 92093

The suggestion that primordial undifferentiated material may exist in the Earth's mantle has recently been revived on the strength of Nd isotope data for two types of young continental rocks—flood basalts[1] and kimberlites[2]. The limited published data show a clustering of Nd isotopic compositions close to those for meteorites with chondritic relative rare-earth (REE) abundance. In contrast, we now present data for samples from the Columbia flood basalt province of the northwestern United States which show large isotopic variability suggestive of mixing processes acting after the separation of the primary magmas from their mantle source.

The Columbia province contains ~200,000 km^3 of predominantly basaltic rocks which were fed from fissure eruptions 6–17 Myr ago[3]. The province is in the volcanically and tectonically active Pacific north-west of the US, to the east of the present locus of Cascade andesitic arc volcanism. This area is the most extensively studied of the major flood basalt provinces[3–5]. Five main stratigraphic units in the basalts have been identified and in rough stratigraphic order, are named: Imnaha, Picture Gorge, Grande Ronde, Wanapum and Saddle Mountains. The field relations and major element composition of these units are detailed elsewhere[3].

We have analysed the Nd and Sr isotopic composition of samples from each of the stratigraphic units, and from a series of unclassified Columbia basalts of variable composition which overlie the Grande Ronde in northeastern Oregon[6] and also mafic lavas from various localities in northern California. Collection localities and major and trace element composition of these samples are given elsewhere[7]. The Sr data measured here augment studies[5] of the Columbia region, and demonstrate how combined Nd and Sr isotopic analysis aids the understanding of the origin of complex chemical and isotopic variations found in these lavas.

Isotopic results are shown in Fig. 1. Analytical techniques have been described elsewhere[7,8]. All Nd data are fractionation corrected to ^{148}NdO/^{144}NdO = 0.242436 (corresponding to ^{146}Nd/^{144}Nd = 0.7219). Sr values are fractionation corrected to ^{86}Sr/^{88}Sr = 0.1194 and are reported relative to a value of ^{87}Sr/^{86}Sr = 0.71014 for NBS 987 Sr.

Figure 1 shows the large isotopic variability within the basalts of the Columbia group. Particularly important is the good correlation between Nd and Sr isotopic variation. Note the general correlation between isotopic composition and stratigraphic position as the variability extends in the order, Picture Gorge ($\varepsilon_{JUV} = +7.7$ to $+7.4$), Imnaha (7.8 to 5.9), Grande Ronde (+4.0 to +0.3), Wanapum (+1.2 to +0.6) and Saddle Mountains (−3.6 to −10.8). In particular, the basalts of the Grande Ronde group, which represent the largest volume of the Columbia sequence, exhibit ε_{JUV} values ranging from +4.0 to +0.3, which correlates roughly with stratigraphic position within this group. The volume weighted average Nd isotopic composition is thus resolvably displaced to values of $\varepsilon_{JUV} > 0$. However, the high degree of correlation of Nd and Sr isotopic variations suggests that this range may be the result of mixing between at least two components: primary magma with $\varepsilon_{JUV} \geq 8$, ^{87}Sr/^{86}Sr ≤ 0.7033, and a source of negative ε_{JUV} and high ^{87}Sr/^{86}Sr. At least two sources of negative ε_{JUV} and high ^{87}Sr/^{86}Sr can be proposed: (1) old, metasomatically enriched, mantle[9,10]; (2) materials derived from the continental crust underlying the province. Verification of the former possibility is hindered by the lack of knowledge of the degree and time scales over which heterogeneities are formed and maintained in the mantle. Similar Nd and Sr covariation, to that displayed in Fig. 1, have been reported for volcanic rocks from Patagonia[11] and Italy[12]. In the latter case, the co-variation was interpreted to be the result of mantle heterogeneity rather than crustal contamination primarily due to a positive correlation between Sr concentration and ^{87}Sr/^{86}Sr in these lavas. This argument cannot be applied to the Columbia basalts because they exhibit, in general, poor correlations between Sr and ^{87}Sr/^{86}Sr. In the only group that shows good Sr versus ^{87}Sr covariation, the Saddle Mountains group, Sr concentration decreases with increasing ^{87}Sr/^{86}Sr. Support for a chemically and isotopically heterogeneous source for the Columbia lavas comes from the fact that major and trace element compositions of these lavas cannot be simply related by mixing between two end-member components[4,5]. For example, the Saddle Mountains group contains members which are relatively primitive chemically, and others which are highly fractionated, although these all have $\varepsilon_{JUV} \leq -3.6$ and ^{87}Sr/^{86}Sr ≥ 0.7075. However, considering the complexity of magma storage and transport in the upper mantle and crust, it is possible to construct a model which explains much of the elemental and isotopic diversity found for the Columbia lavas, assuming that they were all generated from a single homogeneous source.

The inset to Fig. 1 includes Nd and Sr isotopic data for a xenolith recovered from a flow of the Wanapum group. This xenolith was ~3 cm in diameter and consisted primarily of quartz with minor cristobalite. Its major element composition

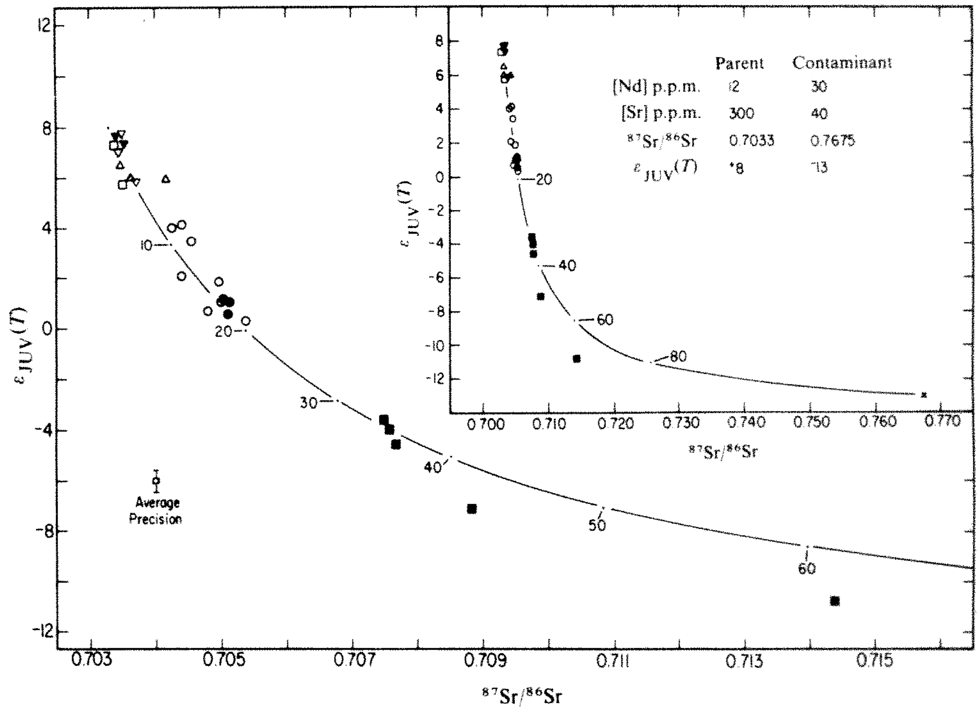

Fig. 1 Nd–Sr isotopic variation of Columbia River and some northern California basalts. Data for a metasedimentary crustal xenolith are included in the inset (×). The line is a calculated mixing curve between end-member compositions given in the inset. Numbers on the curve are the percentage of 'contaminant' in the mixture. The deviation from the curve of the two points with large negative ε_{JUV} suggests that these two basalts may have assimilated material with lower $^{143}Nd/^{144}Nd$ and/or $^{87}Sr/^{86}Sr$ than measured for the xenolith. All data have been corrected for isotopic evolution since the time of eruption. ▼, Picture Gorge; ▽, Imnaha; ○, Grande Ronde; ●, Wanapum; ■, Saddle Mountains; □, NE Oregon; △, North California. ε_{JUV} is the relative difference of the samples $^{143}Nd/^{144}Nd$ (in parts per 10,000) from that measured for the eucrite Juvinas ($^{143}Nd/^{144}Nd = 0.512636$).

and texture suggest a metasedimentary crustal protolith. This xenolith has very high $^{87}Sr/^{86}Sr$ (0.768) and negative ε_{JUV}. Sm–Nd and Rb–Sr model ages for the xenolith, calculated in the T_{ICE} manner[8], are 1,320 and 1,420 Myr, respectively. The near agreement of these two ages suggests both that little Rb–Sr or Sm–Nd fractionation occurred during the entrapment of the xenolith in the lava, and that this may represent the formation age of the protolith material. If true, this xenolith may be the first identified example of a Precambrian crustal section existing beneath the Columbia Plateau.

While both the major element and oxygen isotopic composition of this particular xenolith argue against its being the specific crustal end member involved, it can be used to illustrate what effect assimilation of crustal materials would have on the Sr and Nd isotopic composition of the Columbia lavas. For example, Fig. 1 shows a calculated mixing curve between end-member compositions given in the inset. The 'parent' end member has the composition of the primitive lavas of the Picture Gorge sequence. The 'contaminant', with identical Nd and Sr isotopic composition and Sr concentration as the measured xenolith, requires an ~78% higher Nd concentration than found for the xenolith to give the curve in Fig. 1. The calculated curve lies within analytical uncertainty of all but two basalt data points. Similar mixing calculations using a crustal end member with less radiogenic Nd and Sr isotopic composition and a higher Sr/Nd would produce a mixing curve with less inflection than that shown and hence provide a better fit to the basalt data. Although the exact crustal end member is not defined by present data, the coherence of the basalt Nd and Sr isotopic data about a single curve strongly suggests that mixing between primary magma and materials derived from the continental crust played a major part in controlling the isotopic variability of the lavas.

Using the end-member compositions given in Fig. 1, magmas of the Grande Ronde group may have assimilated between 10 and 20% of their Sr and Nd contents from the continental crust. Considerations of the thermal effects of basalt intrusion into the continental crust[13] also suggest that "basalt sheets at 10 km depth, for example, can develop partially molten zones of country rock equal to 10–20% of their own thickness". This implies that the ε_{JUV} values which approach zero for the largest volume of the Columbia group, the Grande Ronde, may reflect a most probable mass balance between primary magma and assimilated crust due to the degree of heat transfer possible from the Grande Ronde lavas to the crust. This hypothesis could also be extrapolated to the other occurrences of continental flood basalts, but is, of course, subject to the elemental and isotopic composition of the crustal end member which may have been involved in each province.

Although the Nd and Sr isotopic variation of the Columbia lavas can be explained by mixing between two components, major and trace elements do not show good co-variation among the groups defined by the isotopic data. However, when controlled by mixing, the resultant isotopic composition of the mixture is determined only by the mass fractions of the various components. This is not necessarily true for the major and trace element composition of the mixture. If processes such as fractional crystallization and various degrees of mixing between highly fractionated magmas and newly injected, rather primitive, magmas occurred simultaneously with crustal assimilation, major and trace element composition of the resulting magmas would be controlled largely by these processes rather than assimilative mixing. Furthermore, the passage of these lavas through the crust may have had a considerable effect on the chemical composition of the residual materials left behind in the crust. In a volcanic province where eruption occurred at a rather rapid rate over a considerable span of time (11 Myr for Columbia[3]) magmas might be expected to accumulate preferentially and be transported in paths and storage reservoirs created by previous magma batches. Therefore, later magmas would not encounter the original 'sialic' crust but would have to interact with the more mafic material left behind by previous magma batches. This could account for the very high Fe and Ti and relatively low Si concentrations of the Wanapum group compared with the lavas of the Grande Ronde sequence, although these two groups have overlapping ranges in Nd and Sr isotopic composition.

A qualitative model for both the compositional and isotopic variation in the Columbia basalts assuming that they were derived from a homogeneous source region, would require: (1) different degrees or conditions of partial melting in the mantle; (2) transport and storage of primary magmas in crustal storage reservoirs where assimilation of Precambrian crustal material of varying composition, fractional crystallization in response to assimilation, and mixing between dense, Fe rich, highly fractionated liquids and newly injected, rather low density, unfractionated magmas occurred.

Picture Gorge magmas may have escaped the effect of this crustal contamination by their eruption from vents occurring well to the south-west of the majority of dyke swarms in the Columbia province. This hypothesis requires complex modelling and a better understanding of what really occurs when a basic magma is injected into the lower continental crust before quantitative modelling is possible. However, the very good correlation between Nd and Sr isotopic variation in these lavas and the demonstration that Precambrian continental crust exists under the province, strongly supports the viability of crustal contamination as an explanation for the chemical characteristics of the Columbia group.

If these lavas were derived from a homogeneous source and later modified by a series of complex geochemical interactions, then the parental mantle of the Columbia lavas had an isotopic composition of $^{87}Sr/^{86}Sr \leq 0.7033$ and $\varepsilon_{JUV} \geq +8$. These values are very similar to those measured for interoceanic island arcs and marginal basins of the Western Pacific. Whether these results can be extrapolated to other flood basalt provinces is unknown. However, the suggestion of a primordial (that is, $\varepsilon_{JUV} = 0$) source for the Columbia lavas[1] is clearly in error. The present results for the Columbia group do not exclude or confirm the existence of primordial material in the mantle. Rather they indicate the importance of the physical, chemical, and thermal phenomena which would accompany the transport and eruption of large volumes of mafic lavas, such as those of the Columbia province, through an ~30 km thick section of continental crust in a relatively short period of time.

We thank J. Holbrook for performing chemical separations, and W. H. Taubeneck, D. A. Swanson, T. L. Wright, E. Mullen and R. Stern for providing some of the samples. M. Menzies and M. Tatsumoto provided constructive reviews. This work was supported by NASA grant NGL05-009-150 and NSF grant EAR78-24060.

U series and amino acid dates from Jersey

D. H. Keen*, R. S. Harmon† & J. T. Andrews‡

* Department of Geography, Coventry (Lanchester) Polytechnic, Coventry CV1 5FB, UK

Understanding of the raised beach and other interglacial sequences in the southern part of the British Isles has been improved through use of the amino acid racemization technique. This method has permitted correlation of these isolated and fragmentary marine deposits[1,2] which, except for the Portland site, are located around the shores of the Bristol Channel[1]. By applying this technique with the U-series method, we have obtained a geochronometric date from the '8-m' raised beach of the Belle Hougue Cave, Jersey, Channel Islands. Our results suggest that the 8-m raised beach of the Channel should be correlated with isotope stage 5, and that raised beaches above this altitude in the area may pre-date this stage, and thus also the Ipswichian interglacial which forms part of it.

Although there are many raised beaches around the coasts of the western English Channel[3–5] the non-calcareous nature of the bedrock geology of the area means that few of these are fossiliferous. The raised beach of the Belle Hougue Cave, although on a base of rhyolitic agglomerate of the Jersey Volcanic series, is strongly cemented by interstitial calcium carbonate and in places contains discrete travertine layers. In the matrix of the beach are the remains of nine species of Mollusca and mammalian bones[6]. Specimens of *Patella vulgata* Linné and fragments of travertine were collected from the beach for analysis (Fig. 2), the shells for the determination of amino acid racemization ratios and the travertine for U-series dating. The resulting D-allo:L-iso ratios and $^{230}Th/^{234}U$ dates place an absolute age on the Belle Hougue beach and provide reasonable grounds for correlation with other more northern raised beach sites.

The Belle Hougue Cave lies on the north coast of Jersey (Fig. 1). The beach gravel occurs ~25 m in from the cave entrance and has a height range between 4 m and 8 m above mean sea level (Fig. 2). The gravel contains abundant molluscan remains. Three shells of *P. vulgata* were collected from the main shell concentration in the beach which lies between 30 and 60 cm below the top of the deposit (Fig. 2). The fragmented shells were heavily cemented by $CaCO_3$ and required careful cleaning before being prepared and analysed for amino acid ratios[2]. The total ratio of D-alloisoleucine to L-isoleucine is given in Table 1. All of the analyses are similar giving a mean D-allo:L-iso value of 0.12±0.02, except AAL-1219b which has a significantly higher value. This anomalous value may be related to the high degree of cementation of this sample.

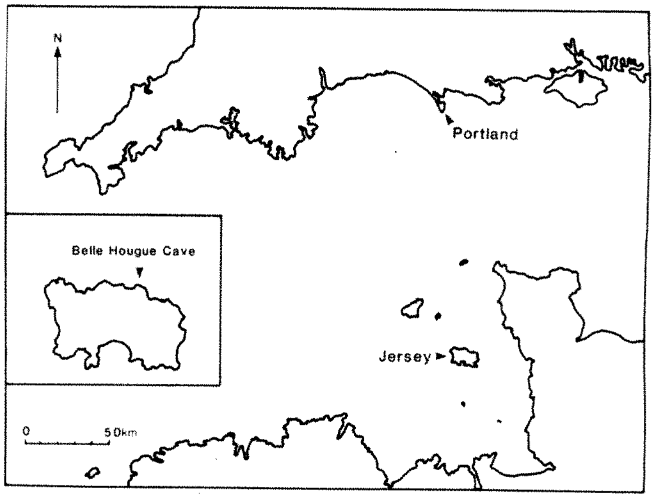

Fig. 1 Location diagram of the western Channel showing the positions of Jersey and Portland. Inset, the site of the Belle Hougue Cave.

The travertine was collected from a layer largely free of pebbles and shell, ~20 cm above the mollusc sample point (Fig. 2). A sample of 200 g was collected and subsplit for duplicate U-series analysis following the technique of Harmon *et al.*[7]. Analytical data and the U-series age of the sample are given in Table 1. The age of ~121 kyr BP indicated by the two runs has a slightly greater than normal uncertainty because of the presence of some detrital Th, and the fact that Th yields were low (<10%) due to the slightly contaminated nature of the travertine. The $^{234}U/^{238}U$ ratio, although perhaps rather high, is typical of the ratios obtained from secondary carbonates. Nevertheless, an age within isotopic stage 5, the last interglacial in the marine oxygen-isotopic record[8], is clear and a stage 5e correlation is suggested.

A stage 5e age for the beach is supported on palaeontological grounds. One of the species of Mollusca found in the beach gravel is *Astralium rugosum* (Linné) which has a present northern limit near La Rochelle, some 340 km south of Jersey. The occurrence of *A. rugosum* probably indicates a sea surface temperature for the Belle Hougue beach of 3–4 °C above that of the present temperature of the English Channel, a value

compatible with that expected from the higher temperatures generally suggested for the last interglacial in both marine[8] and terrestrial records[9].

Although a broad stage 5e age for the Belle Hougue raised beach is clear, in terms of wider correlations, several problems occur. The closest agreement of the amino acid values with those noted by Andrews *et al.*[1] is with their group 2 sites at Portland and in the Burtle Beds, which give amino acid values between 0.11 and 0.15. However, these sites both relate to sea levels about 15 m above OD[10,11] and Portland contains a fauna rather cooler in aspect than that of the present Channel[12]. On faunal grounds, therefore, correlation from Belle Hougue to these sites further north is not exact. Slightly different post-depositional environmental conditions may have occurred at Belle Hougue giving higher amino acid values than would be the case further north where lower temperatures prevailed for the period after the abandonment of the raised beaches. The present mean annual temperature at Portland is 10.7 °C, while in Jersey (St Helier) it is 11.9 °C. A temperature difference of at least this magnitude has probably occurred throughout the past 100 kyr.

Despite the problem of the correlation of the amino acid and sea levels, the absolute age for a raised beach at ~7.5 m above mean sea level supports Bowen's contention[13] that beaches at this general level in western Channel are of Ipswichian (stage 5) age, and not dated to an earlier interglacial as suggested by Stephens[14]. Outside the Channel similar sea level stands ~5–10 m above present sea level have been dated by ^{230}Th/^{234}U to ~120 kyr.

In Mallorca, Butzer's[15] cycle YI is dated to 120 kyr and has a sea level between 9 and 15 m above the present. In Barbados, Mesolella *et al.*[16] note a sea level 'above the present' at 125 kyr. In New Guinea, the Complex VIIb of Bloom *et al.*[17] has a sea level of +6 m at 125 kyr, and in the stable carbonate platform of Bermuda and in the Bahamas, Harmon *et al.*[18] and Neuman and Moore[19] recognize a +4 to +6 m level stand at 125 kyr. All these results are comparable to the Belle Hougue data in both timing and elevation of the last interglacial sea level maximum, thus allowing correlation of the 8-m raised beach of the western Channel with a similar sea level stand in the Mediterranean, Atlantic and Pacific. This correlation and radiometric date then suggests that the beaches of Andrews *et al.*'s[1] stage 2, and

Relative departures in July temperatures in northern Canada for the past 6,000 yr

J. T. Andrews, P. T. Davis, W. N. Mode, H. Nichols & S. K. Short

Institute of Arctic and Alpine Research, University of Colorado, Boulder, Colorado 80309

There has been concern about recent temperature trends and the future effects of CO_2 concentrations in the atmosphere[1,2]; but instrumental records only cover a few decades to a few centuries and it is essential that proxy data sources, such as pollen spectra from peats and lake sediments, be carefully interpreted as climate records. Several workers have shown statistically significant associations between the modern pollen rain and climatic parameters, an approach that by-passes the recognition of pollen/vegetation units. Statistically defined equations that associate abiotic and biotic elements are called transfer functions. We report here on the application of transfer function equations to nine middle and late Holocene peat and lake sediment sequences from northern Canada (Fig. 1).

Two transfer function methods are used[3]; the first follows the work of Imbrie and Kipp[4], whereas the second uses multiple stepwise regression to associate present climatic estimates with pollen percentages[5–9] directly. Modern pollen spectra from two transects are used; one trends SW–NE from south of the treeline in Keewatin to Clyde River, Baffin Island (ref. 9 and H. Nichols unpublished data) (KWA transect), whereas the other is oriented N–S from Fort Chimo in Labrador to Clyde River (ECA transect) (Fig. 1)[10,11]. Along the KWA transect, Nichols collected ⩾ 10 replicate mosses at 29 sites. The ECA transect consists of 87 surface samples from five major collecting localities (Fig. 1)[10,11].

Average July temperatures vary between 13 °C and 4 °C along the transects. Pollen data were regressed against this parameter. Pollen percentages were initially computed for all taxa. Many taxa were rare, hence percentages were recalculated on the basis of 13 common taxa for the Keewatin and for 19 taxa for the eastern Canadian Arctic transects. Thus, only common pollen types were used in the transfer function equations. Relevant data are listed in Table 1. We have compared the results from the Imbrie–Kipp and multiple regression approaches and shown that the two methods yield comparable results[6,8,9]. Equation MKWA-1B is based on the mean pollen percentages at the 29 sites, whereas MKWA-1 is calculated on 293 individual samples. All results indicate that mean July temperatures may be estimated on the basis of only a few taxa. Standard errors on the residuals are ⩽ ±1 °C (Table 1).

We applied our transfer function equations to a series of sites (1) to compare broad temperature trends; and (2) to recognize andcorrelate high frequency events. All sites that we use have been described previously[12–14]. Nichols[12] interpreted the diagrams from Ennadai, Thompson Landing and the two sites at Coppermine (Fig. 1) in terms of fluctuations in treeline and average July temperature. Transfer function equations MECA and MKWA were applied to lake/peat sites from Labrjor/Baffin Island and Keewatin, respectively. The resulting temperature estimates were smoothed. Finally, relative departures of July temperature were computed for each time-series as: $(x-\bar{x})/s$, where $\bar{x}$ and s are the mean and standard deviations (Table 2), respectively. Oscillations in temperature estimates could be simply 'noise'; thus, we examined residuals from time/temperature linear correlation models by the Runs Test, the null hypothesis was rejected in all cases but Thompson Landing. These results imply that the runs of temperature departures on Fig. 2 are not spurious.

Graphs of relative departures of average July temperature from their means are shown on Fig. 2. We only consider the past 6,000 yr so that changes in the pollen spectra primarily reflect climatic stresses rather than migrational histories of the different taxa. This statement may not be accurate for Labrador where an unusually late migration of conifers several thousand years after deglaciation took place[13–15].

The most important information in the time-series is the negative trend in the relative departures of July temperatures that begins between 3,000 and 2,500 yr BP.

Table 1 Information on the transfer function equations

	ECA-1	MECA-1B	MECA-2	KWA-1	MKWA-1B	MKWA-1
No. of samples	18	18	87	29	29	293
No. of taxa entered	19	19	19	13	13	13
No. of taxa selected in the equation	4	4	4	4	4	4
Multiple *r*	0.9	0.92	0.76	0.95	0.95	0.89
Standard error (±)	0.93	0.86	1.3	0.75	0.79	1.06
Names of the critical taxa	NA	*Alnus* *Picea* *Salix* Gramineae	*Alnus* *Picea* *Betula* Rosaceae	NA	*Alnus* *Picea* *Betula* Gramineae	*Alnus* *Picea* *Betula* Gramineae
Reference	6	6	6	9	9	9

The pollen taxa are in percentages. The climatic parameter estimated is July average temperature (°C). MECA and MKWA designate transfer function equations based on multiple, stepwise regression analysis. The Imbrie–Kipp approach has also been used and gives comparable results[2,8]; these results are designated ECA and KWA. NA, not applicable.

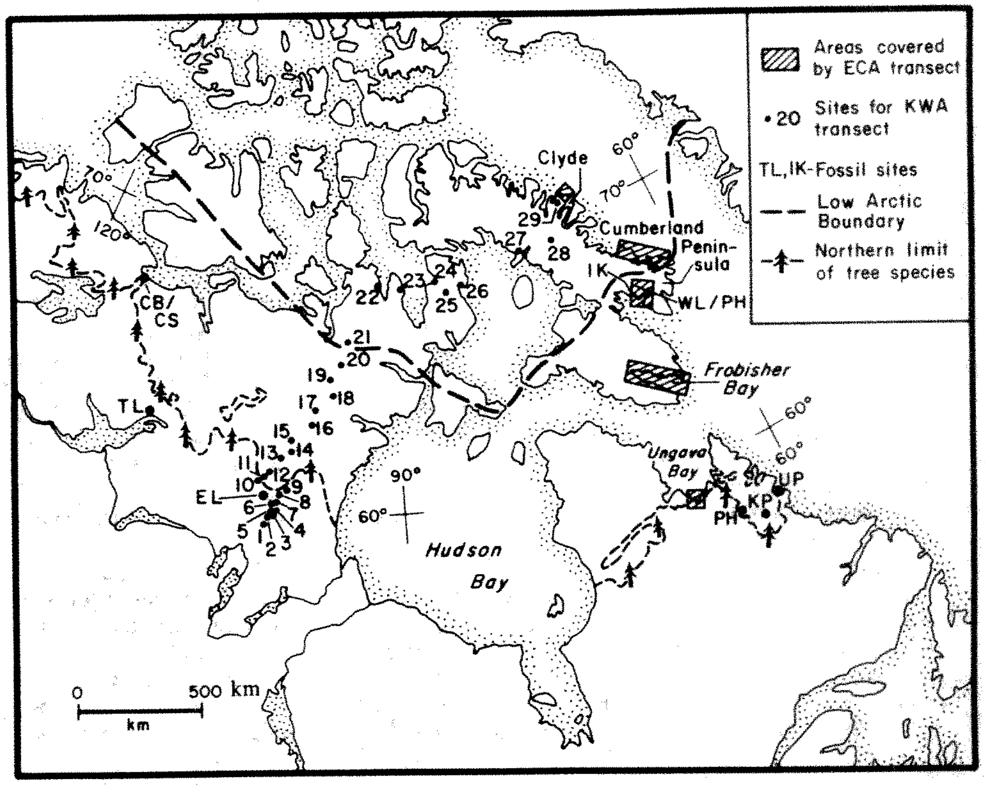

Fig. 1 Location of the two transects of modern surface pollen samples. Keewatin to Baffin Island sites numbered 1–29; Labrador to Baffin Island sites outlined as rectangles. Treeline and the Low Arctic vegetation boundary shown. Peat sites: EL, Ennadai Lake; TL, Thompson Landing; CB and CS, Coppermine Beach and Saddle; WL/PH, Windy Lake/Pass Head. Lake sediment sites: IK, Iglutalik Lake; UP, Ublik Pond; KP, Kogaluk Plateau Lake; PH, Pyramid Hills lake.

On Baffin Island, both records show a statistically significant decrease in average July temperature over the period of record (Fig. 2). The local thermal maximum terminated between 5,300 and 5,000 yr ago. The lowest estimated July departure during the past few thousand years occurred between 600 and 200 yr ago, although both records indicate continuously cool summers after ~2,300 yr BP. Present July temperatures are closely predicted by modern surface pollen spectra for this region; hence, the present temperature estimates are as warm, if not warmer, than any values estimated for the past 1,000–2,000 yr. The ages for the Windy Lake peat are based on a uniform sedimentation model. Davis[11] argued that a nonlinear relationship better fitted the 14 ^{14}C dates. Figure 2 shows alternative positions for peaks and troughs of temperature departures. However, the uniform model gives a satisfactory agreement with Iglutalik Lake.

In Labrador[13], the Ublik Pond site is our oldest record, and the July temperature departures >6,000 yr BP might be influenced by migrational lags in vegetation. The transfer functions predict that the major late Holocene cooling did not begin until 2,500 yr ago, and that the local thermal maximum occurred 4,000–3,000 yr BP. The other two sites from Labrador support this interpretation[13,14]. However, the record from Kogaluk Plateau Lake ends at ~2,500 yr BP, so that late Holocene changes are not recorded at that site.

Four sites have been examined from Keewatin[12]. Data from the Coppermine Beach showed no statistically significant trend of departures against age. The Beach site is on a dry, raised beach, whereas the Coppermine Saddle site is wetter.

Most of our sites (Fig. 2) indicated that July temperature departures became, on average, more negative over the last few thousand years. However, this does not preclude rapid climatic changes at certain times. Nichols[12,16] argued that the pollen evidence from Keewatin favoured a series of synchronous step changes in climate across the mainland of arctic Canada, which were superimposed on a general decline in July temperatures. Certain temperature graphs from our work show evidence for similar rapdi changes (Fig. 2). In particular, the very rapid

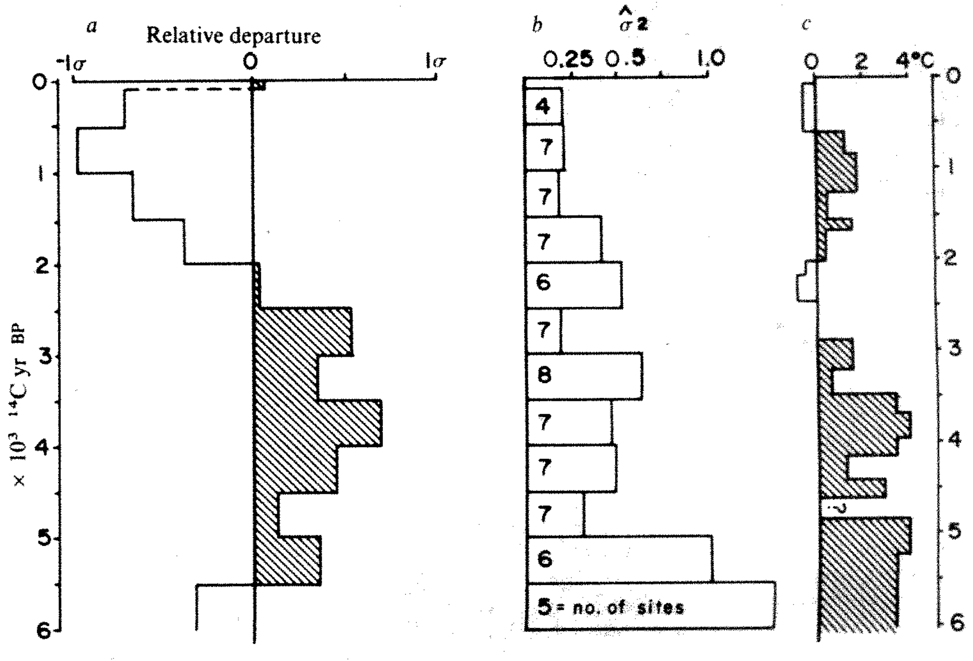

Fig. 2 Time-series of estimated July temperatures at nine sites across northern Canada. Temperatures expressed as relative departures from the smoothed mean of each series. Table 2 lists $\bar{x}$ and s for each series. A–A^1, and so on, refer to different timings of peaks at Windy Lake depending on which sedimentation model is used.

$\bar{x}$ and s are mean and standard deviation for each time series.

cooling that began in the late Holocene is notable. At Coppermine Saddle, a temperature drop of about 2 °C in 150 yr between 1,400 and 1,250 yr BP is estimated. At Ennadai Lake, Windy Lake and Ublik Pond, July temperatures fell 1–2 °C close to 2,500 yr BP.

The timing and direction of these changes were determined by averaging the data (Fig. 2) in 500-yr time-blocks and expressing the departures as ± values about the mean of each series (Fig. 3). If regionally offsetting departures were present, we would expect the average departure to be close to zero. However, regionally synchronous changes in estimated July temperatures can be identified on Figs 2 and 3. Our study area extends across the region covered by one of the main upper atmospheric troughs. As this trough shifts to the east of west, out-of-phase climatic trends may occur, at least on short time scales[17,18]. However, arguments for and against synchrony of climatic change on the longer time scales of centuries occur[12,18,19].

Between 5,500 and 6,000 yr ago, in northern Canada, mean July temperature departures were, on average, negative. July temperature departures then rose to above average values until 2,500 yr BP, with a reversal between 5,000 and 4,500 yr BP (Fig. 3). The highest average departures from July conditions occurred 3,500–4,000 yr BP, which apparently represents a Holocene local thermal optimum for the eastern and central Canadian Arctic. Between 3,000–2,500 and 1,000–500 yr BP, the average departures declined steadily and reached a trough in the latter interval.

Nichols'[12] graph of departures of July temperatures from modern values is reproduced on Fig. 3. The major difference between that reconstruction and ours is the interpretation of events after 2,500 yr BP; our reconstruction shows a steady decline to values well below the mean of the nine time-series, whereas Nichols' reconstruction shows less of a decline and, in fact, has temperatures above present between 2,000 and

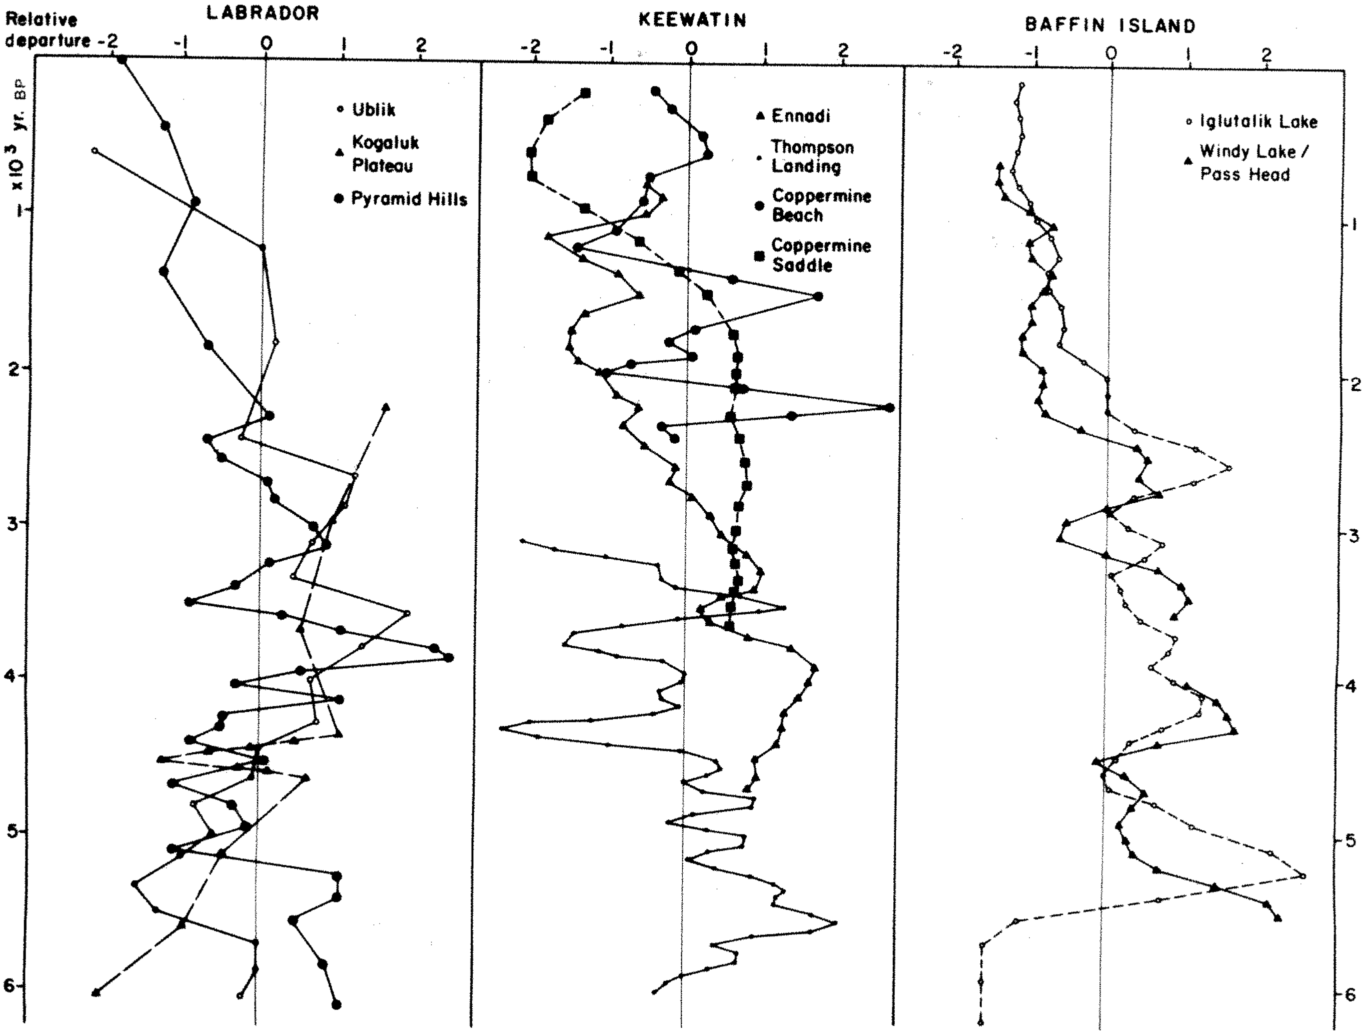

Fig. 3 *a*, Average relative departures for all sites for 500-yr time blocks; shaded area indicates period when relative departures were above the average July temperature (°C) for the past 6,000 yr. *b*, Variance of the relative departures, number within each block represents the number of curves available for each interval. *c*, Nichols' model of variations in July temperature (°C) for central, northern Canada based on an analysis of fossil pollen spectra. The temperature history of the past 200 yr is inferred and based on comparison of present average July temperatures compared to the fossil record.

600 yr BP. We have yet to examine our data for how far the variance of Fig. 3*c* is due to pronounced regional differences in our estimated July temperature records, or how far it is associated with uncertainties in the pollen transfer functions, or how much is associated with problems of ^{14}C dating organic poor sediment[13,20].

Our data indicate that the most useful northern analogue for a 'warm' summer world during the past 6,000 yr is between 3,500 and 4,000 yr ago. Figures 2 and 3 indicate that July temperatures in the central and eastern Canadian Arctic departed, on average, by about 0.75 standard deviation from the 6,000-yr mean, or ~1 °C. Locally, estimated July temperature reconstructions are predicted to have been 2 °C to 3 °C warmer than at present.

Footprints of a Pleistocene hominid in northern Kenya

Anna K. Behrensmeyer

Peabody Museum and Department of Anthropology,
Yale University, New Haven, Connecticut 06520

Léo F. Laporte

Earth Sciences Board, University of California, Santa Cruz,
California 95064

We report here that in 1978, while studying Koobi Fora Formation sedimentary environments and fossils in northern Kenya, we discovered single footprints and trails of large vertebrates in a number of different strata. One of these trails is that of a bipedal hominid, the second known record of early hominid tracks in Africa, the other being that reported at Laetoli, Tanzania[1].

The Koobi Fora Formation is exposed for 2,600 km^2 along the northeastern shore of Lake Turkana. It is up to 325 m thick and consists of laterally variable facies deposited in lacustrine, lake margin and fluvial environments[2,3]. Within the Upper Member of the Koobi Fora Formation, in the vicinity of Koobi Fora (Fig. 1*a*), is a poorly consolidated 10–20-m sedimentary complex of tuffaceous sands and silts designated the Koobi Fora Tuff[4]. This has yielded a scatter of radiometric dates with a preferred estimate of 1.5–1.6 Myr (ref. 5). Correlation based on lithology and stratigraphic position can be made from the Koobi Fora Tuff to the Okote Tuff (Karari area) and Lower/Middle Tuff (Ileret area) to the north[2,3], although outcrops between areas are discontinuous (Fig. 1*a*). The Okote and Lower/Middle Tuffs are also dated at 1.5–1.6 Myr (ref. 5). Biostratigraphic correlations to other dated sequences including the Omo Shungura Formation[6] and Olduvai Gorge[7,8] support this date.

Table 1 Numerical data for the Koobi Fora Tuff hominid tracks

Hominid print	Width (cm)	Length (cm)	Maximum depth (cm)	Orientation	Notes
L1	13.0	26	6.0	80°	Deepest near first toe, morphology poorly preserved
R1	18.0	32	6.0	90°	Deepest under ball of foot, morphology poorly preserved
(L2)	—	—	—	—	Missing, probably due to locally hard substrate
R2	7.0	—	1.5	~87°	Incomplete print, probably heel only
L3	10.5	27	4.0	51°	Includes partial toe prints, deepest at heel
R3	10.0	26	3.0	92°	Probable minor slipping during step
L4	—	—	—	~88°	Partial, superimposed on composite hippopotamus prints
R4	9.5	25	2.5	92°	Greatest depth at heel and along outside edge

R = right foot, L = left foot; numbered from west to east in the direction of movement. Width is measured at the ball of the foot, length from toe to heel along the midline.

There are extensive exposures of the Koobi Fora Tuff in Area 103 (lat 3° 53′N, long 36° 15′E), 13 km SSE of the Koobi Fora research camp, in a series of fault blocks. In 1978, step trenches revealed over 20 distinct strata with sedimentary structures which, in cross-section, seemed to be imprints of large vertebrate feet on originally soft, muddy substrates[9]. The sediments record marginal lacustrine environments and are vertically complex, with alternating thin units (1–15 cm) of sand and mud. Within the uppermost 1 m, cross-sections of particularly well preserved footprints were found in a unit of sandy mud (Fig. 1*b*). An area of 1 m^2 of the upper surface of this unit was cleared of overlying sediment to determine the shapes, in plan view, of the footprints. Excavation revealed several deep, four-toed impressions of hippopotamus feet and a shallow depression resembling a human footprint. Kimolo Mulwa and Bernard Kanunga of the National Museums of Kenya were responsible for the uncovering and recognition of this first hominid track (R4). Excavation of a second 1-m^2 area exposed two further complete human-like prints in line with the first, confirming the discovery of a hominid trail. Excavation in 1979 expanded the area of exposed bedding surface to 12 m^2 and revealed two further complete hominid tracks together with those of many other vertebrates (Fig. 1*c*).

The footprints are in a homogeneous, pinkish-buff sandy mud (sand : silt : clay = 12 : 59 : 29) about 12 cm thick, interbedded with ripple-laminated, fine pumaceous sands of comparable thickness, with sharp upper and lower contacts. The underlying muddy sand unit has slight, concave-upward deformation of laminae beneath the hippopotamous footprints, which penetrate through the sandy mud to within 1 cm of its base. This deformation shows the effects of the weight of the animals and indicates that the sand under the sandy mud was relatively compact when trampled. Muddy sand (sand : silt : clay = 81 : 10 : 9) infillings of the footprints are slightly coarser than the overlying sand and include fine silt laminae, concentrations of heavy minerals, and in some cases abundant sand-coated mudclasts. The footprint layer has an irregular upper surface with higher rims around the deeper tracks, apparently a result of displacement of the mud as the foot penetrated the substrate. There seems to have been no overall scouring before burial of the mud; the sand-bearing currents simply filled and buried the tracks. The sandy mud was viscous enough to form thin, 10-cm-high walls between tracks, and it is doubtful that these would have survived even slight erosion by current action. There are no mudcracks in the footprint unit as evidence for subaerial exposure, although a sample of the sandy mud readily developed cracks when wetted and dried. We conclude that the footprints were formed when the mud surface was submerged under quiet

0028–0836/81/030167—03$01.00

water. The track of a small wading bird indicates that the water was shallow, < 10 cm deep.

On the 12 m^2 of excavated surface, 89 distinct depressions between 2 and 23 cm deep can be identified as the tracks of large vertebrates (Fig. 1*c*). Of these, 22 indicate a foot similar to that of modern hippopotamus, and in 15 there are clear impressions of toes. In some cases the toe-marks show that the animals slipped while stepping in the mud. Three distinct trails record one hippopotamus going north-east and two going west. The larger prints (25–32 cm wide) can be attributed to the large fossil hippopotamus, *Hippopotamus gorgops*, recognized from the Koobi Fora Formation at that time[10]. The smaller ones (18–20 cm wide) could be due to juveniles of this species or may belong to the fossil pigmy species, *Hippopotamus aethiopicus*[10]. Four of the other, smaller tracks resemble those of modern large Bovidae (the size of a topi, *Damaliscus korrigum*, about 120 kg) but are not sufficiently well preserved for definite identification. There are also two distinct bird prints, one large and one small. The larger is a clear, three-toed impression 20 cm wide, similar in size and morphology to that of a modern bustard or crane. The smaller, which is 2.0 cm wide, resembles tracks of a small shore bird such as a plover.

Five of the depressions on the surface are complete tracks made by the feet of a bipedal hominid (Fig. 1*c*). Two additional

Inset shows location in Kenya. *b*, Stratigraphic section showing upper 2.6 m of the Koobi Fora Tuff and the position of the footprint unit (arrow). Muddy sand units stippled, sandy mud blank. Heavy dashed line indicates top of Koobi Fora Tuff. *c*, Map of the excavated surface of the footprint layer, with hominid footprints (shown in black). Dashed lines indicate direction of movement for the more distinct trails (light stipple in hippopotamus footprints forming the trails). Track of small wading bird is circled.

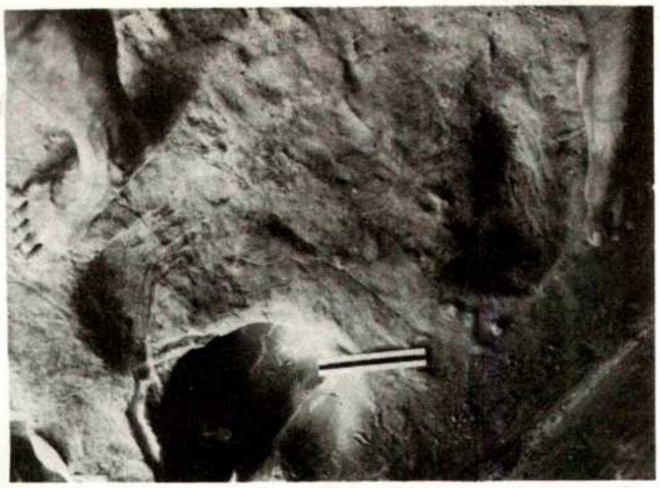

Fig. 2 Two of the best-preserved footprints in the 1.5-Myr old trail discovered in northern Kenya, framed by the modern feet of *Homo sapiens* (27 cm long). These prints are referred to as L3 and R3 in Fig. 1*c*. Scale bar, 15 cm. (Photograph by Léo F. Laporte.)

tracks can be attributed to the same individual although they would not be identifiable as hominid if observed separately from the trackway defined by the other five footprints. The complete tracks are shallower towards the east, in the direction of movement (Table 1). The westernmost tracks (L1 and R1) are oversized and poorly shaped compared with the others, and bear evidence of minor erosion and slumping before burial. The absence of an L2 track is puzzling, but may be due to a patch of substrate that was compact enough to bear the weight of the hominid or to local scouring before burial. More hominid tracks would probably be uncovered if the excavation were extended westward along the line of the trackway, although the increasing amount of overburden would make that a difficult operation.

From the dimensions of the best-preserved tracks, L3, R3 and R4, we estimate that the hominid foot was about 26 cm long and 10 cm wide (Table 1). These fall close to average dimensions for American *Homo sapiens* males[11]. Other tracks in the series are enlarged or incomplete and cannot be used to reconstruct foot shape. The height of the hominid can be estimated at 1.6–1.7 m based on the relationship of foot length to stature for American negro and white males[11], and 1.8 m based on those for San bushmen[12]. The hominid prints are longer and relatively narrower than those recorded at Laetoli, which average 18.5 cm long and 8.8 cm wide (trail 1) and 21.5 × 10 cm (trail 2)[1].

In the study of footprints, a standard definition of 'stride' is the distance from a point on one foot (left or right) to the same point on the next impression of the same foot[13]. The length of the stride of the hominid is about 80 cm, less than that of modern humans with feet of comparable size during normal walking[14]. This, along with the orientation of the feet, seems to indicate a hesitant, somewhat sideways progression across a slippery surface with one mis-step (L4) into a deep hippopotamus track, which may have been concealed by turbid water.

At least two bipedal hominid taxa are represented by fossil bones from the Koobi Fora Formation at the time of deposition of the footprint unit: *Homo erectus* and *Australopithecus robustus*[15–17]. In Area 103, only the remains of *H. erectus* have been found in the Koobi Fora Tuff although in the Karari and Ileret regions both taxa occur in units correlated with the Koobi Fora Tuff. The *H. erectus* specimens from the Koobi Fora Tuff occur within its lower 6 m; none has been found within the upper part where the hominid trackway is recorded. It is not possible to determine which hominid made the footprints.

Trails of early hominids known from the Pliocene Laetolil Beds in northern Tanzania were preserved in subaerial volcanic ash strata dated at 3.60–3.75 Myr (refs 1, 12). They occur with a large series of tracks and trails representing a wide diversity of savannah animals. The hominid tracks are thought to belong to the same species as hominid fossils from the Laetolil Beds, designated as *Australopithecus afarensis*[1,12,18]. In contrast, the Koobi Fora footprints occur on a muddy lake margin with tracks of a limited number of semi-aquatic vertebrates. The Koobi Fora footprints contribute a reference point on hominid foot morphology, locomotion, behaviour and ecology 2 Myr younger than the Laetoli occurrences and ~1 Myr older than late Pleistocene human footprints in Europe[19].

A latex mould and plaster cast of the Koobi Fora hominid footprints described here is stored at the National Museums of Kenya, Nairobi. We thank the Government of Kenya, the National Museums of Kenya and the International Louis Leakey Memorial Institute for African Prehistory for their cooperation and support. Richard Leakey, Meave Leakey, Glynn Isaac, Kamoya Kimeu and Tim White are acknowledged for their suggestions and help. The excavation crew, headed by Muteti Nume and Mukilya Mun'goka, were directly responsible for the technical work that led to the discovery of the trackways. Hilde Schwartz and Mahmood Raza assisted with the excavation work. Palaeoecological research was sponsored by NSF grant EAR77-23149 and is a part of the overall Koobi Fora Research Project, which is supported by grants from the National Geographic Society, the NSF and the W. H. Donner Foundation.

Relationship between fungus and alga in the lichen *Cladonia cristatella* Tuck

Vernon Ahmadjian* & Jerome B. Jacobs†

*Department of Biology, Clark University, Worcester,
Massachusetts 01610
†St Vincent Hospital and University of Massachusetts Medical
School, Worcester, Massachusetts 01605

The nature of the lichen symbiosis is not clear. It is generally thought to be mutualistic but this concept is not supported by experimental evidence[1]. Early workers[2,3] considered that lichens represented algae parasitized by fungi—as evidence, they noted algal cells in a lichen thallus that were dead or penetrated by fungal haustoria. Others, however, cited the seemingly healthy and long-lasting nature of lichens as evidence of mutualism. As we report here, our observations of artificial syntheses of the mycobiont *Cladonia cristatella* ('British soldiers') with different algae suggest that the relationship in this lichen is one of controlled parasitism. The mycobiont formed squamules mostly with algae related to its natural phycobiont, an indication perhaps of a long period of co-evolution between the symbionts of this lichen.

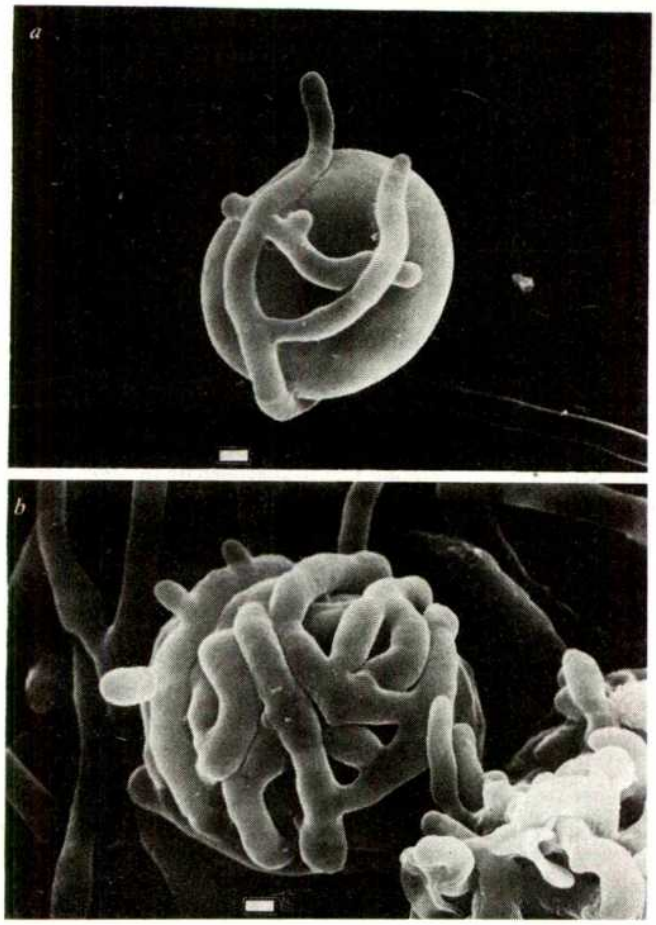

Fig. 1 Envelopment of cells of *Trebouxia erici* by mycobiont. With the aid of a dissecting microscope, mica strips with colonies of resynthesized lichens were cut into 13-mm pieces and placed in Petri dishes filled with 2% glutaraldehyde in 0.1 M phosphate buffer, pH 7.2, and fixed for 30 min. The colonies were rinsed briefly in phosphate buffer and then fixed for 30 min at room temperature in 1% OsO_4 in 0.1 M phosphate buffer. The specimens were rapidly dehydrated through an ascending alcohol series and dried by the critical point method. Specimens were cemented to specimen stubs, sputter coated with approximately 100 Å of gold, and examined at 20 KV in a JEOL JSM 35U scanning electron microscope. *a*, Algal cell encircled by branches from one hyphal filament. A thin gelatinous matrix around the alga binds the hyphae. *b*, Algal cell almost fully enveloped by hyphae. Haustorium has penetrated the cell at the top and along one hypha are three new branches. Scale bars, 1 μm.

Procedures used are described in Table 1 legend. After 2–3 weeks of axenic culture, the fungus formed squamules with five species of *Trebouxia* phycobionts and presquamules with *Trebouxia italiana* and *Friedmannia israeliensis*. The phycobionts were isolated from 13 different lichens. The fungus did not form lichenized structures with 17 algal symbionts, the free-living algae *Chlorella vulgaris* and *Pleurastrum terrestre* or unlichenized representatives of the Chlorococcales (Table 1). The fungus was not specific in its attachment, encircling glass beads (10–15 μm in diameter) in the same manner as algal cells, although the hyphae could be easily dislodged from the beads.

Algal cells were covered by a substance which bound the fungal hyphae (Fig. 1*a*) similar to that seen between the symbionts of the natural lichen and in a different lichen synthesized previously[4]. When initial contacts were established, the fungus, depending on the alga contacted, formed lichenized associations or destroyed the cells with its haustoria. Initial contacts (Fig. 1*a*) were followed by further encirclement of the algae, some cells being almost completely enveloped (Fig. 1*b*). After the fungus had secured small groups of algal cells and formed presquamules (Fig. 3*a*), a network of hyphae formed over the presquamules (Fig. 3*b*) linking them into a common structure. Thickened and fused hyphae with irregular extra-hyphal material developed first in small patches and later over a broader area of the mixed culture, forming the upper cortex and network of hyphae which covered the squamules. Further differentiation resulted in an algal layer and medulla. The morphology and dimensions of the thallus layers were identical to those of the natural squamules.

aureola)
Trebouxia gelatinosa
(UTEX 905; *Parmelia caperata*)

Algal and fungal symbionts were separated into culture using standard isolation techniques. The algal symbionts were grown on Bold's basal medium (BBM)x3N + 1% glucose agar slants. Single spore isolates of the fungal symbiont were cultured in Lilly and Barnett liquid medium or malt–yeast extract broth liquid medium[13]. The fungal cultures were centrifuged at 10,000 r.p.m., washed with distilled water and recentrifuged at the same speed. Clumps of hyphae were taken from the pellet and mixed with different algae. These symbiont mixtures were inoculated onto the surface of newly cleaved mica strips (1 × 7.5 cm) which had been soaked in BBMx3N solution. Each strip was located in a 125-ml Erlenmeyer flask; one end of the strip was embedded in 20 ml of plain 2% agar and the other end rested against the flask. The flask was plugged with non-absorbent cotton covered with aluminium foil. The relative humidity in the flask was about 95%. Incubation of the flasks was at 3000 lx, 12/12 light–dark cycle, at 21 °C during the light period and 19 °C in the dark period. Scanning electron microscope observations were made 2 months after inoculation.

* Mycobiont used in these crosses was isolate no. 6.

Haustoria were common in the natural and synthetic lichens (Fig. 2*a*), but in the former, about twice the proportion of algal cells was penetrated than in the latter (Table 2). Algae in the newly synthesized squamules were probably dividing more rapidly than those in the natural thalli, thus being less susceptible to fungal contacts.

Algae that were incompatible with the fungus (Table 1) were parasitized and destroyed (Fig. 2*b*). These included many green and one blue-green phycobionts and non-lichenized forms. Because initial binding of the fungal hyphae to algal cells seems to be similar in all cases, compatibility must be a secondary phenomenon. Perhaps there is algal resistance to fungal parasitism; that is, some algae may succumb more slowly than others to particular fungi.

In *C. cristatella*, the relationship between fungus and alga seems to be controlled parasitism. In the natural lichen, although more than 50% of the phycobiont cells were penetrated by haustoria, the algal population seemed healthy. In our successful laboratory syntheses, we saw algal cells apparently killed by haustoria and hyphae growing through them. Therefore, any resistance that compatible algae may have to the fungus is not permanent. In nature, a balanced relationship may have evolved between the symbionts. It is possible that the parasitism of the natural phycobiont is balanced by proliferation of the algal cells. Others have suggested controlled parasitism[5-7] and it may be a general feature of lichens.

The role of the haustoria is not clear. Evidence indicates that they do not transfer metabolites from alga to fungus[8,9]. They might be vestigial structures of ancestral fungi that were more actively pathogenic on other plants. A relationship between lichen fungi and unlichenized fungal parasites is suggested by the concentric bodies, cellular organelles of unknown function found in numerous lichen fungi and ascomycete plant pathogens.

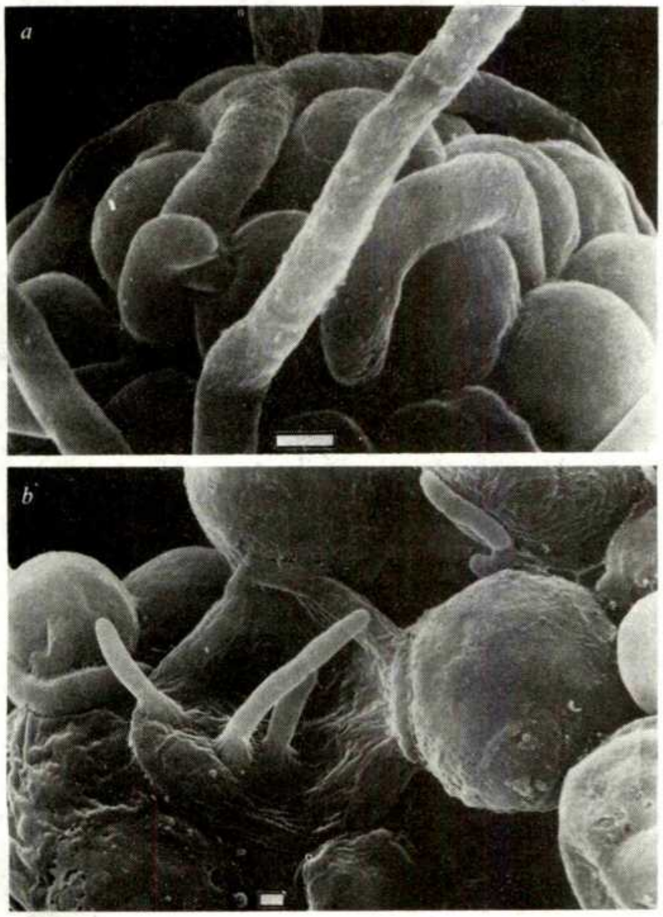

Fig. 2 Fungal intrusions into algal cells. Procedures used were as described in Fig. 1 legend. *a*, Cell of *Trebouxia erici* showing invaginated wall around haustorium. *b*, Three hyphae growing out of collapsed cell of *Trebouxia gelatinosa*. Scale bars, 1 μm.

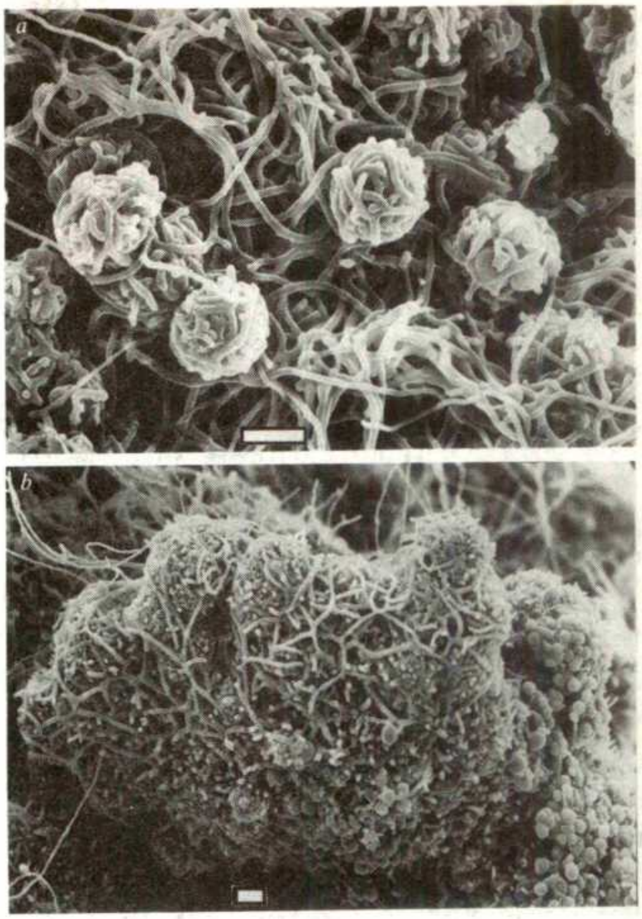

Fig. 3 Development of lichen squamules. See Fig. 1 legend for procedures. *a*, Presquamules formed by algal cells enveloped by mycobiont. *b*, Presquamules linked together by a network of superficial hyphae. Scale bars, 10 μm.

Some algal cells in the early stages of the successful syntheses were almost completely covered by fungal hyphae, which may be a response to the nutritional needs of the fungus. The mica substrate contained only mineral supplements; thus, the algal cells provided the only source of organic nutrients for the fungus. Farrar[10] estimated that 90% of the carbon fixed in photosynthesis by natural lichens is released by the algae but this release virtually ceases when the algae are removed from the

Table 2 Frequency of haustoria in natural and resynthesized squamules of *Cladonia cristatella*

Natural lichen	Total cells observed	Cells penetrated by haustoria	% Cells penetrated
Squamule 1	200	113	57
Squamule 2	100	65	65
Squamule 3	184	107	58
Resynthesized lichens			
C. cristatella s.s.8 × *Trebouxia excentrica* (*Cladonia leporina*)	200	54	27
C. cristatella s.s.8 × *Trebouxia erici*	100	24	24

Squamules were placed in a drop of Loeffler's methylene blue or lactophenol cotton blue and gently crushed with a cover slip using sufficient pressure to rupture vegetative cells. The ruptured cells extruded their contents and left only the empty shell. Haustoria adhered strongly to the algal wall and were not dislodged by the crushing. Haustoria were readily visible because there were no algal contents to mask their presence and they stained whereas the algal wall remained unstained. Empty algal cells over 5 μm were counted randomly during transects from one side of the slide to the other. Crushed cells were not counted.

symbiosis. The algae we used were growing separately in culture and presumably released little or no carbohydrate. The initial extensive contacts of algal cells by fungal hyphae may be necessary to re-establish permeability of the algal cells. We did not find an extensive hyphal covering of algal cells in the natural lichen. Collins and Farrar[9] reported that in *Xanthoria parietina* only 20% of the algal wall was in contact with fungal walls. This minimal fungal coverage may be related to the large release of organic material by the alga in the symbiotic condition.

The lichenization of the free-living alga *F. israeliensis* proceeded only to the presquamule stage. The mixed culture showed numerous patches of dead algal cells killed by fungal intrusions. Cells of *P. terrestre* were enveloped by hyphae but presquamules did not form because the algae could not survive association with the fungus. *Trebouxia* belongs to the order Chlorococcales. *Friedmannia*, like *Pseudotrebouxia*, is in the Chlorosarcinales because it has vegetative cell division and *Pleurastrum* is in the Chaetophorales. Although they occupy divergent taxonomic positions, these algae have similar zoospores and division stages of zoosporogenesis[11,12].

Our scanning electron microscope observations of the natural lichen showed many bacteria on the surface of the squamules. However, the axenic development of squamules in our cultures revealed that bacteria were not involved in the morphogenetic development of this lichen.

Syntheses took place in constant humidity (about 95%) in a closed flask. Other than the initial drying after the wet fungus was placed onto the mica strip, the culture did not dry further; thus, the lichen developed despite the absence of drying and wetting cycles thought to be essential in lichen synthesis.

Most chemical substances of natural lichens are products of the symbiosis. Analyses (TLC and ion-HPLC) of our synthetic lichens revealed the presence of natural secondary products. *C. cristatella* s.s.6 × *Trebouxia erici* showed barbatic acid, 4-*O*-demethylbarbatic acid, obtusatic acid, norobtusatic acid, 3-α-hydroxybarbatic acid, didymic acid and rhodocladonic acid. *C. cristatella* s.s.6 × *F. israeliensis* showed barbatic acid, obtusatic acid and 4-*O*-demethylbarbatic acid.

This research was supported by a grant to V. A. from the NSF (PCM-7921676). We thank Paul Stein for technical assistance and discussions, and Chicita F. Culberson for TLC and HPLC analyses.

Light–shade adaptation of *Stylophora pistillata*, a hermatypic coral from the Gulf of Eilat

Paul G. Falkowski

Oceanographic Sciences Division, Brookhaven National Laboratory, Upton, New York 11973

Zvy Dubinsky

Department of Life Sciences, Bar Ilan University, Ramat Gan, Israel

All reef-forming, or hermatypic, corals harbour photosynthetic endosymbiotic algae called zooxanthellae[1–5], which are assumed to be predominantly a single dinoflagellate species, *Gymnodinium microadriaticum* Freudenthal[6]. The zooxanthellae are essential for the well-being of their hosts[7–9]; nevertheless, little is known about how light affects the symbiotic association, especially regarding the numbers of zooxanthellae, their photosynthetic responses, and their overall productivity[10–14]. On the reefs of the Gulf of Eilat, *Stylophora pistillata* is an abundant hermatypic coral[15]; it is unique in that region in that it can adapt to a wide range of light intensities. In the high light intensities of lagoons or the upper areas of reefs, the corals are markedly lighter in colour than those living under ledges, in grottos, or near the reef floor (~15 m; Fig. 1). We report here on the biochemical and physiological adaptations of *S. pistillata* to variations in light intensity spanning more than two orders of magnitude.

Specimens of *S. pistillata*, adapted to light and shade regimes, were collected from a remote reef near Nabq in the Sinai Peninsula (28.20° N, 034.95° E) and taken immediately to a lagoon near a shore-based laboratory. The corals were kept in shaded (~10% incident light), submerged baskets in the lagoon until used. Within 2 h of collection, samples were weighed and photographed against a calibrated grid, and chlorophylls were extracted by freezing in liquid N_2 and thawing in 90% acetone on a reciprocating shaker under dim light for 1 h. Extraction was considered complete when little or no chlorophyll fluorescence was observed on the coral branches under long wavelength UV light[16]. The absorption spectra of the acetone extracts were scanned from 400 to 750 nm on a Beckman DB-G grating spectrophotometer and chlorophylls *a* and *c* were calculated according to equations of Jeffrey and Humphrey[17]. Soft tissue protein, extracted in boiling NH_3OH, was measured by the method of Lowry[18] using bovine serum albumin as a standard. To determine coral surface areas, photographs were made of individual branches (of known weight) against a calibrated grid and projected onto graph paper. The two-dimensional surface areas were obtained by tracing the coral branches and weighing the paper cutouts of the branches. These two-dimensional areas (that is, cross-sectional areas) were multiplied by π to estimate three-dimensional surface areas, assuming that the coral branches approximate a series of cylinders.

Zooxanthellae were removed from branches with a Water Pik (Teledyne)[19], suspended in fresh seawater, and counted by light

† Surface area to mass ratio.

microscopy with a haemocytometer. Suspensions were filtered onto Whatman GF/C glass fibre filters; chlorophylls were extracted by grinding the filters in 90% acetone and quantified spectrophotometrically.

To determine photosynthetic responses, coral branches were placed in 250-ml Wheaton bottles in a constant temperature bath with a self-stirring oxygen electrode (Yellow Springs Instruments, model 5420A) connected to a 356H operational amplifier. Light was provided by a 500 W quartz halogen source and attenuated with Wratten neutral density filters. To provide more even illumination, a mirror was placed directly behind the branches. The size and number of photosynthetic units (PSUs) were estimated by measuring chlorophyll *a*/P_{700} ratios with an Aminco DW-2a spectrophotometer[20,21]. Light intensities were measured *in situ* with a Lambda LI 185 quantum meter interfaced with a 192S underwater sensor.

S. pistillata can be divided into two major morphological groups: light- and shade-adapted individuals (Table 1). The former have thinner and more numerous branches (Fig. 1), giving a ratio of surface area/weight 1.9 times greater than that of shade-adapted corals. In most cases shade-adapted colonies are subspherical, and only rarely have we observed the flattening previously described[22,23]. Protein/surface area ratios were remarkably constant for all individuals, however, and it is inferred that ratios of protein per gramme are directly proportional to surface areas per gramme for a given coral species.

Shade-adapted corals contained 7.4 times more chlorophyll *a* per gramme (3.9 times more per square centimetre) than those adapted to high light intensities. Differences in pigmentation reflect the intracellular pigment content of the zooxanthellae and cannot be attributed to differences in numbers of zooxanthellae per surface area of coral (Table 1). Those differences were primarily associated with changes in the number of chlorophyll *a* molecules per photosystem I reaction centre, P_{700}. The number of reaction centres was virtually constant in light- and shade-adapted zooxanthellae, suggesting that adaptation is mediated by changes in the size, rather than the number of PSUs, as has been observed in free-living unicellular algae[24,25]. The range of sizes of PSUs observed in *G. microadriaticum* (approximately 400–1,800 chlorophyll per P_{700}) is similar to those found in free-living dinoflagellates[24,25], but is larger than for chlorophytes (approximately 450 chlorophyll per P_{700})[25] and higher plants (approximately 350–500 chlorophyll per P_{700})[26]. Such changes were associated with changes in the photosynthetic responses to changes in irradiance (that is, P–I curves, Fig. 2). On the basis of coral surface area, light-adapted specimens had lower photosynthetic capacities and higher compensation light intensities than shade-adapted individuals (Fig. 2*a*). Instantaneous light-saturated net photosynthetic O_2 production by zooxanthellae exceeded coral respiratory demands in both light- and shade-adapted specimens. In neither was photoinhibition observed, even at intensities approaching 2,100 μeinstein m^{-2} s^{-1} (full noon sunlight in the summer in the surface waters of the Gulf of Eilat). When P–I curves are calculated on the basis of chlorophyll content (Fig. 2*b*), maximum photosynthetic capacities were not significantly different in light- or shade-adapted corals. However, shade-adapted corals appeared to utilize light more efficiently, as indicated by steeper initial

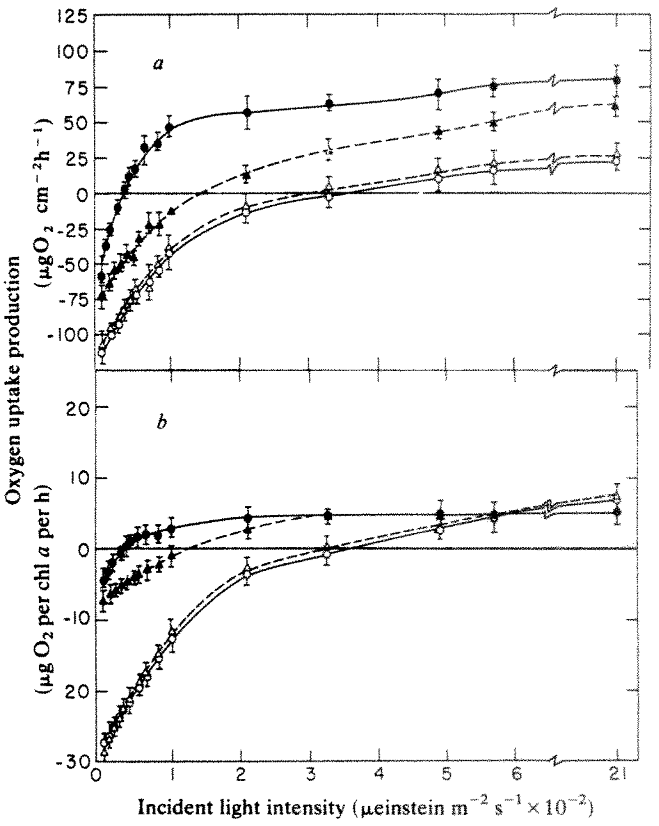

Fig. 2 Photosynthesis–irradiance profiles for light-adapted, shade-adapted, and transplanted *S. pistillata*. *a*, Light curves expressed on a surface area basis: ○, light-adapted; ●, shade-adapted; ▲, light-to-dark transplant after adaptation for 30 days; △, dark-to-light transplant after adaptation for 30 days. *b*, Light curves expressed on a chlorophyll *a* basis. The symbols used are the same as in *a*. Data points represent means and standard deviations ($n = 3$ for light adapted, $n = 3$ for shade adapted, $n = 2$ for dark-to-light transplants, $n = 3$ for light-to-dark transplants). All measurements were made at 28 ± 1 °C.

slopes of the P–I curves. These P–I responses were qualitatively similar to those observed in the foliaceous coral *Pavona praetorta* Dana from Enewetak Atoll[12] and are consistent with theoretical arguments that changes in the size of PSUs ought to affect the efficiency of light utilization[21,24,25].

Corals were able to adapt when transplanted from one light regime to another (Table 1, Fig. 2). The process was quicker for transplantation from lower to higher light intensities, being effectively complete after 4 weeks. Corals transplanted from high to low light intensities were not fully shade adapted after 4 weeks, but continued to adapt slowly for 6 to 8 weeks. During that period, light-to-shade transplant pigmentation increased in those corals and P–I responses were intermediate between the two extremes. The difference in adaptation time between the two types of transplants may be related to temperature in the two environments[16,27].

Previous attempts to transplant corals in this way have not generally been successful as the corals often show signs of physiological stress. This has been interpreted as indicating that light- and shade-adapted corals represent locally adapted populations or ecotypes[23]. Usually a particular species appears to be associated with an optimum light regime, and changes in light intensity result in changes in species composition[28]. Our reciprocal transplant results strongly suggest, however, that changes in coral zonation associated with a gradient in light intensity are not necessarily caused by the inability of zooxanthellae to adapt to wide variations in light regimes. It would seem that in the case of *S. pistillata* the wide range of light intensities tolerated by this coral is not due to zooxanthellae populations of distinct ecotypes as described for the West Indian coral *Montastrea annularis*[23]. In particular, the ability of *S. pistillata* to adapt to various light regimes suggests that light- and shade-adapted corals are not always ecotypes and that the niche width of a coral species with respect to light *per se* is not limited by its zooxanthellae.

This research was supported by the US-Israel Binational Science Foundation and assisted, in part, by the US Department of Energy under contract DE-ACO2-76CH00016. We thank Jacob Schafer, Ruth Benaksas, David Sherf and Tova Sa'adon for technical assistance, and Dr M. Avron for the use of the Aminco spectrophotometer.

Heterozygous advantage expressed through sexual selection in a polymorphic African butterfly

D. A. S. Smith

Department of Biology, Eton College, Windsor,
Berkshire SL4 6EW, UK*, and Department of Life Sciences,
University College at Buckingham, Buckingham, UK

A field study of the polymorphic African butterfly *Danaus chrysippus* L. at Dar es Salaam, Tanzania (1972–73) indicated that mating may be non-random between forms *dorippus* and *aegyptius*[1] and that seasonal sexual selection occurs[2]. Subsequently, a long-term breeding programme revealed a heterozygous phenotype[3] which closely resembles *dorippus*, and allowed estimates of heterozygote frequency in the field[4]. Analysis of mating records (1974–75) shows that males visibly heterozygous at the controlling C locus (from *transiens*)[3,4] possessed a highly significant mating advantage over both homozygous phenotypes throughout the study period, although pair composition among the three genotypes was random. I propose here that balancing selection, mediated mainly through male competition for mates, makes a decisive contribution to the control of the polymorphism.

Sampling was carried out several times a week for 17 consecutive months (April 1974–August 1975). All captures were marked before release to avoid double counting. The data (Table 1) consist of 340 observed pairings and 1,519 unmated males. As monthly samples were too small to be of much value, they were amalgamated into two annual seasons, one being verdant and relatively cloudy, wet and cool (April–August), when the frequency of *aegyptius* rises rapidly, and the other hot and dry punctuated by a short rainy season (September–March), when *dorippus* predominates[5]. Heterogeneity between mated and unmated samples was tested in $2 \times 3 \times 3$ contingency tables and χ^2 analysed[6] (Table 2).

The analysis shows that *transiens* males had consistently and very significantly higher success in mating than both homozygous phenotypes and that the effect was independent of season and changes in morph-ratio. Residual heterogeneity was not significant. As *CC* and *Cc* butterflies are not always recognizable phenotypically, genotype numbers (Table 3) are estimated by applying a correction for expressivity based on breeding data. The expressivity of *c* in known heterozygotes is modified by a closely linked B locus: 75% $(n = 173)$ of *B-Cc* and 45% $(n = 129)$ of *bbCc* butterflies were *transiens*[4], and these values were used to estimate *Cc* numbers from the number of *transiens* observed. Fitness (Table 3) of *CC* males was low (9–18%) in both wet seasons, rising to 79% in the dry season. In contrast, *cc* males had a fitness of 60–64% in the wet seasons, falling to 15% in the dry season. Differential and seasonally alternating mating fitnesses of this magnitude must make a major contribution to the synchronized cycling in morph frequency observed in four successive years (1972–75)[4,5]. Within seasons, there is no evidence for non-random mating among the three C-locus genotypes (within the mating samples) or for sexual selection in females.

How could such powerful selection for heterozygous males operate? Female preference for them could contribute but is probably not the key factor because it would imply synchronized seasonal switches of the secondary preference (for either *CC* or *cc* males) by all three female genotypes—if this were not the case, non-random mating would be detectable in large samples. *Cc* males (but not females) are significantly larger than both

	Total	905	556	398	1,859	

homozygotes[4], which could give them a competitive edge through faster flight. However, the mean forewing length of mated males ($\bar{x} = 37.9$ mm, $n = 161$) did not differ significantly from those unmated ($\bar{x} = 38.0$ mm, $n = 881$) between October 1974 and September 1975; thus selection based on size alone is ruled out. Alternatively, the male aphrodisiac pheromone, essential in courtship[7–9], might differ qualitatively or quantitatively between genotypes, although this possibility received no support from a chemical analysis of 50 pairs of hairpencils and wing pouches from each genotype (J. Meinwald, personal communication). However, it is known that male *D. chrysippus* must spend several days collecting pheromone precursors (pyrrolizidine alkaloids) from plants; therefore those males able to maintain the highest foraging rates are likely to achieve earlier matings and greater overall success.

The major colour differences between the genotypes (see ref. 4, Figs 1–16) could influence metabolic rate and hence activity levels. The amount of black and brown pigment is greatest in *aegyptius* and least in *dorippus* with most *transiens* intermediate. The darker coloration of *aegyptius* could allow it to maintain a higher body temperature, due to superior absorbance of radiant heat, during the cooler, cloudier months. It is interesting that *aegyptius* is the only form in the cooler subtropical parts of the species' range at both its northern and southern limits. Conversely, enhanced reflectance could provide relative protection for *dorippus* during the hot, dry season, a suggestion supported by the fact that it is the only form in the arid regions of northern Kenya and Somalia[4,10]. The intermediate heterozygote could be better adapted than either homozygote to median radiation values and therefore better able to maintain optimum activity through the vicissitudes of a climate which can feature substantial wet or dry periods out of season, with successive years rarely having a consistent pattern.

Table 2 Analysis of χ^2

Source of variation	χ^2	Degrees of freedom	Probability
Morphs × periods	124.16842	4	9.00×10^{-10}
Proportions mating × periods	14.66944	2	6.52×10^{-4}

	Fitness	*0.178*	*1*	*0.643*	

Genotype numbers are based on corrections for expressivity (see text).

These results are of interest in three respects: (1) they provide a rare[11] and unusually explicit example of heterozygous advantage at a single locus in a wild population. (Linkage disequilibrium involving the C and two other loci[3-5] and epistasis[4] implies that the real unit of selection is a supergene or inversion.) (2) The data show that heterozygous advantage is a mechanism capable of both conserving and releasing as required the genetic diversity on which selection can act cyclically in an oscillating climate. I emphasize here that the generation time of *D. chrysippus* is short in equatorial regions with 13–14 overlapping generations a year and that similar marked changes in morph frequency are known in other tropical species such as *Catopsilia florella*[12] and *Hypolimnas misippus*[13,14], (3) I conclude that male competition predominantly determines the outcome of sexual selection in *D. chrysippus* and outweighs female choice, receptivity or allure which are more often identified as critical factors in insects[15].

I thank Professor J. Meinwald for pheromone analyses on male *D. chrysippus* from Dar es Salaam and Dr P. O'Donald for helpful suggestions.

Fluoromevalonate acts as an inhibitor of insect juvenile hormone biosynthesis

Gary B. Quistad, David C. Cerf, David A. Schooley & Gerardus B. Staal

Departments of Biochemistry and Biology, Zoecon Corporation,
975 California Ave, Palo Alto, California 94304

The potential of analogues of insect juvenile hormones (JHs) for pest control has been demonstrated by the application of methoprene for the selective control of certain insects, including several mosquito species, the cigarette beetle and the hornfly[1]. Compounds that impede JH production could offer a potentially more attractive method of control because accelerated metamorphosis would shorten the lifetime of the larvae, the stage that usually does maximum damage to the host plant. Of the few anti-juvenile hormone (AJH) agents described[2–5], only precocenes evoke all the required biological responses, but they affect a few insect taxa of minor economic importance. Their activity is thought to result from cytotoxicity[6,7] in the corpora allata. In view of similarities between the biosynthesis of the carbon skeletons of insect JHs[8,9] and farnesyl pyrophosphate (a precursor of steroids and other terpenoids[10]), compounds that inhibit the early steps in the biosynthesis of cholesterol might be expected to suppress JHs. Although this concept has already been explored without success[11,12], we now report the inhibition of juvenile hormone biosynthesis (AJH activity, see Table 1 legend) by a fluorinated mevalonate (tetrahydro-4-fluoromethyl-4-hydroxy-2H-pyran-2-one, FMev, Fig. 1) which until now was known only to be hypocholesterolaemic[13–15].

AJH activity was observed initially when 0–24-h third-instar larvae of the tobacco hornworm (*Manduca sexta*) were treated topically with 100 μg of FMev, which induced three types of effects, all directly related to JH deficiency. First, intense black pigmentation was often observed after the succeeding moult (to fourth instars). In *Manduca* this is known to result from JH deficiency[16,17] and it therefore serves as a diagnostic tool in screening for JH suppressing activity. There were further signs of antagonism at the end of this instar, when many larvae started to show the prepupal burrowing behaviour normally occurring one instar later. In this case, the subsequent moult (to the fifth instar) often resulted in miniature pupae or intermediates between larvae and pupae with a varying mosaic of larval and pupal cuticle (Fig. 2). These morphologically premature pupae and intermediates were generally nonviable. Given higher doses, third-instar larvae started prepupal burrowing at the end of the third instar and produced pupal intermediates in the fourth instar. All these effects of FMev could be averted by concurrent application of a very active juvenoid such as hydroprene; this 'rescue' confirms that the observed symptoms can be attributed to JH deficiency. A high dose of FMev (2.5 mg) injected into adult *M. sexta* 1–2 h after eclosion also prevented the maturation of eggs. This anti-gonadotropic activity is consistent with the expected properties of an AJH compound.

A considerable morphogenetic effect was observed after treatment of fifth-instar *Galleria mellonella* larvae with FMev. Untreated larvae normally developed through three additional instars before forming pupae approximately 15 mm long. Larvae treated with FMev produced premature pupae in any of these three subsequent instars, the smallest sixth-instar pupae being 4 mm long. Some of the large premature pupae survived to generate precocious miniature adults of otherwise normal appearance.

The AJH properties of FMev seem to be manifest only in lepidoptera. Larvae of the six moth species examined responded in various degrees to the AJH effects of FMev (Table 1). No such effects were found when the larval stages of the following non-lepidopteran insects were treated with FMev: *Musca domestica* (housefly), *Aedes aegypti* (yellow fever mosquito), *Schistocerca nitens* (vagrant grasshopper), *Dermestes maculatus* (hide beetle), *Hypera postica* (alfalfa weevil) and *Oncopeltus fasciatus* (milkweed bug).

Table 1 Anti-juvenile hormone* activity of FMev on several lepidopteran species

Insect	Instar treated	ED_{50} (mg per g)
Manduca sexta (tobacco hornworm)	Third	0.7
Samia cynthia (Cynthia moth)	Third	1.0
Phryganidia californica (California oak moth)	Third	1.0
Galleria mellonella (greater wax moth)	Fifth	40
Spodoptera exigua (beet armyworm)	Third	44
Heliothis virescens (tobacco budworm)	Third	>200

0–24-H larvae of the indicated instar of each species were treated topically with 1 μl acetone dilutions of FMev and reared to the last larval instar. Observations were made throughout the bioassays. The ED_{50} (effective dose causing 50% of the treated larvae not showing acute toxicity from FMev to demonstrate precocious metamorphosis or prepupal behaviour) is based on the mg mass of compound per g of insect. In the case of *H. virescens*, the ED_{50} was never achieved, although a small percentage of the treated larvae did manifest premature pupation.

* We use the term 'anti-juvenile hormone (AJH) agents' to describe those chemicals which induce symptoms of JH deficiency, including premature metamorphosis. This general term can encompass the precocenes (cytotoxic to the corpora allata[6,7]), FMev (inhibitor of JH biosynthesis) and AJH agents of as yet obscure[3–5] mechanism of action.

FMev exhibits moderate toxicity at high doses for lepidoptera which are less sensitive to the AJH effects of FMev. However, for more sensitive species such as *M. sexta*, toxicity is minor (5–10% at ED_{50}). Because this acute toxicity also occurs in insect species not responding with precocious metamorphosis and because concurrent application of a juvenoid did not rescue this mortality, we conclude that this toxicity is not related to inhibition of JH biosynthesis and results from another mechanism. A possible explanation for the nonspecific mortality is metabolic conversion of FMev to fluoroacetate, a potent biocide. Treatment of *M. sexta* larvae with ethyl fluoroacetate revealed substantial toxicity without AJH effects.

We originally tested FMev for AJH activity based on the rationale that it could serve as an antimetabolite of mevalonate and/or homomevalonate. Preliminary studies affirm that FMev

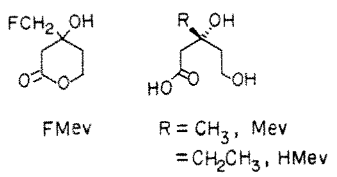

Fig. 1 Fluoromevalonolactone (FMev), mevalonate (Mev, precursor of cholesterol and insect juvenile hormones) and homomevalonate (HMev, biosynthetic precursor of several insect juvenile hormones). FMev has been synthesized previously[14,15], but we synthesized it by treating ethyl fluoroacetate (highly toxic) with allylmagnesium bromide, followed by ozonolysis of the resultant diallylcarbinol from the Grignard reaction. The ozonide was reduced with sodium borohydride to give 3-fluoromethyl-1,3,5-pentanetriol, which was selectively oxidized to FMev with chromium trioxide in aqueous sulphuric acid (Jones reagent).

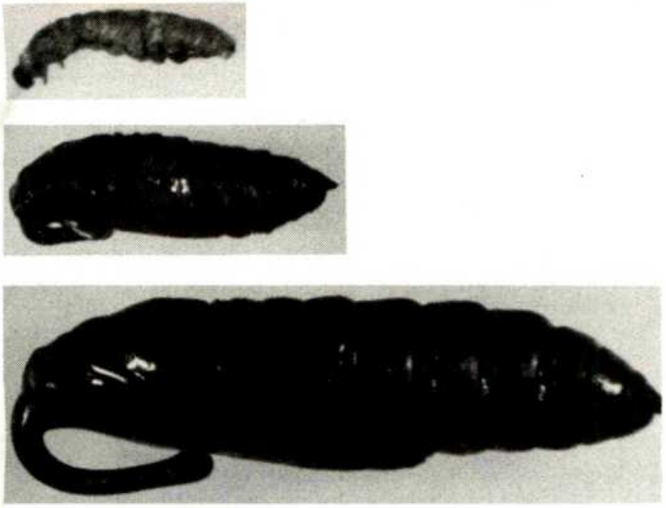

Fig. 2 A larval–pupal intermediate, precocious pupa and normal pupa (from top to bottom) for *Manduca sexta* (tobacco hornworm). The accelerated metamorphosis for the intermediate and precocious pupa was induced by treating third-instar larvae with 100 μg of FMev.

inhibits the biosynthesis of insect JHs. The titre of JHs in *M. sexta* haemolymph is markedly reduced when larvae are treated topically with the physiologically effective dose of FMev (J. P. Edwards and B. J. Bergot, unpublished). An *in vitro* study with homogenates of *M. sexta* corpora allata showed significant inhibition of metabolism of ^{14}C-mevalonate and ^{3}H-homomevalonate to subsequent precursors of JHs (F. C. Baker, unpublished).

We have synthesized many analogues of FMev, mevalonolactone and related compounds. Five of them show AJH activity on lepidopteran larvae, but are less active than FMev. Four of these marginally active compounds are likely to be active because of their facile metabolism to FMev (for example, 3-fluoromethyl-1,3,5-pentanetriol). The difluoromethyl analogue of FMev was five times less active on *M. sexta* then FMev, whereas the trifluoromethyl analogue was devoid of AJH properties.

We have thus found that a compound which is hypocholesterolaemic may also have AJH activity; perhaps other hypocholesterolaemic agents may serve as chemical structures which can be manipulated by analogue synthesis to optimize AJH activity. However, tests of several chemically unrelated materials with similar hypocholesterolaemic activity have revealed no other active inhibitors (ref. 12 and G.B.Q. *et al.* unpublished).

The activity of FMev by itself is not sufficiently high, even on lepidopteran pests, for commercial exploitation. Nevertheless, FMev should be an invaluable tool in studies of lepidopteran physiology and endocrinology. We hope the novel mode of action—inhibition of JH biosynthesis—can form the basis for new selective insect-control agents.

A protein called immaturin controlling sexual immaturity in *Paramecium*

Nobuyuki Haga & Koichi Hiwatashi

Biological Institute, Tohoku University, Aoba-yama,
Sendai 980, Japan

As in many metazoans, clones of some species of *Paramecium* have, after conjugation, a period of immaturity during which the cells cannot mate. The duration of immaturity is measured by the number of cell generations, which remains fairly constant, although duration in time varies with rate of cell reproduction[1–3]. Genic involvement is shown by mutants with reduced periods of immaturity[4]. In three different groups of *Paramecium* species, the cytoplasm of immature cells apparently contains the same substance which represses mating activity when injected into sexually mature cells[5–7]. The immaturity-inducing substance seems to be absent from sexually mature cells, as brei made not only from mature cells in the stationary phase (mating-reactive cells), but also from those in the log phase (mating-non-reactive cells), does not repress mating activity when injected into mature cells[5]. Variations in the amount of the substance during immaturity suggest that it controls the duration of the period[8]. We have isolated and partially characterized the substance—a single protein called immaturin. The activity of immaturin is dose dependent and associated with a heat-labile protein of molecular weight (MW) 10,000.

For quantitative assay of immaturin activity by microinjection, we grew each injected cell in a glass capillary (0.6 mm inside diameter, 75 mm long) containing 20 μl fresh lettuce-juice medium inoculated with a non-pathogenic strain of *Klebsiella pneumoniae* 1 day before use[9]. The cell in each capillary produces exactly 16 cells which then enter synchronously into stationary phase. The 16 cells are isolated and then provided with mating-reactive cells of complementary mating type. If they are mature, at least 13 of the 16 form mating clumps with the cells of complementary type (each clump consisting of one cell of the type being tested, and a group of reactive cells of the opposite type). The activity of injected immaturin was measured by the percentage of sets of 16 forming less than 13 clumps (the clumps were usually from 10 to 0 when the injection was effective).

The immaturity period of the strains of *Paramecium caudatum* we used was about 50 fissions after conjugation. For isolation of immaturin, cells ($\sim 9 \times 10^7$), about 20 fissions after conjugation, were washed with solution A (10 mM KCl, 5 mM $MgCl_2$, 10 mM Tris-HCl, *p*H 7.4) and then with solution A′ (solution A + 0.25 M sucrose) by slow centrifugation (100–200*g*). The pellet was homogenized with an injection syringe[10] and the brei thus obtained was centrifuged at 105,000*g* for 60 min at 2 °C. The supernatant was filtered through a 0.45-μm Millipore filter. The filtrate was applied to a Sephadex G-50 column and each fraction was assayed by injecting 15-pl samples into mature cells. When the most active fraction (no. 32) was injected, 16 clones out of 20 formed less than 13 clumps when tested. Among those 16 clones, 4 formed no clumps and 10 formed less than 8 clumps. When the same fraction from mature cells was injected, 40 out of 51 formed 16 clumps and the remaining 11 formed more than 12 clumps. Then, the active fractions (nos 31, 32 and 33 in Fig. 1) were chromatographed on a DEAE-Sephadex A-25 column. The activity of immaturin was eluted as a single peak at about 400 mM NaCl (Figs 1, 2). In the test of the peak fraction (no. 10), 15 clones out of 19 injected formed less than 13 clumps. Among those 15, 10 formed less

Table 1 Purification of immaturin

Step	Total protein obtained (mg)	No. of cells injected	Activity (%)	Protein injected per cell (pg)	Specific activity
(1) 105,000*g* supernatant	154.4	22	72.7	15	4.8
(2) Sephadex G-50 chromatography	3.6	25	88.0	0.7	125.7
(3) DEAE-Sephadex chromatography	0.013	25	80	0.03	2666.6

Activity is % of mature clones which contained more than 25% immature cells after injection. Specific activity is defined as activity per pg injected protein. Amount of protein was determined by the method of Lowry *et al.*[21].

than 9 clumps. The degree of purification was calculated on the basis of the activity of the 105,000*g* supernatant.

The relation between concentration of immaturin and activity of each concentration was first examined by injecting a dilution series of the supernatant. The activity (% of immaturity brought about by injection) wasnearly proportional to the amount of protein injected. When specific activity was defined as activity per pg injected protein, three purification steps increased the specific activity of immaturin about 550-fold (Table 1). To determine the purity of each fraction, samples from the DEAE fractions were subjected to acrylamide-gel electrophoresis by a modified method of Davis[11]. Lyophilized material from the peak fraction (no. 10) of the DEAE-Sephadex elution was dissolved in 300 μl of solution A and 100-μl samples were applied to a gel containing 11.25% acrylamide. Only a single band was strongly stained with Coomassie brilliant blue, and no minor band was detected (Fig. 3).

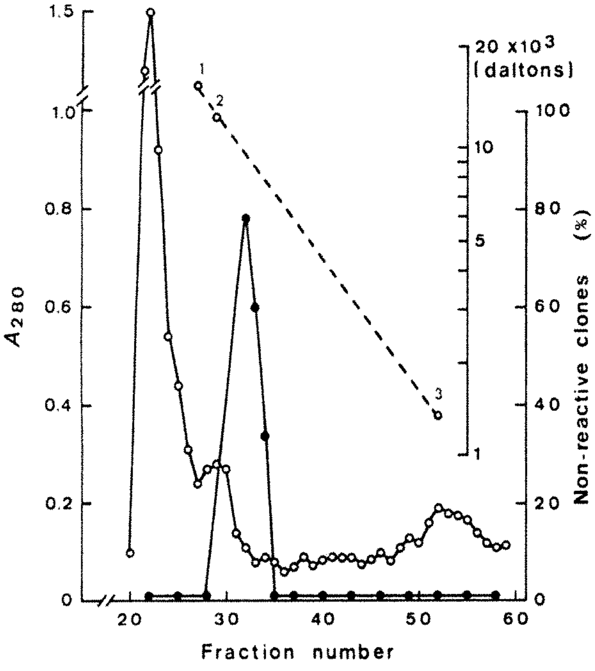

Fig. 1 *a*, Sephadex G-50 elution profile of the soluble fraction of sexually immature cells. A 2.5-ml sample of the supernatant obtained by homogenization and 105,000*g* centrifugation of immature cells (9×10^7) was applied to a Sephadex G-50 (Pharmacia, fine) column (2.5×70 cm) and chromatographed at 5 °C. Each fraction (4.4 ml) was assayed by injecting 15-pl samples into mature cells. ○, 280-nm absorbancy; ●, activity of immaturin (% of non-reactive clones brought about by the injection). Broken line, calibration curve of MWs: 1, myoglobin, 18,500; 2, cytochrome *c*, 13,000; 3, cyanocobalamin, 1,355 (all Sigma). *b*, DEAE elution profile. Active fractions (nos 31–33) from the Sephadex G-50 filtration were applied on a DEAE-Sephadex A-25 column (0.9×15 cm) containing 4 ml gel. Before application of the sample, the column was equilibrated with 50 ml solution A (see text). The elution medium was a linear gradient of from 0 to 500 mM NaCl in solution A. Size of each fraction was 4.4 ml ○, 280-nm absorbancy; ●, activity; broken line, concentration of NaCl.

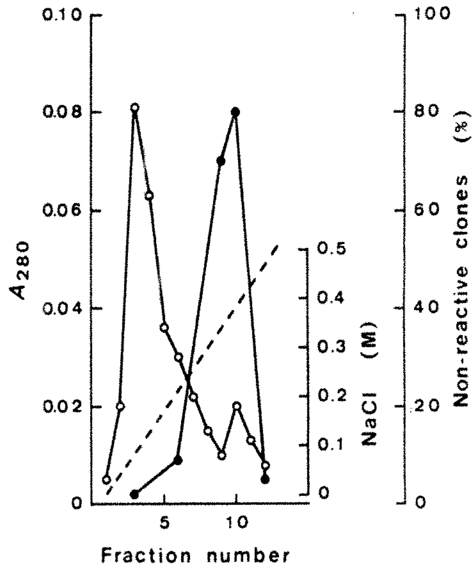

Fig. 2 Polyacylamide-gel pattern of the peak fraction of the DEAE chromatography (see text for details).

The MW of immaturin was estimated to be about 10,000 from Sephadex G-50 chromatography by comparing with marker molecules (cyanocobalamin, cytochrome *c* and myoglobin, Fig. 1). Determination of the MW using SDS-polyacrylamide gel electrophoresis was unsuccessful because the standard curve of MWs <11,000 was not linear. Immaturin lost its activity when exposed to polyacrylamide gel-bound insoluble trypsin (Sigma) for 65 min at 27–28 °C, whereas no loss of activity was observed when exposed to heat-inactivated, insoluble trypsin or agarose-bound, insoluble ribonuclease (Sigma) (Table 2). The activity was completely destroyed when exposed to 100 °C for 6 min.

Table 2 Activity of immaturin when treated with enzymes and heat

Treatment	No. of cells injected	No. of non-reactive clones	Activity (%)	Confidence interval (90%)
None	28	22	78.6	62–92
Trypsin	28	1	3.4	0.1–14
Heated trypsin	25	17	68.0	48–84
Ribonuclease	26	14	53.8	36–72
100 °C, 6 min	26	0	0	0–10.2
No injection	30	0	0	0–10

Insoluble trypsin (2.5 U, Sigma) or insoluble ribonuclease (5 U, Sigma) was added to fraction no. 9 from the DEAE-Sephadex column, in a solution containing 10 mM KCl, 5mM $MgCl_2$ and 10 mM Tris-HCl (*p*H 7.4), and incubated in a waterbath with shaking at 27–28 °C for 65 min. The particle-bound enzymes were removed by centrifugation at about 1,000*g* for 5 min and the supernatants were assayed for immaturin activity by injecting about 15 pl into mature cells. Heated trypsin was obtained by heating at 100 °C for 6 min. Activity is per cent of mature clones which contained more than 25% immature cells after injection (here called non-reactive clones).

From these results we conclude that immaturin is a heat-labile protein, which we isolated almost free of other proteins. We did not rigorously test the sample for purity from organic substances other than protein, but the purification procedure described above probably removed most of them. As repeated washing by ultrafiltration through a Diaflo membrane UM2 (Amico) at 4 °C under a pressure (2.0 kg cm^{-2}) of nitrogen gas did not decrease the activity of immaturin, it is unlikely that small molecules attached to protein have the immaturin activity. This experiment also seems to eliminate the possibility that loosely bound, small molecules are cofactors of immaturin, though it does not completely eliminate the possibility that tightly bound small molecules are cofactors or the site of immaturin activity.

Mating ability in *Paramecium* depends primarily on the presence of sexual cell-recognition molecules, located on the ciliary membranes and called the mating substances[12,13]. Specificity of the mating substances is known to be controlled genetically[9,14,15]. Immaturin evidently inhibits the expression of mating substance activity but the mechanism of its action, or its target of action within a cell, remains to be investigated. Immaturin may be comparable to several factors controlling gene expression, such as insulin and steroid hormone receptors in higher animals[16,17], repressors in *Escherichia coli*[18], CGA of *E. coli*[19], and the inhibitor of rRNA synthesis in *Xenopus*[20]. Isolation and characterization of immaturin should facilitate study of mechanisms of genic control of mating ability in *Paramecium*, of genic regulation of life-cycle phases in clonal ageing, and of cell differentiation in general.

We thank T. M. Sonneborn, D. L. Cronkite and G. H. Beale for helpful comments on the manuscript. This work was supported by grant 348001 from the Ministry of Education, Science and Culture to K.H.

Lyt 1^+23^- cells appear in the thymus before Lyt 123^+ cells

Bonnie J. Mathieson*, Susan O. Sharrow†, Yvonne Rosenberg* & Ulrich Hämmerling‡

* Laboratory of Microbial Immunity, National Institute of Allergy and Infectious Diseases, Bethesda, Maryland 20205
† Immunology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

Most thymocytes are either immature or functionally deficient and express a series of lymphocyte cell-surface antigen markers designated Lyt 1, Lyt 2 and Lyt 3 (refs 1, 2) which have been useful in distinguishing functional subsets of T cells[3,4]. In contrast, a small population of cortisone-resistant thymocytes (CRT), confined to the thymic medulla after acute corticosteroid treatment are functionally more mature. These cells, like peripheral T cells, have restricted expression of Lyt antigens and mostly are either Lyt 1 or Lyt 123 cells[3–5]. It has thus been assumed that all thymocytes initially are Lyt 1^+, 2^+, 3^+ and by differentiation lose either Lyt 1 or Lyt 2, 3 to result in Lyt $1^+(23^-)$ and Lyt $(1^-)23^+$ cells[6–8]. Using immunofluorescence (IF) and flow microfluorometry (FMF) analyses to detect Lyt antigen expression quantitatively without the requirement for cell lysis, we have now re-examined the expression of Lyt 1, 2 and 3 antigens on murine fetal thymocytes from 14 to 19 days of gestation and on normal thymocytes from birth to 2–3-month-old adults. These studies demonstrate that cells with the Lyt 1^+23^- phenotype first appear in the thymus several days before Lyt 123^+ thymocytes are detected, and suggest either a micro-environmental or site-specific influence for phenotypic differentiation and/or two independent, pre-committed lineages.

The details of the methods used for FMF detection of IF for Lyt have been reported previously[5]. For these studies, in addition to alloantisera prepared in our laboratory, monoclonal reagents for Lyt 1.1 and Lyt 2.2 specificities have been used to avoid any problems of nonspecific reactions. In our experience, these monoclonal reagents give patterns of reactivity both in adult lymphoid tissue distribution and strain distribution equivalent to the related, allelically specific antisera described by others[9].

Data from one experiment are shown in Table 1. With fetal thymocytes from C57BL/6-Ly-1^a mice, an increased proportion of Lyt 1^+ thymocytes are observed between 15 and 19 days of gestation. Using monoclonal anti-Thy 1.2, 80% of the fetal thymocytes are positive for Thy 1 expression at the 15 and 16 day points, whereas >97% are positive for Thy 1 at later time points (data not shown). These positive cells also express quantitatively increased amounts of Lyt 1 antigen. This latter conclusion is drawn from the increase in median fluorescence units (FU) for the thymocytes at each time point and can be seen more explicitly in data from an additional experiment in Fig. 1. This increase in the level of Lyt 1 expression per cell occurs despite the fact that cell size is decreasing through this period, as reflected by the decrease in the median light scatter units. For comparison, these same parameters are shown for adult thymocytes. Thus, in contrast to adult thymocytes[10], the quantitative level of the Lyt 1 phenotype is not related to cell size.

Until day 17 of gestation, almost no cells expressing Lyt 2 or Lyt 3 antigen are seen (Table 1). Figure 2 shows the IF profiles of Lyt 3.2 expression on thymocytes from embryos at days 16 and 17 of gestation. In a series of six experiments, a marked increase in the proposition of thymocytes expressing both Lyt 2 and Lyt 3 is seen (7–15% above control background on days 14–16 to >70% on day 17). The adult phenotype, 10% Lyt 1^+23^- : 90% Lyt 123^+ which we previously described[5], is observed at 18 days, about 24 h before birth in this strain. At no time are all the fetal thymocytes Lyt 123^+.

The dramatic appearance of the Lyt 123^+ cells on day 17 of gestation follows differentiation of cortical histological sites in the murine thymus observed by others at 15 days of gestation[11,12]. The appearance of these cells also corresponds to a marked increase in cell number which occurs at this time. These data suggest either than Lyt 123^+ cells are derived from Lyt 1^+23^- precursors, or that two separate pre-committed lineages for Lyt 1^+23^- and Lyt 123^+ cells in the thymus take up residence at different times during ontogeny. The concept of two independent lineages of cells, either or both of which may

0028–0836/81/030179—03$01.00

Table 1 Lyt expression on fetal thymocytes

Fetal age (days)	Lyt 1 Minimum % positive	Lyt 1 Median FU of positive cells	Lyt 2 % positive	Lyt 3 % positive	Median LSU of viable cells	% Large cells	No. of cells per thymus
15	50.1	201 (77)	6	ND	606	70	4×10^5
16	51.8	236 (69)	15	13	600	68	5.7×10^5
17	95.8	375 (42)	72	73	564	63	3.3×10^6
19	96.5	365 (39)	79	80	516	52	4×10^6
Adult	98.4	439 (31)	91	91	440	21	$1\text{-}2\times10^8$

Fetal age was determined by calculating from the date of detection of a vaginal plug (plug date = day 0). Minimum % positive was determined by the number of stained cells above the intersection of the IF profile of anti-Lyt 1.1 plus fluoresceinated goat anti-mouse immunoglobulin (FlGAMIg) stained cells and the IF profile of the cells treated with FlGAMIg alone. This type of intersection is seen in Fig. 1. The median values for Lyt 1^+ cells are calculated above the intersection (145 FU) for this experiment. FU are calculated as previously described[10]. For comparison the value for surface immunoglobulin on B cells is ~6,000 FU. Median FU for the controls are given in parentheses next to the FU values for Lyt 1^+ cells. Light scatter units (LSU) are arbitrary units of measurement reflecting cell size which have been described by others and which we have used previously for comparison of thymocytes[5,27]. Large thymocytes are reduced to about 20% of the total thymocyte population within 1 week of birth. The number of cells per fetal thymus was determined from the total cell recovery of 7–12 embryos at each time point. ND, not determined.

subsequently be subdivided, is certainly not a new proposal for thymocyte differentiation. However, the characterization of these two lineages with different thymocyte phenotypes in the fetal development of the thymus has not been demonstrated previously.

This finding that Lyt 1^+23^- cells are present in the fetal thymus before Lyt 123^+ cells contrasts with the previously proposed concept that all thymocytes are Lyt 123^+ before differentiative loss of Lyt 1 or Lyt 2 and Lyt 3 (ref. 4). After birth, CRT[3–5], the thymus migrant population[13] and thymocytes non-agglutinated with peanut lectin[10] all contain both Lyt 1^+23^- and Lyt 123^+ cells, presumably in a more mature state of differentiation. In normal adult thymocytes, Lyt 1^-23^+ cells are not seen by IF with the quantitative methods used here[5,10]. Therefore, if one still wishes to assume that all thymocytes and T cells differentiate through an Lyt 123^+ state, it is required that at least during ontogeny Lyt 1^+23^- cells generate Ly 123^+ cells, and from those, more mature Lyt 1^+23^- cells and Lyt 123^+ cells which exit from the thymus. These data do not exclude the possibility that some Lyt null precursors express all three Lyt antigens simultaneously, nor do they exclude the possibility that a small number of Lyt 123^+ precursors are instantly driven to Lyt 1^+23^- in early ontogeny.

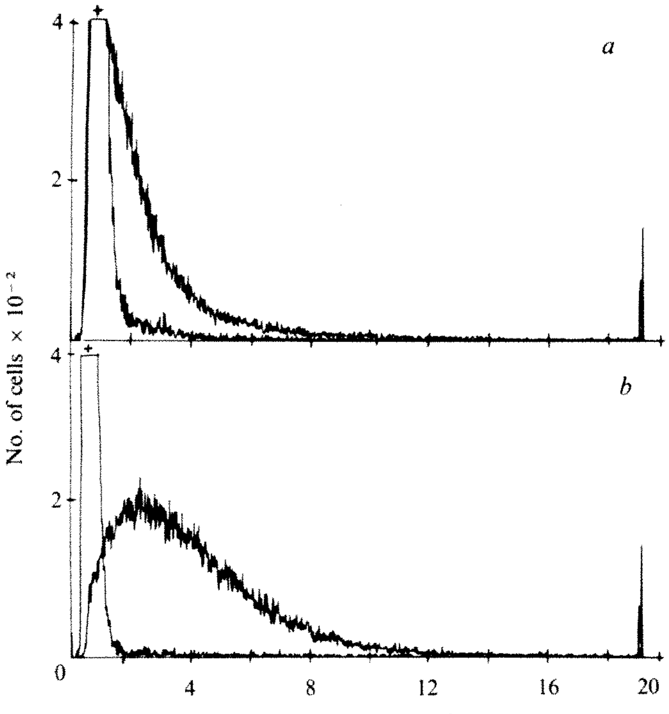

Fig. 1 Fetal thymocytes from B6-Ly 1^a mice which express the Lyt 1.1 antigen were treated with anti-Lyt 1.1 monoclonal antibody (clone line 39/107) and FlGAMIg. The details of the fluorescent reagents and the IF procedure are published elsewhere[5] as are the details of the use of the FACS-II (Becton Dickinson) for quantitative FMF analysis[5,27]. The data configurations presented in *a* and *b* as the IF profiles on 50,000 cells per sample are also described elsewhere[28]. In *a*, 15-day fetal thymocytes, the positive cells (cells with >160 FU), are compared with negative control fetal thymocytes from B6 mice which express the Lyt 1.2 antigen. As seen in *b*, the fetal thymocytes at day 17 of gestation are much more positive, with a reduced overlap between the positive cells and the negative control, in this case FlGAMIg treatment alone.

The fetal thymus of the mouse develops in a particular histological pattern of differentiation. Initially, the thymic rudiment appears as a largely epithelial structure with a sparse lymphoid population, comparable in both lymphoid type and size to the medullary area of the differentiated adult thymus. Subsequently, the densely lymphoid cortical areas which are largely composed of small thymocytes appear and a particular histological type of cortical epithelial cell develops in the fetal thymus[11,12,14]. It is almost certain that some stem cells in the early fetal thymus are capable of differentiating into Lyt 123^+ cells, because Owen and Ritter[14], Mandel and Russell[11,12], and Kamarck and Gottlieb[8] have observed small cortical thymocyte differentiation in murine fetal thymus organ cultures deprived of traffic of additional cells from the periphery. Furthermore, Kamarck and Gottlieb[8] indicated that Lyt 123^+ cells could differentiate in these fetal organ cultures. This is being tested further with fetal thymus transplants, which are derived from mice expressing allelically different Lyt specificities.

Thus, the microenvironment of the thymus may be critical for phenotype generation. When the early 'medullary' epithelial environment is predominant, perhaps only Lyt 1^+23^- cells can develop. Once the cortical epithelial cells[11,12,14] have differentiated an appropriate site for Lyt 2, 3 expression, these antigens may then be detected on populations subsequently differentiating in the thymus. This would presume a common precursor with no site-specific homing, but site-specific differentiation would predict that adult thymic repopulation studies would show the adult Lyt phenotypes and not the sequential pattern seen in ontogeny.

The alternative possibility of two separate lineages would more easily explain both the finding that there are, from an early time point in ontogeny, Lyt 1^+23^- thymocytes as demonstrated here, and that a small proportion of thymocytes with this phenotype are found throughout adult life[5]. This could also explain other phenotypic subset analyses of the differential expression of Thy 1 in the thymus[15], as well as sequential reactivity of fetal thymocytes to phytohaemagglutinin and concanavalin A[16].

Avian thymus studies indicate that the differentiation involves two lineages which may even have different pre-thymic path-

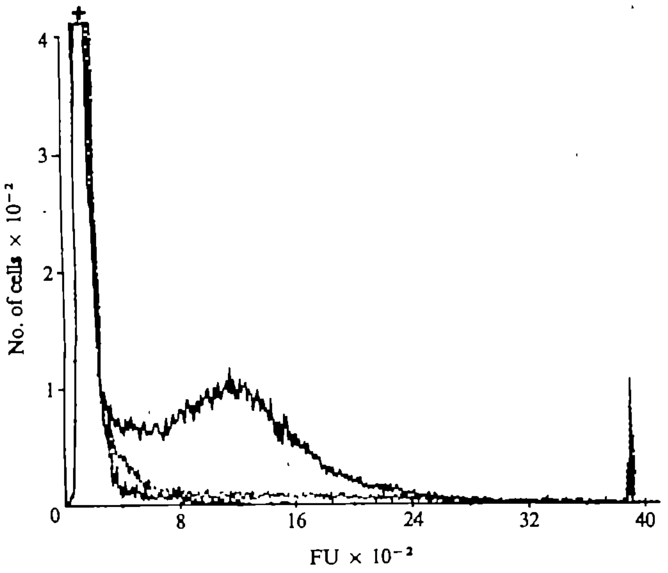

Fig. 2 Fetal thymocyte from B6-Ly-1^a mice which express the Lyt 3.2 antigen were treated with anti-Lyt 3.2 serum[9] and FlGAMIg antibodies. At 17 days gestation (——), the IF is seen as a peak of positive cells whereas at day 16 (----) the IF is less than 10% above the 16-day fetal thymocytes treated with FlGAMIg (—·—·) alone. The median value of the Lyt 3^+ cells was not noticeably changed in these experiments and varied only between 1,200 and 1,600 FU. The FlGAMIg control has 3.8% cells >400 FU and 1 6% of cells >800 FU.

ways[17,18]. An early cohort of thymic cells passes through the bursa of Fabricius, a B-cell differentiation site in birds, and takes up residence in the thymus. Cells, which populate thymus at a later time in development, apparently bypass the bursa. This parallels the two-stage distinct sequential appearance seen for the two Lyt phenotypes reported here. One might even consider that precursors of Lyt 1^+23^- cells pass some similar B-cell site at which a T-helper function is in some way induced or programmed in the lineage. This is clearly hypothetical in the mouse, because no comparable unified B-cell generation site is known. However, there is evidence of separated functions of isolated subpopulations of Lyt differentiated peripheral T cells[19].

Finally, a combination model is proposed in which Lyt 1^+23^- cells give rise to two separate lineages only one of which 'seeks' a cortical site or pathway. This Lyt 123^+ lineage may require multiple divisions in the cortex for both functional and phenotypic differentiation and for repertoire development. The requirement for cell division has been documentated in other differentiation systems[20]. This model of separate lines with site-specific differentiation would be consistent with data and models of thymocyte differentiation presented by several investigators, including Weissman[21], Shortman and Jackson[15], Zinkernagel[22] and Stutman[23]. Although Leckband and Boyse[24] previously indicated a correlation with TL^- phenotype of CRT, a presumably more mature medullary thymic subpopulation, recent observations of Kisielow *et al.*[25] show TL^+ cells with differentiated Lyt phenotypes. Data obtained from analysis of thymic lymphomas[26] led us to propose earlier that such immature thymocytes might exist which were TL^+ but differentiated for Lyt phenotype. Thus, we favour this latter combination model which presumes independent pre-committed lineages with site-specific differentiation and therefore presumes nothing about the maturity of cells found in either the cortical or medullary site in the thymus.

We thank the members of the Laboratory of Microbial Immunity who have encouraged and supported our work, especially Dr R. Asofsky and Ms B. J. Fowlkes for provision of fluorescent reagents used in these studies, and V. Shaw and O. Childers for preparation of the manuscript. We also thank Dr E. A. Boyse for provision of the original breeding stocks of the B6-Ly congeneic mice, Dr M. Potter for provision of experimental mice, through a NCI contract, and Drs J. Wunderlich, N. Jerne and H. Holtzer for stimulating discussions during this work.

Selective inhibition of T suppressor-cell function by a monosaccharide

Ulrich H. Koszinowski* & Michael Kramer

Institut für Immunologie und Genetik, DKFZ, 6900 Heidelberg, FRG

Interactions between regulatory T lymphocytes and other cells are assumed to occur at the level of the cell surface. T cells which suppress the generation of specifically effector cells have been described as having antigenic, idiotypic, allotypic and I-region specificity[1–4]. Other T suppressor cells generated by *in vitro* cultivation with or without mitogenic stimulation[5,6] have suppressive activity for T and B cells but no specificity can be assigned to them. These T suppressor cells (T_s) inhibit various lymphoid functions—this either reflects their polyclonal origin or indicates that the structures recognized by the T_s receptors must be common for many cell types. Carbohydrates on cell membrane-inserted glycoproteins or glycolipids might function as specific ligands for recognition by cellular receptors or soluble factors. Almost all cell-surface proteins of mammalian cells are glycosylated. There is evidence for lectin-like carbohydrate binding proteins not only in plants[7] but also in toxins[8], viruses[9], prokaryotic cells[10] and even mammalian cells, including T cells[11]. A functional role for these lectin-like proteins has been described for slime moulds and suggested for the selective association of embryonic cells[12,13]. We report here that addition of a monosaccharide can counteract the effect of T suppressor cells during the generation of alloreactive cytotoxic T cells (CTLs) *in vitro*.

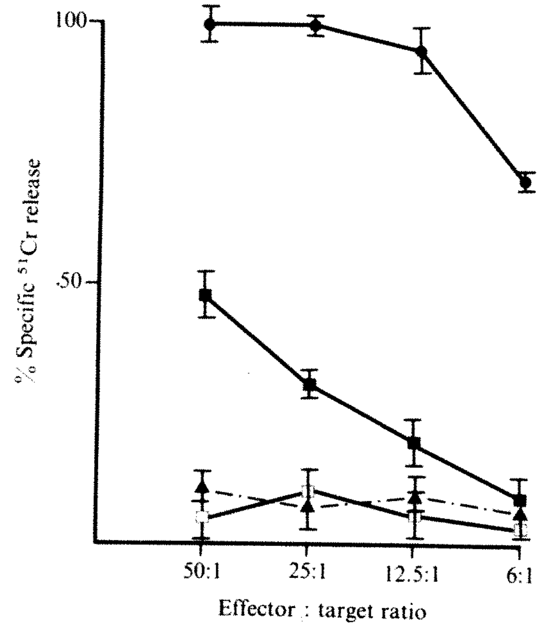

Fig. 1 Regulatory effects of MM on suppressor-cell function. Alloreactive CTLs were generated from C57BL/6J responder spleen cells by incubation with 2,000 rad-irradiated allogeneic DBA/2J spleen cells (6–8 week-old mice from the Institut für Versuchstierzucht, Hannover). Cells were cultivated in 24 flat-bottom Linbro plates (Flow) at a responder/alloantigen ratio of 1 : 1 and a concentration of 2.5×10^6 responder cells per ml RPMI medium supplemented with 10% heat-inactivated fetal calf serum and antibiotics. Cells were collected 6 days later and tested for cytolytic activity in the ^{51}Cr-release assay[17] using P-815 mastocytoma cells as targets. ●, Suppressor cells (T_s) from C57BL/6J mice were generated by precultivation in the absence of alloantigens using the method of Rollwagen and Stutman[15] with the modification that erythrocyte lysis was omitted. When tested for cytolytic activity after 6 days, these cells were found to be negative (▲). After addition of these precultivated cells to new cultures containing responder cells and alloantigens at the ratio of responder/T_s varying from 1 : 2 to 1 : 8 (this experiment 1 : 4), production of alloreactive CTLs was abolished (□). Addition of 10 mg ml^{-1} MM (Roth; Sigma; Calbiochem; Hoechst) counteracted the suppressive effect (■). Experiments were carried out in triplicate. Bars indicate standard deviations.

Nonspecific suppressor-cell production in *in vitro* cultivated lymphocytes by the plant lectin concanavalin A (Con A) can be inhibited by the addition of methyl-α-D-mannopyranoside (MM) during the induction phase[14]. We wondered whether similar phenomena could be demonstrated in a system without Con A. T_s were produced *in vitro* in cultures of spleen lymphocytes incubated in complete medium without antigenic stimulation for 6 days, as described elsewhere[15]. Suppressor cells produced in this way inhibit a variety of immune responses nonspecifically and without H-2 restriction. When added in graded numbers to a primary mixed leukocyte culture (MLC) on day 0, these cells were able to suppress or abolish the generation of alloreactive CTLs. This inhibitory activity was neither due to cell crowding effects (data not shown) nor to cytolytic activity in the suppressor cell populations[16]. Data from a representative experiment showed that generation of CTLs is abolished in the presence of suppressor cells (Fig. 1) and that these cells were not cytolytic after cultivation with antigen. Addition of 10 mg per ml MM to the culture system counteracted the suppressive effect, resulting in the reconstitution of a cytolytic response.

Treatment of the transferred cells with anti-Thy-1.2 and complement abolished their suppressive effects, demonstrating that the MM-sensitive suppression is a T cell-dependent phenomenon (Fig. 2).

Table 1 Ability of methyl-α-D-mannopyranoside (MM) to inhibit the function of suppressor cells

Molar concentration of sugar during CTL induction	Ratio of responder: suppressor cells	Ratio of killer: target cells required for 1 LU	r^2	% T_s activity
—	1 : 0	10.0	0.97	0
—	2 : 1	39.1	0.95	100
10^{-2}	2 : 1	15.8	0.99	20
10^{-3}	2 : 1	17.2	0.98	25
10^{-4}	2 : 1	18.6	1.00	30
10^{-5}	2 : 1	27.2	0.97	59

Methyl-α-D-mannopyranoside (Roth) was re-crystallized and added at different molar concentrations to the culture containing responder cells, allogeneic stimulator cells and suppressor cells. Effector cells produced in these conditions were tested for cytolytic activity at 4 effector: target cell ratios (third column). The killer: target cell ratio required for 1 lytic unit (LU), arbitrarily defined as the ratio resulting in 33% specific lysis in the 4-h assay period, was calculated by logarithmic curve fitting[17]. *r*, Coefficient of determination. The cytolytic capacity of suppressed responder-cell cultures was taken as 100% T_s activity.

Addition of the carbohydrate alone to the culture medium did not inhibit the generation of alloreactive CTLs. MM therefore does not interfere with antigen recognition, differentiation and expansion of alloantigen-specific T cells (Fig. 3*a*). Furthermore, no inhibition by MM was seen in the effector phase of cytolytic T

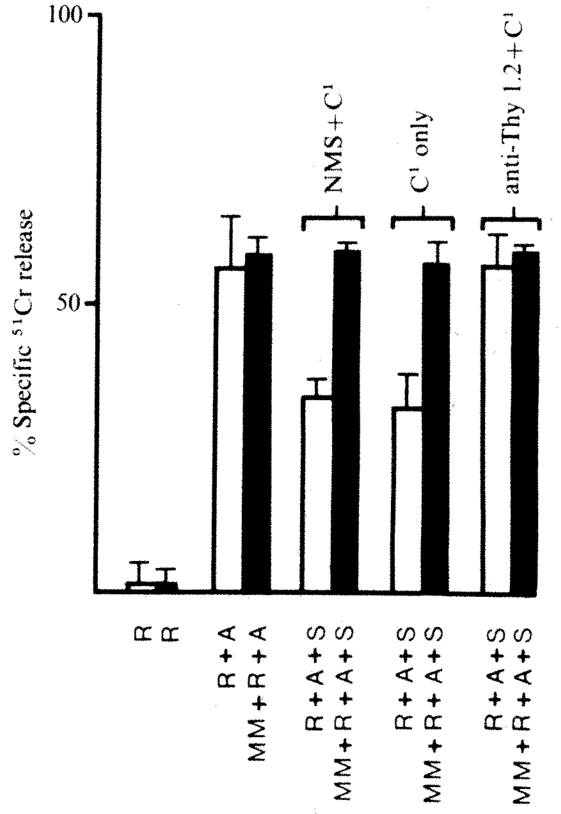

Fig. 2 Characterization of the MM-susceptible suppressor cells. Generation of alloreactive CTLs in presence or absence of MM and suppressor cells. After the 6-days induction phase, suppressor cells were incubated with either normal mouse serum (NMS) or anti-Thy-1.2 serum (1 : 20 final dilution) for 30 min at 20 °C, centrifuged and resuspended in freshly thawed selected rabbit serum as a source of complement. Further incubation was at 37 °C for 30 min. R, C57BL/6J responder cells (2.5×10^6 ml^{-1}); A, DBA/2J allogeneic cells (2.5×10^6 ml^{-1}); S, suppressor cells (0.6×10^6 ml^{-1}); MM, methyl-α-D-mannopyranoside (10 mg ml^{-1}). Effector: target cell ratio, 25 : 1; target, P-815 mastocytoma cells.

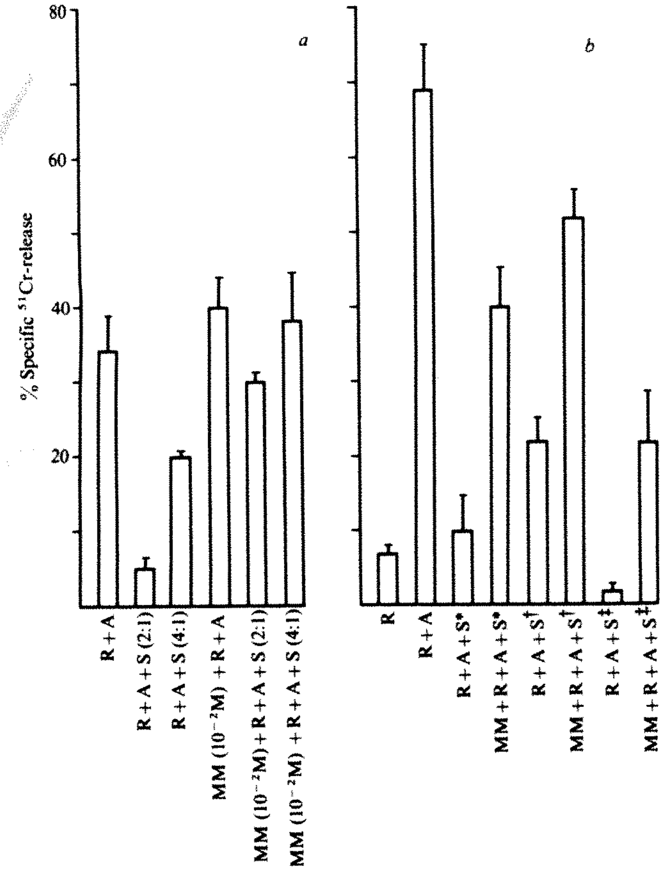

Fig. 3 Effect of MM on the generation of effector T cells. *a*, Effect on killer-cell generation. Responder cells (R) in presence of allogeneic cells (A) (see Fig. 1 legend) generate CTLs (first column). This effector-cell generation is suppressed in presence of suppressor cells (S) added at different R:S ratios at the start of culture. Addition of MM (10^{-2} M) inhibits suppressor-cell function (columns 5, 6) but not the generation of CTLs in the absence of suppressor-cells (column 4). *b*, Effect on suppressor-cell generation. * Suppressor cells (S) were generated as described in Fig. 1 legend and added to the culture to suppress CTL generation in presence or absence of 10 mg per ml MM. † Suppressor cells were cultivated for the first 72 h of the 6-day induction period in the presence of MM (10 mg ml^{-1}) and then tested for function in presence or absence of MM. ‡ Suppressor-cell generation in presence of MM during the 6-day induction period. Effector/target cell ratio in both experiments, 50:1; responder/suppressor cell ratio in *b*, 4:1.

cells because target cell lysis was the same in the presence or absence of MM (10 mg ml^{-1}) (data not shown). Similarly MM did not affect the induction phase of suppressor-cell generation (Fig. 3*b*). Spleen cells were cultivated in presence of MM either for the initial 72 h or the whole 6-day induction period before addition to the second culture. Both populations were found to have comparable suppressive activity when transferred to the MLC. This indicates that MM does not affect the generation of T_s from their precursors. Furthermore, we found no evidence for reduced DNA synthesis (^{3}H-thymidine incorporation) or decreased viability of T_s in culture in the presence of MM (data not shown). However, the capacity of the suppressor cells to inhibit a primary CTL was inhibited when MM was added to the second culture (Fig. 3*b*). Due to the different susceptibility to carbohydrate in the culture medium, our results clearly define cytotoxicity and suppression in this system as two separable manifestations of effector T-cell functions, a fact which is only shown with difficulty during regulation of CTL generation by T_s[18].

The effect of MM on T_s effector function could be attributed to the carbohydrate and not to impurities of the reagent used because MM from different sources (data not shown) and also the re-crystallized sugar were equally effective (Table 1). Osmotic effects seem unlikely because several other monosaccharides were ineffective (Fig. 4). A toxic effect of MM on lymphocytes is also unlikely because concentrations even 100-fold higher than those active in our system were not toxic to leukocyte function[19].

Our study demonstrates that cell interactions can be blocked by monosaccharides. Only the regulatory function of T_s is counteracted—neither CTL effector function nor the generation of T_s and CTLs is inhibited. At this stage it is impossible to determine how the T_s interact with their targets during CTL activation. Alternative mechanisms must be considered. The sugars may sterically interfere with structures involved in recognition of target cells by T_s. MM could also have reversible selective inhibitory effects on T_s metabolism, affecting function but not differentiation, perhaps by interfering with the glycosylation of recognition structures. We favour the hypothesis that recognition structures on T_s or secreted T_s products, by interaction with complementary structures on their target cells, mediate suppression and that the carbohydrate competitively blocks this interaction. Results obtained with stem cells[20] and T cells[21] suggest that differentiation may be accompanied by a change in carbohydrate binding capacity of cell-surface components.

The fact that D-mannose is often found in mammalian glycoproteins either as core or end groups[22] does not mean that the specificity resides only in this sugar. Other mono-, and in particular, oligosaccharides should be tested for specificity by determining the concentration required to inhibit the regulative T-cell interaction. The advantage of our system is that it studies functional interactions. However, one disadvantage is that the incorporation of sugar into cells may decrease their capacity to compete at the extracellular level and the concentration of

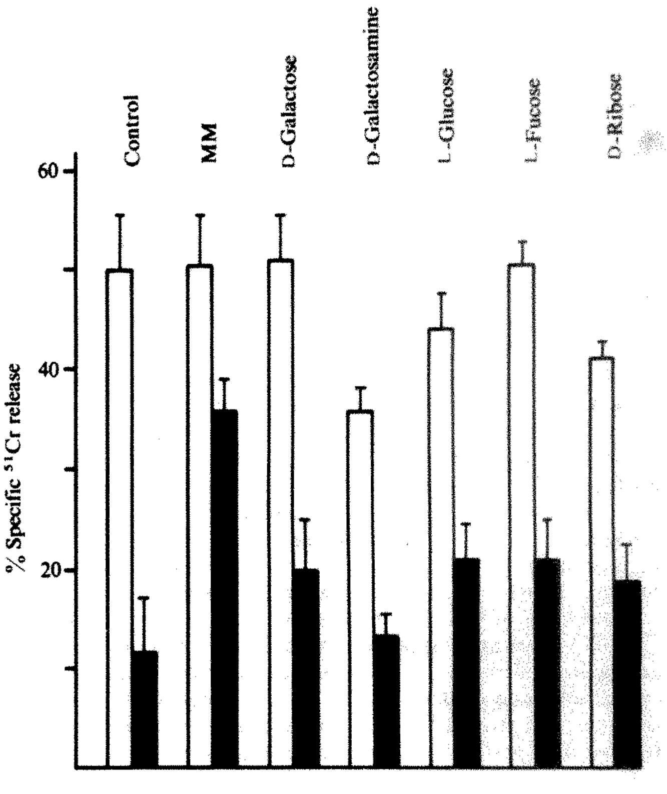

Fig. 4 Specificity of the carbohydrate effect on suppressor-cell functions. For suppressor and responder culture conditions, see Fig. 1 legend. The control shows the activity of responder cells incubated in absence (open columns) or presence (solid columns) of suppressor cells. In the other experimental groups different carbohydrates were added at 10^{-3} M concentration during the induction phase to the suppressed and non-suppressed cell cultures.

carbohydrates not toxic to effector-cell generation may not be sufficient to inhibit measurably suppression.

No definite function has been ascribed to oligosaccharides although their role in cell recognition has been suggested. Our observations on the counteraction of suppressor-cell activity suggest that carbohydrates play a part in T-cell regulation.

We thank Ms Ulrike Ette for technical help, Ms Ursula Rohmann for preparation of the manuscript, and our colleagues, in particular Dr M. Simon, for their criticisms. This work was partially supported by DFG grants Ko 571/5 and 571/7.

Is erythropoietin the only factor which regulates late erythroid differentiation?

Barbara Fagg[*]

Biologie Cellulaire, Swiss Institute for Experimental Cancer
Research, CH-1066 Epalinges s./Lausanne, Switzerland

Haematopoiesis is a useful model system for studying differentiation and the regulation of precursor cell populations intermediate between the multipotential stem cell and terminally differentiated end cells. For many years, erythropoietin (Epo) was recognized as the hormone which controls red cell production *in vivo*[1]. Although other substances are now known to be required during the initial stages of erythropoiesis[2,3], late erythroid differentiation is regarded as strictly Epo-dependent[4]. This concept is supported by the recent demonstration that the addition of Epo alone to serum-free bone marrow cell cultures is sufficient to stimulate the CFU-E (colony-forming unit-erythroid—a late erythroid precursor cell approximating to a proerythroblast) to complete differentiation into mature erythrocytes.[5] However, the data reported here indicate that mature erythroid colonies (indistinguishable from those formed by CFU-E + Epo) are formed when adult bone marrow cells are grown for 2 d in methyl cellulose cultures containing spleen cell-conditioned medium (SCM) but no added Epo. SCM is a rich source of growth factors[6,7] and initial observations[8] suggested that its 'Epo-like' activity could be attributed to: (1) Epo, or (2) a factor which enhances the activity of small amounts of Epo in the culture medium, or (3) a factor(s) distinct from Epo which is also capable of stimulating late erythroid differentiation. The experiments reported here, which include a partial characterization of the 'Epo-like' activity, support the latter interpretation.

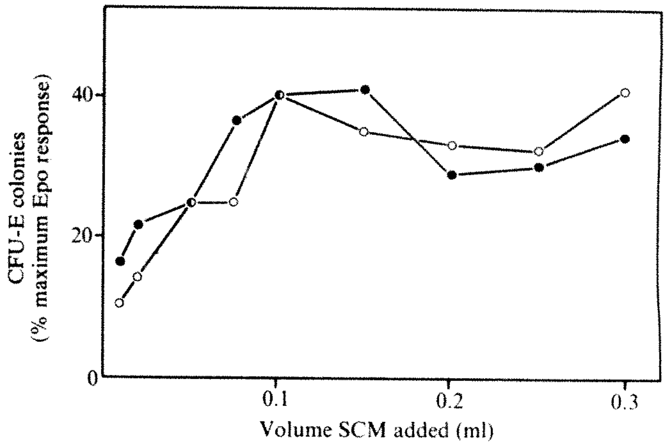

Fig. 1 Formation of erythroid colonies from adult mouse bone marrow cells grown for 2 d *in vitro* in the presence of different volumes of SCM. The number of CFU-E colonies is expressed as a percentage of the maximum response to Epo (0.15 units per ml culture; 307 ± 31 colonies per 10^5 cells, mean ± s.e.m. of 19 observations) in the same experiment. Epo was prepared from the urine of an aplastic anaemia patient according to Iscove *et al.*[5,12]. Either 20% (●) or 0% (○) fetal calf serum was added to the culture medium. Bone-marrow cell cultures contained 0.8% methyl cellulose, fetal calf serum (0% or 20%), 32 μg ml^{-1} lecithin, 18 μg ml^{-1} cholesterol, 3.6×10^{-6} M human transferrin, 1% deionized BSA and 8×10^4 cells ml^{-1}. They were evaluated as described by Iscove *et al.*[12].

SCM was collected from mouse spleen cells which had been stimulated with allogeneic irradiated spleen cells[9]. Adult DBA/2J mouse bone marrow cells grown for 7–10 d *in vitro* in the presence of SCM produced granulocyte/macrophage, megakaryocyte, erythroid (bursts) and mixed colonies. Similar results have been described previously using this type of SCM or that obtained from pokeweed mitogen(PMW)- or concanavalin A (Con A)-stimulated spleen cells[10,11]. The novel finding in the present study was that after 2 days *in vitro*, in the presence of SCM but no exogenous Epo, adult bone marrow cells produced colonies of 8–60 haemoglobinized (benzidine-positive) erythroid cells which were indistinguishable from those stimulated by Epo. Experiments designed to characterize this response in more detail showed that the number of erythroid colonies (cultured in the presence of 20% serum) increased in direct proportion to the amount of SCM added to the culture and reached a plateau value that was maintained at high SCM doses (Fig. 1). At a dose of SCM which maximally stimulated colony formation there was a linear relationship between the number of bone marrow cells plated ($0.25–4.0 \times 10^5$ cells per plate) and the number of erythroid colonies (correlation coefficient, $r = 0.98$). This indicates that the response occurs at the level of the individual cell and that colony growth is not dependent on cooperation between cells in the culture.

Fetal liver cells are often used to assay growth factors because they are generally more responsive and contain a higher proportion of precursor cells than adult tissues. SCM had a similar 'Epo-like' effect on 12-day fetal liver cells in culture to that on adult bone marrow cells. SCM from Con A- and PWM-stimulated spleen cells (one sample of the latter was provided by Dr G. R. Johnson, Melbourne, Australia) were also examined and found to contain a low level of 'Epo-like' activity when tested on adult bone marrow cells (data not shown).

All seven SCM preparations tested were active, although the level of 'Epo-like' activity varied between batches; the maximum response to SCM was between 41% and 80% of the maximum response to Epo, and required 33–150 μl of SCM per ml culture medium. The activity did not seem to be derived from the serum used to prepare SCM, because batches of SCM containing 1, 2 or 20% (v/v) serum gave similar results and

---

0028-0836/81/030184—03$01.00

equivalent amounts of the same serum tested alone did not exhibit any 'Epo-like' activity on bone marrow cells.

Further experiments were carried out to test whether the 'Epo-like' activity in SCM was: (1) Epo released by the spleen cells, (2) a factor present in SCM which enhanced the activity of undetectable amounts of Epo in the serum used to prepare the bone marrow cultures or (3) another factor(s) distinct from Epo, which was also able to stimulate late erythroid differentiation. SCM gave a similar dose-response curve whether 20% (v/v) or no serum was included in the bone marrow culture medium (Fig. 1), and the number of colonies formed was not related to the amount of serum added (data not shown). These results suggest that SCM is not enhancing the activity of any Epo which might be present in the culture medium.

Does SCM contain Epo or another factor(s)? To answer this question a comparison was made between the physical properties of the 'Epo-like' activity in SCM and those of Epo. The biological activities of both Epo and SCM were unaffected by dialysis against 0.16 M NaCl (Amicon PM 10 membrane; 10,000 MW cutoff), or by heating at 56 °C for 30 min, but both were rapidly inactivated by boiling at 100 °C. However, the SCM activity could be distinguished from Epo by column chromatography. Two peaks of activity were detected when SCM was passed over a Con A-Sepharose column (Fig. 2*a*)—the first small peak was eluted immediately after the void volume in a similar position to Epo. The second larger peak was eluted with α-methyl mannoside and coincided with the granulocyte/macrophage stimulating activity (GM-CSA). Two regions of activity were also observed after chromatography on Sephadex G-100 (Fig. 2*b*), the first of which ran with the serum proteins and had a MW similar to a bovine serum albumin (BSA) standard. The second was more pronounced, had an apparent MW of 20,000–40,000 and overlapped with the GM-CSA. In contrast to the results from separation on Con A-Sepharose, no activity was detected where Epo elutes from G-100 (Fig. 2*b*). Thus, both affinity and gel filtration chromatography demonstrate that SCM contains an erythroid colony-stimulating activity which is physically distinct from Epo but has a similar biological activity. Protein sequencing studies are necessary to determine whether this factor contains any structural homologies to Epo.

These results indicate that SCM contains a factor(s) capable of stimulating late erythroid differentiation in the absence of exogenous Epo. Factors other than Epo have previously been shown to influence early erythropoiesis[2,3] and in this respect it is interesting that Burgess *et al.*[13] have recently isolated a glycoprotein (apparent MW 37,000 by Sephadex G-150 chromatography; 24,000 following neuraminidase treatment) which induces 7 d erythroid colonies in fetal liver cell cultures in the apparent absence of Epo. The authors concluded that this molecule was similar to burst-promoting activity[2,3]: it possessed no Epo-like activity[13] and earlier studies showed that only selected batches of serum supported the development of haemoglobinized 7 d erythroid colonies[11] (suggesting that additional factors were required for the complete maturation of erythroid precursor cells). Thus, the present study is the first to demonstrate that Epo may not be the sole regulator of the late stages of erythroid development. Further experiments are required to determine the physiological significance of this factor *in vivo* and its relationship with Epo and other growth factors in the regulation of haematopoiesis.

I thank Dr N. Odartchenko for his support and encouragement, Dr H. Engers for help in preparing the SCM and Dr G. R. Johnson for PWM-SCM. This work was supported by an EMBO Research Fellowship, the Swiss NSF and the Schaffhauser Liga für Krebsbekampfuug.

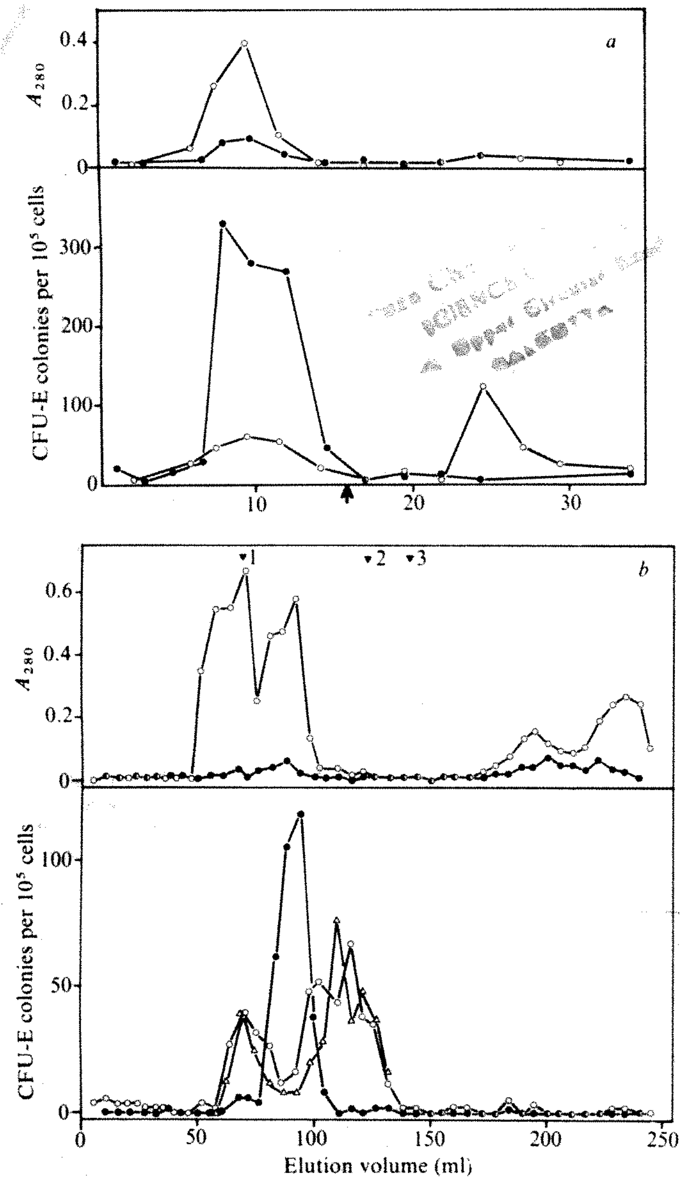

Fig. 2 Erythroid colony stimulating activity in fractions obtained by chromatography of Epo (●) and SCM (○, △) on (*a*) ConA-Sepharose and (*b*) Sephadex G-100 columns. The upper panel of (*a*) and (*b*) shows the A_{280} for each fraction: SCM contained 2% serum which accounts for the major peaks on these profiles. The lower panel shows the number of 2 d erythroid colonies formed in bone marrow cultures containing a 0.2 ml sample of each fraction. In all cases, the erythroid colonies were indistinguishable from those in control cultures containing Epo. *a*, ConA-Sepharose was equilibrated with running buffer (0.05 M sodium acetate, 0.5 M NaCl, 0.5 mM each of $MgCl_2$, $MnCl_2$ and $CaCl_2$, *p*H 6.5) and material bound to the column was eluted by addition of 0.1 M α-methylmannoside to the buffer (indicated by an arrow). Each fraction collected from the Con A column was dialysed against 0.16 M NaCl before assay. Similar results were obtained with other batches of SCM. *b*, Sephadex G-100 fine was equilibrated with 0.16 M NaCl, 4 mM HEPES, *p*H 7.4 containing 0.005% polyethylene glycol, which was also used to elute the samples. The increased A_{280} in the low-molecular weight region of the Sephadex G-100 profiles is due to phenol red which was present in the samples. Arrows 1, 2 and 3 indicate the positions of the MW standards, BSA (MW 69,000), α-chymotrypsin (MW 25,000) and ribonuclease (MW 13,700). The lower panel shows biological activity–elution profiles from two batches of SCM (○, △).

Inhibition of histamine secretion from mast cells

M. Ennis, A. Truneh, J. R. White & F. L. Pearce

Department of Chemistry, University College London,
20 Gordon Street, London WC1H 0AJ, UK

Histamine secretion from mast cells may be inhibited by elevated intracellular levels of cyclic AMP and by several anti-allergic drugs[1–3]. These compounds are claimed to act directly on the calcium-gating mechanism activated by the anaphylactic reaction, preventing influx of Ca^{2+} from the external environment and so blocking exocytosis[4–7]. To examine this hypothesis further, we have compared here the histamine secretion induced by immunoglobulin E-directed ligands in the presence and absence of added calcium and by the ionophore A23187. Exocytosis evoked by these former agents was originally considered to be almost totally dependent on extracellular calcium[8,9] but recent studies have shown otherwise[10–14]. In the absence of added cation, the agents act by mobilizing membrane-bound or intracellular stores of calcium[10–12]. We show here that a variety of anti-allergic drugs are potent inhibitors in the conditions used, suggesting that alternative explanations for their action must be sought.

Rat peritoneal cells were recovered and histamine release determined as previously reported[10]. The effects of cromoglycate, theophylline and 8-bromo cyclic AMP on histamine release induced by antigen and concanavalin A (Con A) are shown in Table 1. The secretagogues produced similar releases of histamine in the presence and absence of added calcium[11,12] and, as in our previous work with the basic inducers, peptide 401, compound 48/80 and polylysine[11,15–17], these drugs were comparably effective in both situations. The inhibitory effects of quercetin and doxantrazole were also essentially independent of added calcium.

Two important differences between ionophore- and antigen-induced histamine release must be considered. First, high concentrations of ionophore can induce much larger releases of histamine than the anaphylactic reaction. Second, the signal produced by antigen is transient and decays rapidly with time, whereas that evoked by the ionophore is much more persistent[18].

The effects of cromoglycate and quercetin on the release induced by maximal and submaximal concentrations of ionophore are shown in Table 2. The compounds were effective inhibitors at the lower concentration of ionophore, which produced a release comparable with that evoked by antigen, but ineffective against the higher concentration. Theophylline, doxantrazole and 8-bromo cyclic AMP also inhibited histamine release induced by suboptimal amounts of ionophore[19]. These results are unlikely to reflect a simple interaction between the test drugs and the ionophore for several reasons. (1) The relative concentrations are inconsistent with such a model: cromoglycate (10 μM) inhibited significantly the release induced by the lower concentration of ionophore, whereas a 100-fold excess of drug was ineffective against a six-fold increase in the amount of

Rats were sensitized to the nematode *Nippostrongylus brasiliensis* and specific antigen was prepared as described previously[11]. Cells (1 ml) were preincubated, as previously reported[15,17], in HEPES-Tyrode buffer[10] containing calcium (1 mM) or EDTA (10^{-4} M) and then challenged with antigen (10 worm equivalents ml^{-1}) or Con A (20 μg ml^{-1}). Brief preincubation with EDTA enhances the secretory response in the absence of extracellular calcium, possibly by removing the cation from regulatory sites in the membrane and facilitating the release of more internal calcium stores[11,12]. Secretion was allowed to proceed for a further 10 min, terminated by addition of ice-cold buffer (2 ml) and assessed as before[10]. Values are means ± s.e.m. Control releases induced by antigen were: *a*: (+) calcium 30.2 ± 5.3, *n* = 6, (−) calcium 32.4 ± 2.7, *n* = 6; *b*: (+) calcium 35.9 ± 5.0, *n* = 4, (−) calcium 34.6 ± 4.6, *n* = 4; and *c*: (+) calcium 29.5 ± 0.9, *n* = 3, (−) calcium 31.2 ± 3.2, *n* = 3. Control releases induced by Con A were: *a*: (+) calcium 39.0 ± 3.9, *n* = 4, (−) calcium 31.5 ± 2.6, *n* = 4; *b*: (+) calcium 38.5 ± 3.8, *n* = 4, (−) calcium 44.8 ± 0.8, *n* = 4; and *c*: (+) calcium 57.1 ± 1.7, *n* = 4, (−) calcium 30.3 ± 3.0, *n* = 3.

Table 2 Inhibition of histamine release induced by different concentrations of ionophore A23187

	% Inhibition of release induced by ionophore at a concentration of:	
	1.5×10^{-7} M	10^{-6} M
a, Cromoglycate (μM)

Cells were stimulated with ionophore (with and without cromoglycate) for the period shown and the reaction terminated as in Table 1. Values are means ±s.e.m. for four experiments.

ionophore (Table 2). (2) The postulated interaction would have to apply to all the named compounds which represent diverse chemical types. (3) The drugs were active against maximal or supramaximal concentrations of ionophore if the cells were stimulated only for short periods of time (see below) or in the absence of extracellular calcium[19]. The concentrations required to effect inhibition in the latter conditions were generally appreciably less than in the presence of the cation and similar to those required to prevent antigen-induced secretion[19]. (4) This phenomenon is not confined to the ionophore and comparable effects (in which the extent of inhibition is dependent on the strength of the releasing stimulus) have been noted for various secretagogues[11,15–17].

To examine the time dependence of the inhibition, cells were stimulated with a maximal concentration of ionophore (with and without cromoglycate) and the reaction terminated after fixed periods. The control release of histamine increased progressively during the experiment but was potently inhibited by cromoglycate during the early stages of the reaction (Table 3). This effect is unrelated to the magnitude of the secretory response, as between 30 and 90 s of incubation there was only a slight increase in the amount of histamine released but a dramatic decline in the inhibitory effect of the drug. Thus, cromoglycate is a most potent inhibitor of exocytosis from cells stimulated with high concentrations of the ionophore for very short periods, conditions which mimic the transient signal produced by antigen. Identical results were obtained with doxantrazole and quercetin[19].

The tested anti-allergic compounds therefore effectively prevent the release of histamine in conditions where the calcium-gating mechanism is circumvented (either by stimulating the cells in the absence of extracellular calcium or with the ionophore in conditions more closely resembling the anaphylactic reaction) and alternative explanations for their action should be sought. The compounds might modulate the calcium signal by activating membrane pumps to extrude the cation from the cytosol or promote sequestration of the ion into internal stores, as does cyclic AMP in other systems[1]. Moreover, cyclic AMP and the anti-allergic compounds used here have been shown to prevent the accumulation of radiolabelled calcium by stimulated mast cells[4,6]. This effect was attributed to a decreased influx of the ion (and taken as evidence for an inhibition of the gating mechanism) but is equally well explained by an increased efflux of the cation. Accumulation studies alone will not distinguish between these possibilities[1]. Alternatively, the drugs might have effects not immediately related to calcium homeostasis and might promote disaggregation of microtubules[20], be involved in the phosphorylation of proteins in the plasma or perigranular membranes and so prevent the fusional changes involved in exocytosis[14,21], or have an as yet ill defined stabilizing effect on the mast cell membrane. Work to distinguish between these possibilities is now in progress.

This work was supported by grants from the MRC, the Wellcome Trust and the World University Service. We also thank Fisons Pharmaceuticals for financial assistance, and acknowledge gifts of cromoglycate (Fisons), doxantrazole (Wellcome) and the ionophore A23187 (Lilly).

Persistent parainfluenza virus shedding in healthy young adults occurred throughout the 8½-month winter isolation period at Amundsen–Scott South Pole Station during 1978. Two episodes of respiratory illness were observed after 10 and 29 weeks of complete social isolation. Throat swabs collected both routinely, and during each outbreak of respiratory illness, were directly inoculated into cell cultures. Parainfluenza virus types 1 and 3 were recovered from both symptomatic and asymptomatic subjects throughout the winter. No other viruses were obtained by these efforts. The presence of parainfluenza virus in these subjects long after the accepted incubation period for viral upper respiratory illness, and when the introduction of new virus to this community was impossible, suggests its persistence in man.

Upper respiratory viruses can be demonstrated just before the onset of coryzal symptoms and for a few days during convalescence. The incubation period of parainfluenza virus illness is short in both natural and experimental human infections and ranges from 2 to 8 days. In long-range epidemiological studies in children, parainfluenza viruses were recovered from daily throat swabs for a period of 3–10 days, with a median of 8 days[1]. Similar brief virus shedding periods are observed following

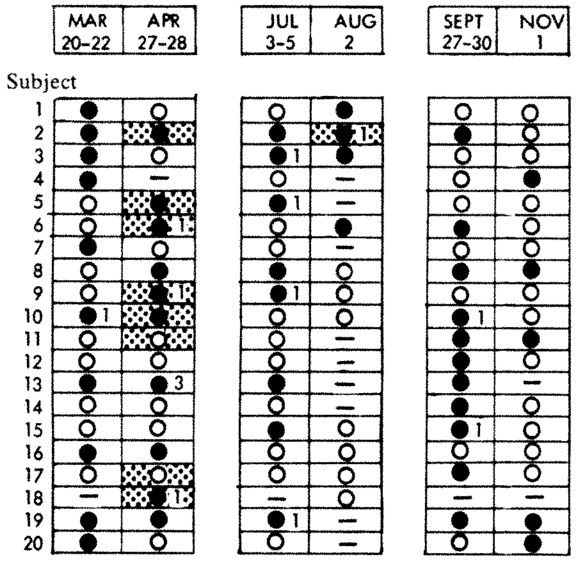

Fig. 1 Recovery of haemadsorbing viruses from throat swabs during the 1978 isolation period at the South Pole Station. Specimens were collected during the days shown for each month. The time interval between April and July and between August and September indicates that more than 30 days elapsed between specimens. ●, Virus recovered; ○, no virus recovered; —, no specimen obtained; ▨ indicates that the subject had an acute upper respiratory infection during this period; ▨ indicates that parainfluenza virus type 1 (or 3) was identified.

experimental infections in adults produced by nasal–oral inoculation of the parainfluenza virus[2]. In long-term studies of respiratory virus infections within open communities, persistent parainfluenza virus shedding has not been observed[3].

The American Antarctic Research Station at the geographic South Pole is totally isolated for 8½ months each year (mid-February to October) because the severe cold (−48 °C and below) prevents any aircraft operation. The summer period, extending from November to mid-February, is the time for station personnel changeover and re-supply. Each year since 1974, the South Pole physician has observed upper respiratory infections ('colds') among the Station personnel (~20 people) occurring after 2–6 months of total isolation, long after the usual short incubation period for these illnesses.

A limited virus laboratory was established at the South Pole Station, and operated during the austral winter of 1978 to attempt recovery and identification of the respiratory virus(es) responsible for these mid-isolation respiratory illnesses. Several continuous lines of mammalian tissue cells were maintained in culture by one of us (J.E.H.) throughout the year. These cell lines were human fetal tonsil, HeLa, Vero and Madin Darby canine kidney (MDCK). The last three lines were obtained as frozen suspensions from the American Type Culture Collection. The fetal tonsil line was isolated and tested by Schmidt *et al.*[4] and obtained as a confluent monolayer.

Cell monolayers were grown as needed on the inner surface of 2.0-ml glass screw-capped vials. The monolayers were nourished using Eagle's minimum essential medium (MEM) supplemented with 10% fetal calf serum (FCS) and antibiotics. Before inoculation, the growth medium was removed and replaced with an appropriate maintenance medium. For HeLa and fetal tonsil cells, Eagle's MEM with 2% FCS and antibiotics was used, but to support growth of influenza viruses and parainfluenza viruses in MDCK and Vero cells, a serum-free medium consisting of Eagle medium 199 supplemented with extra glucose, vitamins and 0.02% trypsin was used[5]. All cell-culture manipulations were carried out under a fibreglass microbiological hood equipped with a UV light source. Removal of either growth or maintenance medium from the cell cultures established in 2.0-ml vials was accomplished with a fresh, sterile, disposable, glass capillary tube connected to a closed-system vacuum source, and through suitable liquid traps, reducing the possibility of cross-contamination of cultures. Details of these miniature cell-culture methods were reported by Parkinson *et al.*[6].

The winter isolation period in 1978 began on 15 February and continued until 1 November. Routine throat swabs and serum specimens were obtained (after informed consent) in March, July and October 1978 from the 20 wintering personnel, all healthy young men. Throat swabs were swirled in a virus transport medium containing penicillin and streptomycin, and the resulting suspensions were inoculated into the monolayer vials and incubated (35 °C) on a roller drum apparatus. Uninoculated control monolayers of all cell lines were set up simultaneously and processed identically with each group of specimens collected. Acute upper respiratory symptoms were noted in a few persons in two episodes beginning on 22 April and 2 August 1978. At those times, additional monolayers were inoculated and processed along with additional controls for the presence of virus by standard virological methods[7]. After inoculation, the original throat-swab specimens were frozen and retained at −70 °C.

During the winter, cultures showing either cytopathic effect or haemadsorption were passaged into fresh monolayers, incubated and stored with the original cultures at −70 °C. After station opening on 1 November 1978, the stored inoculated cell cultures and the original specimens were reinoculated into new cell monolayers from fresh cell suspensions transported to South Pole Station from the US.

Many viruses were recovered by these efforts. The haemadsorbing agents were best detected by the Vero cells, although weak haemadsorption by some isolates could be detected in fetal tonsil cells. None of the control Vero and fetal tonsil cells showed any haemadsorption. No haemadsorbing or other viruses were detected in the HeLa and MDCK cell lines. From the 20 winter-isolation volunteers, haemadsorbing virus was obtained from 48 of 105 throat-swab specimens, a 40% recovery rate. The viruses were identified as parainfluenza virus types 1 and 3 by haemadsorption-inhibition techniques, using known virus-specific antiserum (National Center for Disease Control). Not all virus isolates were typed as the immediately available supply of typing serum was exhausted by the unexpectedly large number of viruses recovered.

Table 1 Serological responses of subjects wintering at South Pole Station during 1978 to parainfluenza virus types 1 and 3 as determined by haemagglutination inhibition

	Subject no.	Sep 1977	Mar 1978	Jul 1978	Oct 1978	Nov 1978
Parainfluenza type 1	5	160	160	20	80	40
	6	40	160	80	80	80
	11	20	10	10		80
	16	20	80	80	80	80
	20	20	20	40	160	80
Parainfluenza type 3	5	320	320	40	80	160
	7	160	80	160	40	40
	8		160	40	160	160
	11	160	40	10		160
	15	40	40	160	80	80
	19		80	320	160	160

Serological responses (underlined) are defined as a fourfold or greater change in haemagglutination-inhibition titre between successive serum specimens.

Virus recoveries throughout the isolation period are recorded in Fig. 1. Some subjects (nos 7, 12, 14, 17 and 18) yielded virus in only one sample, but most subjects shed virus on two or more occasions. Two subjects (nos 13 and 19) shed virus into each specimen collected throughout the winter isolation period. The figure also indicates those subjects experiencing symptoms of upper respiratory illness during the isolation period. Most of the virus shedders were asymptomatic throughout the winter.

After the frozen serum specimens reached the home laboratories, haemagglutination-inhibition tests were performed by standard methods[6,7] using commercial virus antigens (Microbiological Associates). Table 1 shows those subjects in whom four-fold changes of titre occurred. Subject numbers correspond to Fig. 1. Clearly, significant titre changes occurred in asymptomatic (nos 7, 8, 15, 16, 19 and 20) as well as symptomatic (nos 5, 6 and 11) individuals.

This remarkably high frequency of virus recovery indicates viral persistence and shedding throughout the isolation period in this small group of over-winter subjects. Such viral persistence in healthy subjects is contrary to present evidence that virus shedding in respiratory virus infections ends early in convalescence. However, in adult patients with chronic pulmonary disease, parainfluenza virus type 3 has been recovered on successive monthly occasions suggesting that this virus may persist in the abnormal respiratory tract[8]. The coryzal symptoms (colds) observed in the present group of subjects and in those of previous years occurred late in isolation, long after the presently accepted, short incubation period for parainfluenza virus infections. These late illnesses, occurring months into the total isolation period, also imply the continued presence of virus in an effective form which can be shed and cause disease. The South Pole environment is severely cold and dry. The mean ambient temperature is −47 °C, with a range of −18 °C. Only 1.5 cm of precipitation and 15 cm of new snow occur annually and the atmospheric water content (absolute humidity) averages 0.035 g m^{-3}. Whether this extremely cold, dry environment is significant in the observed parainfluenza virus persistence and shedding is unknown.

Allen *et al.*[9] reported a correlation between changes in outdoor temperature and onset of respiratory illness which occurred after 17 weeks of total isolation among members of the 1969 British Antarctic Survey party at Adelaide Island on the Antarctic Peninsula. In another study[10], subjects isolated at the British Antarctic Survey station, Stonington Island, for 5 months during 1971, showed an increased susceptibility to an experimental rhinovirus infection. An attenuated strain of virus was inoculated, but symptoms in subjects at Stonington Island were more severe than expected, with prolonged illness and virus shedding for a longer period (15 days) than observed in a control group inoculated with the same virus at the Common Cold Unit in Salisbury, England.

These earlier observations and our own reported here suggest that exposure of the upper respiratory tract to cold, dry air might impair the immune response of the respiratory mucosa. For example, this cooling and drying effect could lead to a reduced output of a secretory IgA and other anti-viral and anti-bacterial substances, resulting in either reactivation of an existing (persistent) viral infection or an increased susceptibility to reinfection.

Monoclonal anti-Fc receptor IgG blocks antibody enhancement of viral replication in macrophages

J. S. M. Peiris[*], S. Gordon[*], J. C. Unkeless[†] & J. S. Porterfield[*]

Flaviviruses, when complexed with antibody at subneutralizing concentrations, show enhanced replication in human and simian peripheral blood leukocytes (ref. 1, and J.S.M.P. and J.S.P., unpublished observations) and in P388 D1 and other macrophage cell lines[2]. A comparable phenomenon has been demonstrated with alphaviruses and Bunyaviruses in P388 D1 cells, (J.S.M.P. and J.S.P., unpublished observations) but cells lacking macrophage characteristics fail to show antibody-dependent enhancement (ADE) of viral replication. It has been suggested that the macrophage Fc receptor (FcR) provides an efficient route of entry of virus through the attachment of non-neutralized virus–antibody complexes and that for those viruses that escape destruction by the phagocyte, antibody results in a paradoxical increase in virus replication[3]. West Nile virus (WNV) replication in the P388 D1 macrophage cell line provides a reproducible model system for studying ADE of viral replication. Mouse macrophages have two FcRs—FcRI, which is trypsin-sensitive and binds IgG2a, and FcRII, which is trypsin-resistant and binds IgG2b and IgG1 complexes[4]. The FcR has been purified[5] using rat anti-mouse FcR monoclonal antibody which blocks FcRII[6]. We show here that anti-FcR IgG and its Fab fragment block ADE of virus replication by anti-WNV monoclonal antibodies.

The cultivation of P388 D1 cells[7] and preparation of WNV and rabbit anti-WNV serum have been previously described[3], and mouse monoclonal antibodies were prepared (J.S.M.P. and J.S.P., unpublished) by standard techniques[8]. Ascites fluids of clones producing anti-WNV antibody of immunoglobulin subclass IgG1 (F7/101) and IgG2a (F6/16A) were produced. Immunoglobulin subclass was determined by Ouchterlony double diffusion using two independent sources of subclass-specific antisera (Miles; Meloy). Both antiviral antibodies react with WNV antigen to high titre in radioimmunoassay and mediate enhanced plaque formation to a dilution of $10^{-5}-10^{-6}$ in P388 D1 cells. F7/101 neutralizes WNV poorly (50% plaque reduction at 1/10 dilution), whereas F6/16A neutralizes to a dilution of 1/1,280 (ref. 2). For the present experiments, both antibodies were used at subneutralizing concentrations (F7/101 at 1/1,000; F6/16A at 1/10,000). The production and characterization of the anti-mouse macrophage FcR monoclonal antibody and its Fab fragment have been described elsewhere[6].

As the anti-WNV antibody-induced enhancement of WNV yields in P388 D1 cells is correlated with the number of infectious centres (J.S.M.P. and J.S.P., unpublished observations), we used an infectious centre assay (as described in Fig. 1 legend) to quantify ADE of viral replication.

Figure 1 shows that addition of anti-WNV antibody F7/101 resulted in a 189-fold enhancement in the number of infectious centres formed. This effect was blocked by pretreatment of P388

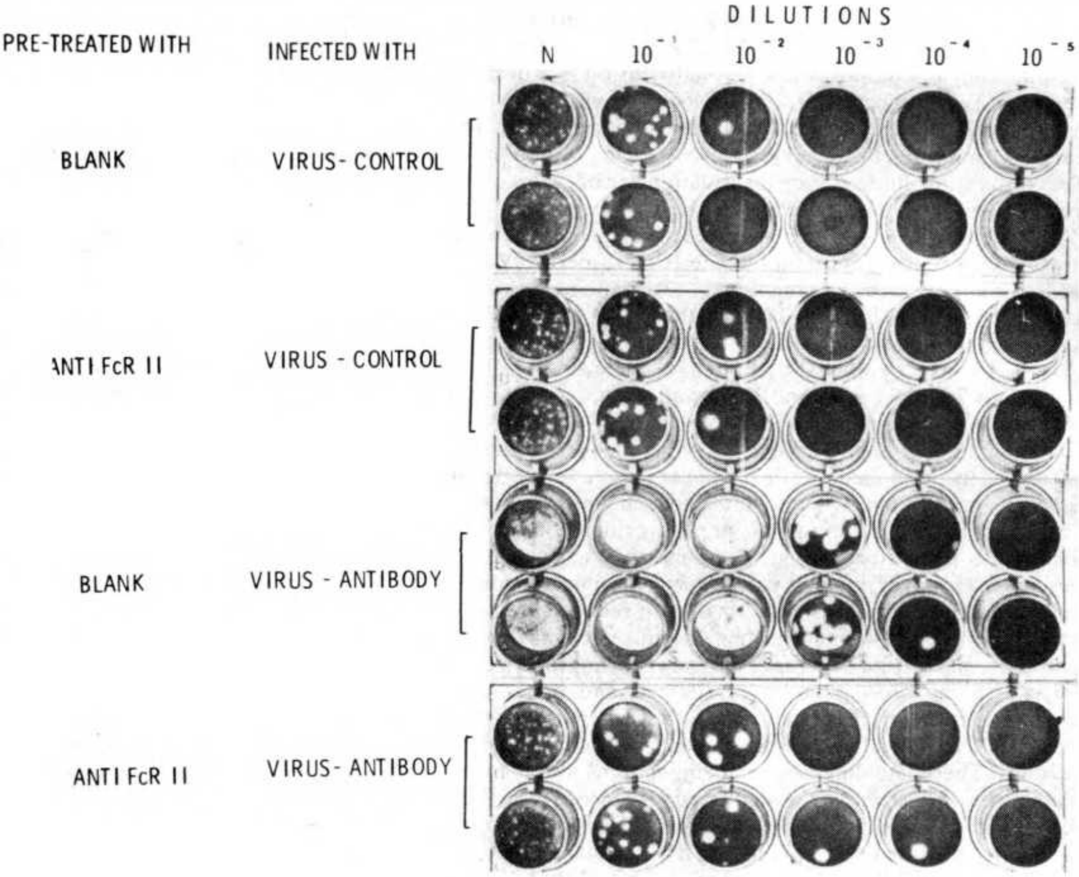

Fig. 1 Effect of anti-FcR antibody on ADE of WNV replication in P388 D1 cells. P388 D1 cells (2×10^6) were preincubated with anti-FcR antibody (240 μg ml^{-1}, 40 min, 4 °C) and infected with WNV (multiplicity of infection 0.04) with or without antiviral antibody F7/101 in the continued presence of anti-FcR (2 h, 4 °C). Cells were washed three times to remove unadsorbed virus and cell dilutions plated on a monolayer of pig kidney cells. An overlay of CM-cellulose was added 4 h later and plaques were stained after 4 days.

D1 cells with anti-FcR antibody, whereas virus replication in the absence of antiviral antibody was not affected. An irrelevant monoclonal antibody specific for mouse macrophages[9] had no effect in this system.

We next compared the inhibitory effect of IgG and the Fab fragment of anti-FcR antibody and examined the effect of antiviral antibody subclass (Fig. 2). Anti-FcR antibody (IgG) almost completely blocked ADE of virus replication induced by either anti-WNV IgG1 or IgG2a antibodies (Fig. 2*a*), in agreement with the ability of intact anti-FcR antibody to inhibit FcRI and FcRII in a macrophage rosetting assay[6]. In contrast, the Fab fragment of anti-FcR antibody showed less marked inhibition of ADE of virus replication, and no significant difference between the two subclasses (89% inhibition with F7/101 and 91% with F6/16A). The inhibition by anti-FcR Fab demonstrates that the inhibitory effect on ADE is due to the antibody combining site and not to the Fc domain. The reduced inhibitory activity of the monovalent Fab fragment may be due

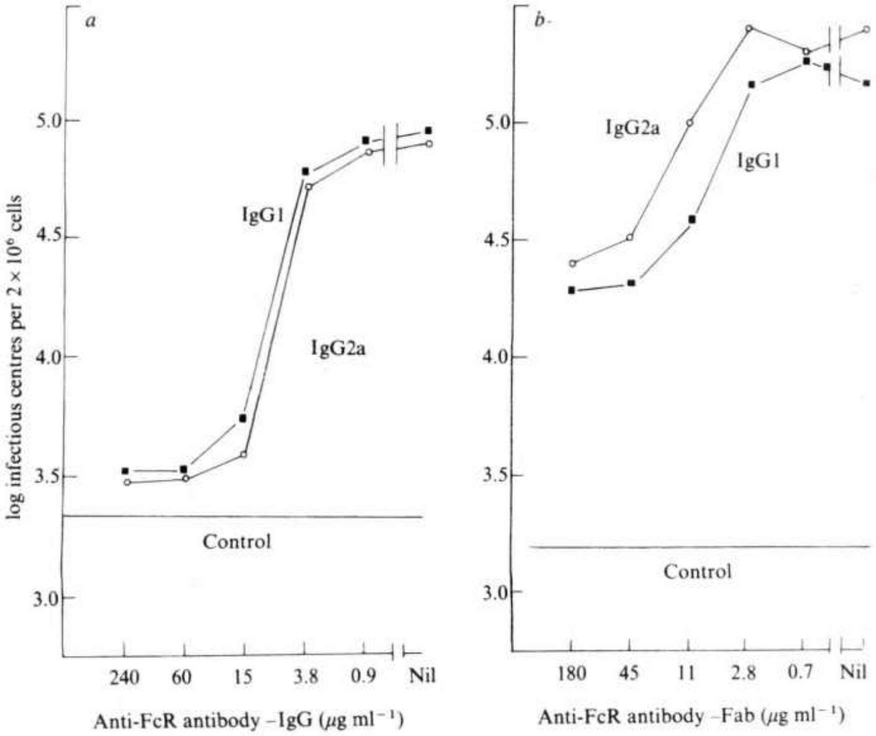

Fig. 2 Effect of the IgG (*a*) and Fab (*b*) fragments of anti-Fc receptor antibody on ADE of virus replication mediated by IgG1 and IgG2a anti-WNV antibodies. The procedures were as described in Fig. 1 legend.

Table 1 Comparison of the ability of anti-WNV IgG and F(ab')$_2$ to enhance replication of WNV

	WNV antibody titre			
Rabbit anti-WNV	Neutralization (50% plaque reduction)	Plaque enhancement	Radioimmune binding assay	mg protein per ml
IgG	1/40	1/2,000	1/3,125	0.86
F(ab')$_2$	1/10	<1/3	1/625	0.46

Anti-WNV IgG was purified by DE52 (Whatman) chromatography and digested with pepsin. F(ab')$_2$ fragments were isolated on Sephacryl S-200 (Pharmacia) and the absence of IgG confirmed by polyacrylamide gel electrophoresis. WNV neutralizing titre of antibody preparations was determined in pig kidney clone D cells[12]. Plaque enhancement was titrated in P388 D1 cell monolayers. The titre is taken to be the highest dilution giving at least threefold increase in plaque counts over controls[2]. For the radioimunoassay, WNV antigen or mock antigen was coated on polyvinyl microtitre plates (Dynatech) and incubated with serial dilutions of antibody. Antibody binding was detected using ^{125}I-labelled conjugated rabbit F(ab')$_2$ anti-mouse F(ab')$_2$. The antibody titre was the highest dilution of anti-WNV giving at least twofold greater binding to WNV antigen than mock antigen[13].

to the fact that binding to the FcR is reversible, whereas no measurable dissociation could be observed for the intact IgG[5]. The inability of Fab to discriminate between the IgG1 and IgG2 subclasses in ADE is surprising because previous studies showed that the same Fab fragment inhibited macrophage rosetting mediated by IgG1- and IgG2b-opsonized erythrocytes but was ineffective against IgG2a-mediated rosetting[6]. However, the binding of monomeric IgG2a to intact cells was inhibited by 15% by the anti-FcR Fab fragment and the binding of the purified FcR to IgG2a-coated beads could be completely inhibited[5].

To confirm that the Fc fragment of the antiviral antibody was responsible for ADE, bivalent F(ab')$_2$ pepsin fragments of anti-WNV rabbit antibody were prepared. The F(ab')$_2$ antibody lost its ability to enhance viral replication but retained substantial neutralizing activity and ability to bind to virus antigens on radioimmune binding assay (Table 1).

Several lines of evidence suggest that ADE of virus replication is involved in the pathogenesis of viral disease. Virus replication *in vivo* (influenza; dengue) increases in animals previously infected with antigenically related viruses or following transfer of low levels of antiviral antibody[10,11] and the dengue shock syndrome may be explained by this mechanism[3]. The present study shows that ADE of replication can be blocked by a monoclonal antibody specific for the Fc receptor. ADE demonstrated in human cultured peripheral blood monocytes can be abolished by removal of the Fc portion of the 'enhancing' antibody[1]. However, the presence of the Fc receptor, though necessary, is not sufficient to show ADE. Resident mouse peritoneal macrophages and the lymphoblastoid cell line WEH1 231 which possess the same FcR determinant as P388 D1 (ref. 6) do not show ADE (J.S.M.P. and S.G., unpublished). Where ADE is observed, it is not clear whether the FcR facilitates virus entry directly or whether, by concentrating virus on the cell surface, it increases infection through an independent receptor for the virus itself.

We thank J. Austyn for the monoclonal anti-macrophage antibody F4/80, A. F. Williams for providing us with rabbit anti-mouse F(ab')$_2$, and D. Millican and J. Wickson for technical assistance. This work was supported in part by the Leukaemia Society of America Inc., PHS grant AI-14603 and a grant from the MRC. J.C.U. is an American Cancer Society research scholar.

Murine DNA repair gene located on chromosome 4

Pin-Fang Lin & Frank H. Ruddle

Department of Biology, Kline Biology Tower, Yale University,
New Haven, Connecticut 06511

Xeroderma pigmentosum (XP) is an autosomal recessive human disease in which affected individuals are prone to develop skin cancers after exposure to sunlight. Cells from XP patients are defective in DNA repair activity and are sensitive to UV light. Most XP individuals have a defect in the excision repair pathway for UV damage. Genetic studies have indicated that excision-defective cells fall into seven complementation groups (A–G). An eighth group of XP is known to be defective in post-replication repair[1–3]. DNA repair enzymes are ubiquitous and can function across species boundaries[4–6]. Primary mouse embryo fibroblasts have normal levels of DNA repair functions[7]. We report here that somatic cell hybrids between primary mouse cells and SV40-transformed XP group A cells can express wild-type levels of DNA repair function. These hybrid cells segregate murine chromosomes in culture. The proportion of cells in a given hybrid cell line which can perform unscheduled DNA synthesis (UDS) correlated well with the percentage of the population retaining murine chromosome 4. This study presents the first example of a direct quantitative comparison of specific gene activity and chromosomal content on a cellular basis.

Table 1 Statistical analysis of the relationship between retention of each murine chromosome and DNA repair activity in 21 hybrid lines

Mouse chromosome	Correlation coefficient	Slope	Intercept
1	0.422	0.446	34.1
2	0.445	0.451	34.3

X	0.451	0.676	34.4

The correlation coefficient *r* measures the degree of fit of the points on Fig. 2 (for chromosome 4), and similar plots for the other chromosomes, to the calculated least-square straight line. Slope indicates the number of murine chromosomes involved in conferring DNA repair ability on mouse–XP cell hybrids. Intercept represents residual DNA activity in the parental XP cells.

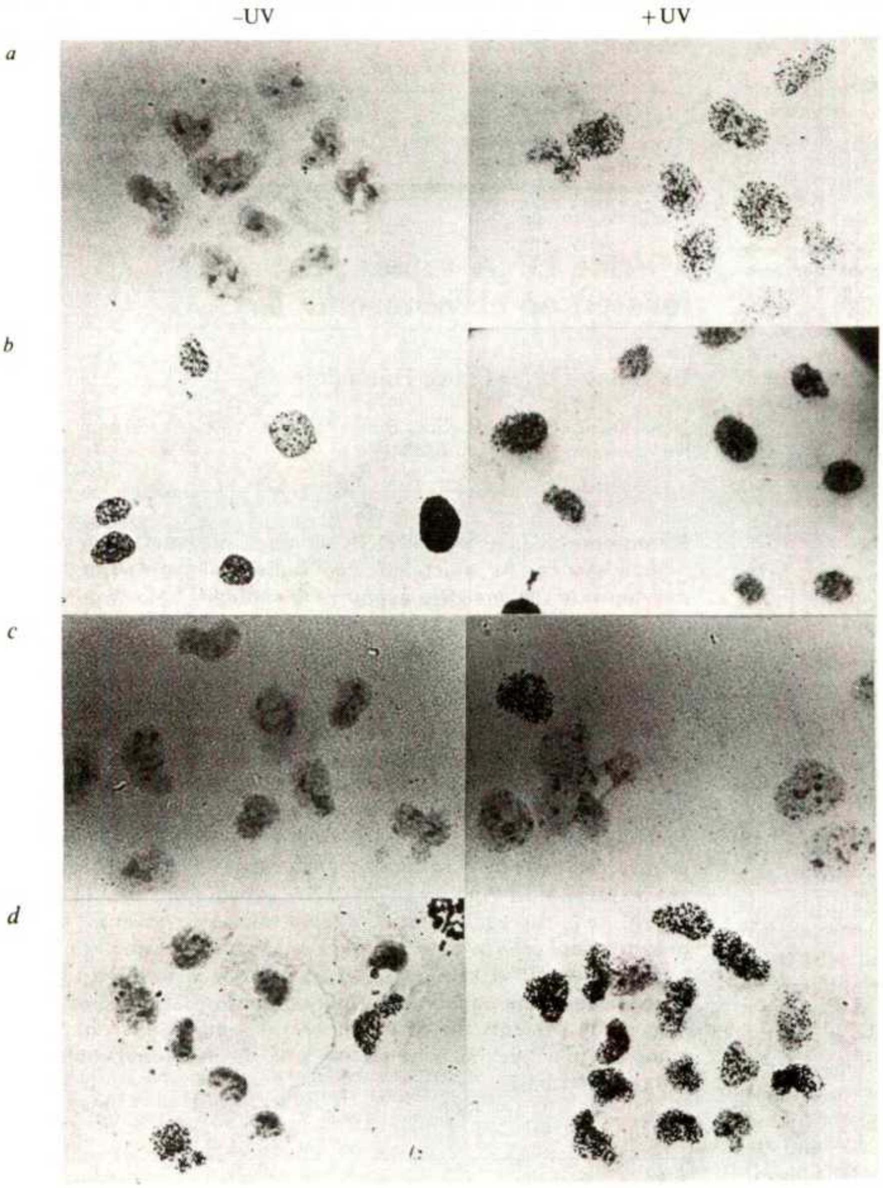

Fig. 1 Autoradiographs showing unscheduled DNA synthesis in parental and hybrid cell lines. Cells were UV-treated (30 J m^{-2}) and incubated in Dulbecco's modified Eagle medium + 10 μCi ml^{-1} ^{3}H-thymidine (specific activity 20 Ci $mmol^{-1}$) + 2 mM hydroxyurea for 2.5 h after irradiation. After washing and fixation, slides were exposed to Kodak NTB-2 emulsion at 4 °C for 7 days, developed then counterstained with Giemsa. Control cells were treated the same way, but were not UV-irradiated. *a*, SV40-transformed normal human cells, WI-18-VA-2 8-azaguanin resistant[11]. *b*, C57BL/6J mouse embryo fibroblast (MEF). *c*, SV40-transformed XP group A cells, 1223. *d*, Mouse–human hybrid cells $G_{31}B_2$ produced by fusion of MEF and 1223. The dark spots in unirradiated mouse nuclei (*b*) are murine chromocentres.

Sixteen independent cell hybrids were generated by fusing C57BL/6J mouse spleen and SV40-transformed XP group A cells and selecting for ouabain 10^{-6} M-resistant colonies[8] or by fusing microcells from mouse embryo fibroblasts and XP cells and selecting for UV (10 J m^{-2})-resistant colonies. The XP group A skin fibroblast (XP 12BE) was obtained from the American Type Culture Collection. Cell fusion was promoted by 50% polyethylene glycol (PEG) 1540 (ref. 9) or concanavalin A (Con A) and PEG (A. Lalazar, personal communication). The hybrids were tested for DNA repair by assay for unscheduled DNA synthesis (UDS) after UV-irradiation[10]. As shown in Fig. 1, cell hybrid $G_{31}B_2$ which contains a full complement of human and mouse chromosomes expresses a normal level of DNA repair activity. This result provides another example of the lack of species specificity for DNA repair. However, we cannot determine which species contributes the active DNA repair enzyme. The functional enzyme may be the mouse form, or activation of the human form may occur in the presence of mouse regulating elements.

It has been shown that after several successive transfers of primary mouse embryo fibroblasts *in vitro*, the ability of these cells to perform excision repair decreases[7]. Note that in the stable hybrid $G_{31}B_2$ there is no apparent change in DNA repair capacity after 20 months in culture.

Most mouse–XP hybrids obtained segregated mouse chromosomes and contain an average of 60 human chromosomes per cell. Chromosome analyses[12] and UDS assays were performed to determine whether there is an association between the segregation of a specific mouse chromosome and the expression of DNA repair function in mouse–XP cell hybrids. To confirm the karyotypic results, cell extracts from each hybrid were also assayed for the presence of 18 murine isozymes which have been mapped (by starch gel electrophoresis) in the mouse genome to 13 chromosomes[13–15].

The DNA repair activity of cell hybrids was tested by UDS and the percentage of cells which could perform DNA repair calculated as follows:

$$\frac{\left(\begin{array}{c}\text{\% cells incorporating}\\ ^3\text{H-thymidine after UV}\end{array}\right)-\left(\begin{array}{c}\text{\% cells incorporating}\\ ^3\text{H-thymidine without UV}\end{array}\right)}{1-(\text{\% cells incorporating } ^3\text{H-thymidine without UV})}$$

This represents:

$$\frac{\left(\begin{array}{c}\text{\% irradiated cells in S}\\ \text{phase and in DNA repair}\end{array}\right)-\left(\begin{array}{c}\text{\% control cells}\\ \text{in S phase}\end{array}\right)}{1-(\text{\% control cells in S phase})}$$

In the experimental conditions 50% of unirradiated SV40-transformed normal human fibroblasts (WI-18-VA-2) and SV40-XP A cells were found to be engaged in DNA replication. After UV irradiation (30 J m^{-2}) ~ 98% of the WI-18-VA-2 cells showed DNA repair activity, whereas the value for SV40-XP A was only 2%.

In this study we analysed 21 hybrid lines (16 primary clones and 5 subclones), which cover the full complement of murine chromosomes except Y. To study the effect of each donor murine chromosome on the expression of DNA repair function in XP cell hybrids, the percentage of cells expressing DNA repair activity was plotted against the percentage of cells retaining a particular murine chromosome for the 21 hybrid lines. Figure 2 shows an example with mouse chromosome 4. For each of the 20 mouse chromosomes a least-square linear regression analysis of these two parameters yielded the results shown in Table 1.

The correlation coefficient r measures the degree of fit of the given points to the least-square straight line and the slope indicates the number of murine chromosomes which are involved in complementing the DNA repair defects in XP cells. The intercept represents the residual DNA repair activity in the parental XP cells which is about 2% (determined experimentally). The analysis shows that the hybrid cells which contain murine chromosome 4 have the highest correlation coefficient value (0.94) and the correct intercept value (2.01). Furthermore, in a Student's t test, for $r = 0.94$, $P < 0.001$. These data indicate that mouse chromosome 4 is responsible for the expression of DNA repair function in XP cell hybrids. The slope of 0.992 further suggests that murine chromosome 4 alone can complement the XP group A defect(s).

Another statistical analysis of expression of DNA repair function and karyotypic data for the hybrid line studies was carried out using a computer program[16] and the results are summarized in Table 2. The positive correlation between the presence of an individual chromosome in a clone and that clone's ability to express DNA repair function was computed with three different measures of dependence. In all three cases, the expression of DNA repair activity was correlated with the presence of chromosome 4.

Table 3 lists the frequency of retention for mouse chromosome 4 and the percentage of cells which regain UDS for five subclones which were derived from four independent hybrids. These data further indicate that a change in the retention frequency of murine chromosome 4 is accompanied by a parallel change in the DNA repair ability in subclone lines.

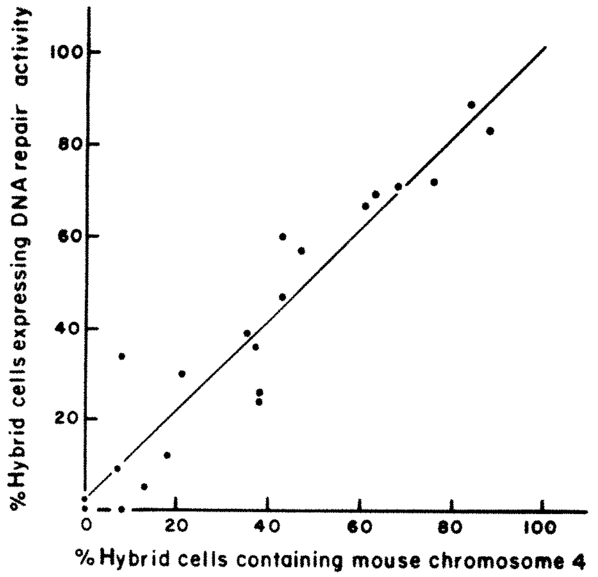

Fig. 2 The relationship between the presence of murine chromosome 4 and DNA repair activity in 21 murine–XP hybrid lines. Cells were treated as in Fig. 1 legend. Over 500 cells were counted for the incorporation of ^{3}H-thymidine for each hybrid. Cells were regarded as unlabelled if there were ten grains or less per nucleus.

Table 2 Assignment of murine gene responsible for restoring DNA repair activity in mouse–XP group A cell hybrids to chromosome 4

Chromosome	UDS/chromosome (no. of clones)				ϕ	χ^2	Overall OR
	+ +	+ −	− +	− −

X	2	13	2	4	−0.23	1.11	1.37

Hybrid cells were considered positive for DNA repair function when over 20% of cells expressed UDS. For chromosomes (+) indicates presence of at least one copy in over 20% of the cells analysed. Statistical analysis was carried out using a computer program, ASSIGN, developed for the purpose of gene assignment with material generated by somatic cell hybridization[16]. To determine the gene assignment, three different statistical procedures were used: χ^2, ϕ and OR. χ^2 was used as a method of dependence, rather than a test of significance, and was calculated in the ordinary way. The ϕ coefficient, which is insensitive to sample size is the ratio of the observed χ^2 to the perfect χ^2. It is calculated by dividing the square root of the regular χ^2 by the square root of the sample size. When there exists a perfect association between a marker and a chromosome, the value of ϕ is +1. Zero indicates no association and −1 a negative association. The OR statistic was designed for determining gene assignments. It is an inverse weighted scoring system, independent of χ^2, which is calculated by assigning each clone a score of 100 and dividing that value evenly among all chromosomes in concordance with the tested marker. The clones are scored, the scores added for each chromosome, and then divided by the number of clones. The chromosome with the highest number is considered a candidate for assignment of the gene under study. Generally an OR score of 7 or above is considered evidence for a positive assignment.

Table 3 The concordant segregation of chromosome 4 and the expression of DNA repair function in subclones

Hybrid line	Frequency of chromosome 4	% Cells with UDS
1. $S \times O_2$	61	67
$S \times O_2 - 1$	37	36
$S \times O_2 - 50$	76	72
2. $S \times A_2$	88	83
$S \times A_2 - 1$	21	30
3. $S \times R5$	35	39
$S \times R5 - 1$	43	47
4. $G_{31}B_2$	84	89
$G_{31}B_2 - 1$	43	60

Therefore we conclude that chromosome 4 contains a gene which corrects the defective DNA repair function in XP A cells. As it is not known if the XP A defect involves a structural gene change or an altered regulatory element, the gene product of chromosome 4 responsible for restoring DNA repair function remains undefined. Extending similar studies to other XP groups should help in elucidating the arrangement of murine DNA repair genes and mechanisms of mammalian DNA repair. The repair pathway for DNA damage in cells is complex, involving many different enzymatic activities; it is important to determine where the genes for these enzymes reside in the genome and whether they are closely linked.

We thank Dr James McDougall for SV40-transformed XP cells; Mrs F. Lawyer and Dr D. Pravtcheva for help with karyotypic analysis; Ms E. Nichols, Mr D. Bonito, Mr V. Salerno and Ms S. Pafka for technical assistance; Ms U. Shankar for performing computer analysis; Mrs M. Reger and Mrs M. Siniscalchi for manuscript preparation and Drs D. Slate and D. Juricek for helpful discussions and criticisms of the manuscript. This work was supported by USPHS grants 5R01/GM09966 and AGO1940 to F.H.R.

Inducible repair of near-UV radiation lethal damage in *E. coli*

J. Peters & J. Jagger

Biology Programs, The University of Texas at Dallas, PO Box 688, Richardson, Texas 75080

We present here the initial characterization of a new repair system which is induced in actively growing cultures of *Escherichia coli* and which repairs a major fraction of lethal damage produced by near-UV (310–400 nm) light. This system is different from the error-prone 'SOS' repair system for DNA, known to be induced in *E. coli* by treatments which damage DNA and/or inhibit DNA replication, such as irradiation by far-UV (254 nm) light or X rays, thymine starvation or treatment with naladixic acid or mitomycin C[1,2]. The SOS response requires induction of an 'X' protein[3], the product of the *recA* gene[4–6], whereas the inducible repair system described here utilizes proteins distinct from the X protein.

The induction of a near-UV repair system different from SOS repair was initially inferred from the unusual survival pattern of *E. coli* K12 AB 2463 observed after irradiation with 366-nm monochromatic light. This strain carries the *recA*-13 allele, which renders it incapable of inducing the X protein or showing the physiological responses associated with SOS repair[7]. 'V'-shaped survival curves were obtained when exponential-phase cells were irradiated in conditions permitting protein synthesis during irradiation (Fig. 1). After the initial reduction of viability with fluences up to 70–100 kJ m^{-2}, further irradiation resulted in recovery of colony-forming ability; that is, cells, which would have been non-viable when plated after lower fluences, were viable when allowed to remain in suspension for additional irradiation before plating. Recovery is maximal after 200–250 kJ m^{-2}, the cells remaining resistant up to fluences of 500 kJ m^{-2}. Although the extent of killing and recovery can be modified by post-irradiation conditions, the V-shaped survival pattern remains, suggesting that the critical repair event(s) occurs rapidly, during irradiation and before plating. Addition of the protein synthesis inhibitor, chloramphenicol (CAM), at the start of irradiation, results in nearly exponential loss of viability, with only a slight low-fluence shoulder (Fig. 2). However, when CAM is added after the cells have received 200 kJ m^{-2}, there is a pronounced shoulder of about 40 kJ m^{-2} (Fig. 2).

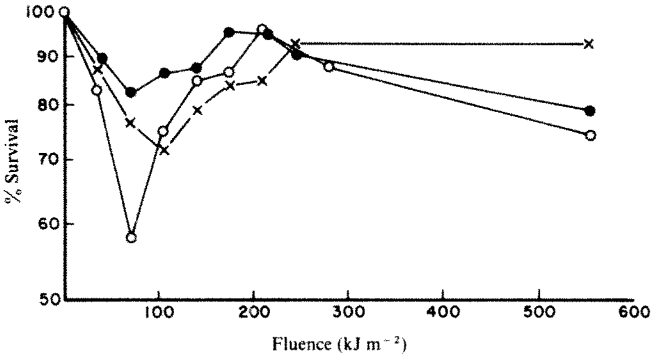

Fig. 1 Percentage survival of colony-forming ability of *E. coli* K12 AB 2463 (*recA*) as a function of 366-nm fluence in different post-irradiation conditions: plated on Luria agar (10 g l^{-1} tryptone; 5 g l^{-1} yeast extract; 5 g l^{-1} NaCl; 15 g l^{-1} agar) and incubated at 25 °C (×), plated on nutrient agar and incubated at 37 °C (○) or at 25 °C (●). Exponential-phase cultures were grown and irradiated (at 5–7.5 × 10^{7} cells ml^{-1}) at 37 °C in complete M-9 mineral salts medium[12] containing 0.4% glucose and supplemented with the auxotrophic requirements: arginine, histidine, threonine and leucine, each at 20 μg ml^{-1}, and thiamine at 5 μg ml^{-1}. The source of monochromatic 366-nm light was a Philips SP-500 high-pressure mercury arc lamp operated in conjunction with a Bausch and Lomb grating monochromator (model 33-86-45-49). A filter (Corning 0-52) was placed at the exit slit to screen out 340 nm and shorter-wavelength UV light. The fluence rate, measured with an Eppley thermopile, was 130 W m^{-2}.

One interpretation of these results is that recovery of viability occurring in conditions that allow protein synthesis during irradiation is due to the induction of a repair system not present in unirradiated cells, or in cells receiving less than the inducing fluence of about 70 kJ m^{-2}. CAM added at the start of irradiation prevents induction of the repair system, whereas the shoulder observed when CAM is added after 200 kJ m^{-2} reflects the time required for decay of induced repair protein(s) to

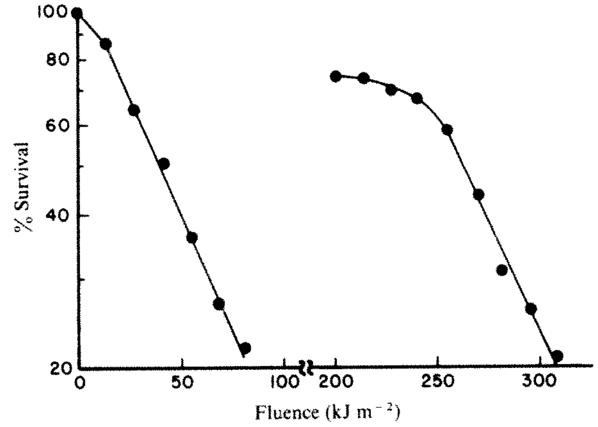

Fig. 2 The effect of inhibition of protein synthesis on colony-forming ability after near-UV (366 nm) irradiation. Cultures of *E. coli* K-12 AB 2463 were grown and irradiated as in Fig. 1 and plated on Luria agar at 25 °C. Chloramphenicol was added to the complete medium to a final concentration of 60 μg ml^{-1} at the start of irradiation (left-hand curve) or after a fluence of 200 kJ m^{-2} (right-hand curve). The fluence rate was 226 W m^{-2}. Complete medium irradiated with or without chloramphenicol had no phototoxic effect when incubated with unirradiated cells.

0028–0836/81/030194—02$01.00

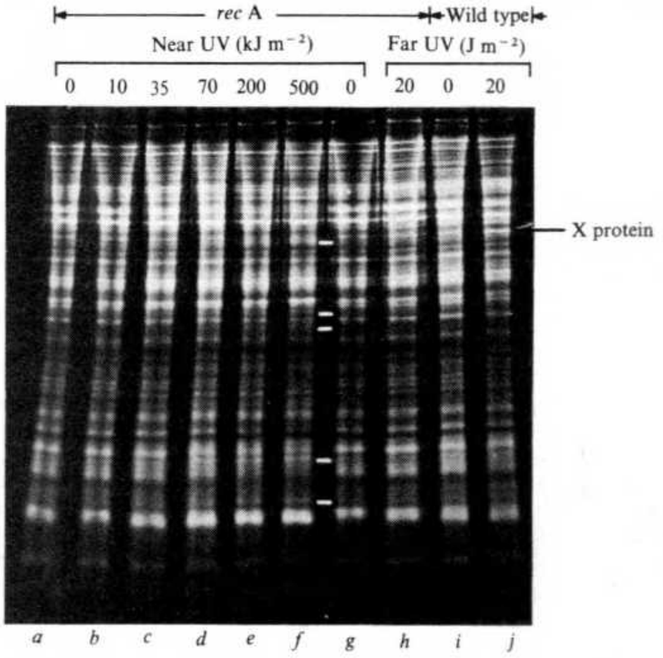

Fig. 3 Autoradiograph of SDS-polyacrylamide gel electrophoresis of total cellular protein of *E. coli* labelled with ^{35}S-methionine. The figure shows new protein bands appearing during near-UV (366 nm) irradiation of *rec*A cells and comparison of the near-UV-inducible proteins with the X protein induced after far-UV (254 nm) irradiation of wild-type cells. Proteins made in unirradiated *E. coli* K12 AB2463 *rec*A cells are shown in lanes *a* and g, and after increasing fluences of near-UV light in lanes *b–f*. The corresponding fluences are shown at the top of each lane. Proteins made in unirradiated wild-type *E. coli* K12 AB1157 cells are shown in lane *i* and in far-UV irradiated wild-type cells in lane *j* and *rec*A in lane *h*. Bands of interest are highlighted by white lines in the gap between lanes *f* and g. The X protein in lane *j* is indicated by the arrow. Growth and near-UV irradiation conditions are as in Fig. 1. Cultures (0.5 ml) were pulse-labelled for 90 s in medium supplemented with 0.5 μg ml^{-1} cold methionine and 50 μCi ml^{-1} of ^{35}S-methionine. Total cellular protein was solubilized and analysed by SDS-polyacrylamide gel electrophoresis using 14.5% gels according to the procedure of Studier[13]. Autoradiograms of dehydrated gels were made using Kodak X-Omat-R X-ray film. Pulse labelling of near-UV-irradiated cultures was done during continued irradiation; the far UV-irradiated culture was incubated for 20 min at 37 °C after irradiation before pulse labelling, to allow induction of the X protein.

physiologically insignificant levels. This period was estimated (from the ratio of the shoulder fluence to the fluence rate) to be 3.5 ± 0.5 min, and it remains constant over a threefold change in fluence rate. In contrast, the biological half life of SOS repair, as measured by the decay of error-prone repair activity, is 20–30 min (refs 8, 9).

This induced repair system must repair at least 90% of the damage produced at 366 nm, as may be seen by comparing the survival when the repair system is fully induced (>200 kJ m^{-2} fluence in Fig. 1) with that when its induction is prevented (left-hand curve in Fig. 2).

The interpretation of these survival data in terms of an inducible repair system is supported by our detection of new proteins synthesized during irradiation, whose appearance coincided with the recovery of colony-forming ability. Cultures of the *rec*A strain were pulse-labelled with ^{35}S-methionine during irradiation with 366-nm light, and total cellular protein was analysed by SDS-polyacrylamide gel electrophoresis followed by autoradiography. Lanes *a* and *g* of Fig. 3 show the pattern of pulse-labelled proteins from unirradiated *rec*A cells, and lanes *b–f* show the proteins from cells that were pulse-labelled after increasing fluences of 366-nm light, from 10 to 500 kJ m^{-2}. Three new protein bands (which we call P_1–P_3 in order of decreasing molecular weight, starting at the top of Fig. 3) appear at about 70 kJ m^{-2} (lane *d*), and the bands corresponding to proteins P_4 and P_5 (indicated by the bottom two white lines in Fig. 3) show large dose-dependent increases in comparison with the unirradiated control. The relative intensity of the bands increases up to about 200 kJ m^{-2} (lane *e*), at which time the recovery of viability is at a maximum (Fig. 1), with the pattern remaining essentially unchanged up to 500 kJ m^{-2} (lane *f*).

Pulse-labelled proteins from unirradiated wild-type parental strain K12 AB 1157 are shown in lane *i* of Fig. 3. Lane *j* shows the proteins from wild-type cells that were pulse-labelled 20 min after irradiation with 20 J m^{-2} of 254-nm far-UV light (the arrow indicating the X protein), whereas the same treatment failed to induce the X protein in the *rec*A strain (lane *h*). This is generally the case with strains carrying mutant *rec*A alleles in a variety of inducing conditions[7,10]. Proteins P_1–P_5, which are inducible in *rec*A cells by near-UV light, can be distinguished from the X protein by electrophoretic mobility, consistent with the idea of a *rec*A gene-independent, inducible repair system.

To distinguish near-UV-inducible repair from SOS repair, the above experiments were carried out in a *rec*A strain, which lacks SOS repair. Although the wild-type parental strain did not show V-shaped survival curves, the following results indicate that the near-UV-inducible repair pathway also makes a major contribution to survival of the wild-type strain after near-UV irradiation: the extensive shoulder characteristic of near-UV survival curves is greatly reduced in the presence of CAM; the fluence at 366 nm required to reduce survival of strain AB 1157 to 10% of the unirradiated controls is 3,500 kJ m^{-2} without CAM and 240 kJ m^{-2} when CAM is added to exponential cultures at the start of irradiation. Proteins P_1–P_5 are also induced in the wild-type strain by near-UV irradiation, as well as in the *rec*A strain.

The maximal solar UV-A (320–400 nm) irradiance is about 5 mW cm^{-2} at sea level[11]. In these conditions, a fluence of 200 kJ m^{-2} is delivered in about 1 h of exposure. Thus, the threshold fluence for the induction of the repair system described here is within the range of physiological exposure to UV-A, and we expect that this type of repair may be an adaptation to environments exposed to near-UV solar radiation.

Evidence for the inducibility of the *uvrB* operon

Michael Fogliano & Paul F. Schendel

Genetics and Cell Biology Section, Biological Sciences Group, Institute of Materials Science, The University of Connecticut, Storrs, Connecticut 06268

A new tool for probing the regulation of non-essential gene products has recently been developed[1]—this is a derivative of bacteriophage Mu into which the *Escherichia coli* genes for lactose metabolism have been fused (referred to here as Mu(lac, amp)). The DNA of this defective virus can insert randomly into the chromosome of a cell and mutants can be retrieved in which the β-galactosidase gene carried on the phage is under the control of the regulatory elements of the operon in which it now resides. We used this phage to generate DNA repair-deficient mutants, one of which was highly UV-sensitive due to insertion of the Mu(lac, amp) into the *uvrB* region of the chromosome. When exposed to UV light, this strain produces β-galactosidase at a much greater rate than unexposed cells. This suggests that the *uvrB* operon is inducible. These results were initially rather surprising. Although various components of the enzyme systems involved in Weigle-reactivation[2,3], post-replication repair[4–6] and repair of alkylation damage[7,8] had been established as inducible, the products of the *uvrA*, *uvrB* and *uvrC* genes which collectively effect nucleotide excision repair[9–11], seemed to be firmly established as a constitutively synthesized repair system. This conclusion was drawn because the activity of these enzymes can be easily detected in uninduced cells[9–11]; and mutations in the genes *recA* and *lexA*, which affect the regulation of most of the inducible repair systems[12], have relatively little effect on *uvrA*, *uvrB*-mediated excision repair[13]. Thus the *uvrA* and *uvrB* gene products seemed to be produced constitutively at maximal or near maximal rates. However, recent reports suggest a role for the *uvrA* and *uvrB* gene products in various inducible repair systems[6,14–17]. Because these studies all relied on indirect measurements of induction, it could never be determined if the results reflected induction of other components of these systems or if the *uvrA* or *uvrB* gene products themselves were regulated. The insertion mutant described here allowed us to monitor expression of the *uvrB* operon directly and provided evidence for regulated synthesis of the *uvrB* gene product.

Our original UV-sensitive isolate, designated CON48, was a derivative of an HfrH strain, CA7092 (see Table 1). To characterize the source of UV-sensitivity in CON48, it was allowed to mate with a multiply-auxotrophic recipient, AB1157. After 30 min the mating pairs were disrupted mechanically and recombinants resistant to both ampicillin and streptomycin were selected. Of 110 Amp^r isolates tested, 74 were found to be Leu$^+$, none were His$^+$, and one was Arg$^+$. Of a further 103 Amp^r colonies chosen, 97 were Gal$^+$. Thus, CON48 seemed to carry the Mu(lac, amp) inserted into a chromosomal segment near the genes for galactose metabolism. The *uvrB* gene is also located in this region and mutants in this gene cause extreme UV-sensitivity[13,21]; thus it seemed reasonable that the Mu(lac, amp) insertion was blocking expression of *uvrB*.

To test this hypothesis and to substantiate the map position of the Mu insertion, the transducing phage Pl$_{clr}$ was grown on CON48. This lysate was used to infect JC3890, a strain deleted for the *uvrB* gene and several adjacent genes, including those for biotin biosynthesis[20,21]. If Mu(lac, amp) was inserted in or near the *uvrB* gene of CON48, we anticipated that all Amp^r transductants would grow in the absence of biotin. This expectation was not fulfilled—most of the Amp^r transductants remained Bio$^-$ while only a small fraction became Bio$^+$. These Bio$^+$ transductants were also Gal$^+$ indicating that they had arisen by a recombination event within the *gal–uvrB* region. One of these isolates was chosen and a temperature-resistant isolate, designated CON481R, which retained its Mu and ampicillin resistance but grew at 42 °C, was selected for further study. The selection of this revertant of the c^{ts} mutation carried on the Mu(lac, amp)[1], was performed so that the cells could be grown at temperatures which produce higher titres of Pl. When Pl lysates were prepared on this host and used to transduce JC3890, 100% of the 132 Amp^r transductants screened also became Bio$^+$ and Gal$^+$. These results suggest that CON48 contains more than one Mu(lac, amp) insertion whereas CON481R carries only one such insertion, that being in or very near the *uvrB* gene.

The *uvrB* region of CON481R was also transferred to AB1157. This produced ampicillin resistant, UV^s transductants. In this recipient only 5 of the 50 Amp^r UV^s transductants screened acquired a Gal$^+$ phenotype. One such transductant was designated CON484 and used along with CON481R in further experiments. Because CON484 had originally been *uvrB*$^+$, any UV-sensitivity it acquired must have resulted from the presence of the insertion mutation.

To establish that the Mu(lac, amp) insertion was in fact causing the cells to be *uvrB*$^-$, two types of experiments were performed. First, the UV-sensitivity of CON484 was compared with that of JC3890 and AB1157. Figure 1 shows that the Mu(lac, amp) insertion produces the same UV-sensitivity as the *uvrB* deletion carried by JC3890. Similar results were obtained with CON481 (data not shown).

Host cell reactivation (HCR) results from the nucleotide excision repair of UV lesions mediated by the *uvrA* and *uvrB* gene products[13]. The ability of CON484 to carry out HCR was compared with that of AB1157 and JC3890. Figure 2 shows that CON484 was as deficient in this process as the *uvrB* deletion strain. These two experiments strongly argue that the Mu(lac, amp) insertion completely blocks *uvrB* expression either because it is inserted within *uvrB*, destroying the integrity of the gene sequence, or because it is inserted within the sequence of DNA coordinately regulated with the *uvrB* gene, but upstream from the gene, thereby totally blocking *uvrB* transcription.

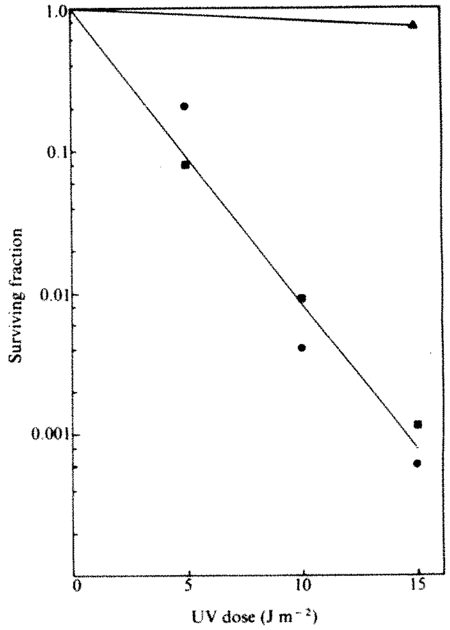

Fig. 1 Cultures (5 ml) of CON484, JC3890 and AB1157 were grown to saturation in L broth[22]. The cells were centrifuged out and resuspended in M9 salts[22] at a density of 2×10^8 ml^{-1}. Samples (1.0 ml) of each culture were irradiated in watchglasses with varied levels of light from a Sylvania G30T8 germicidal lamp, maximum output at 254 nm. Appropriate dilutions were made and the cells plated on LB plates in 2.5 ml of soft agar. Plates were incubated at 30 °C for 36 h before colonies were scored ●, JC3890 (Δ*uvrB*); ▲, AB1157 (*uvrB*$^+$); ■, CON484 (*uvrB*::Mu(lac, amp)). PFU, plaque-forming units.

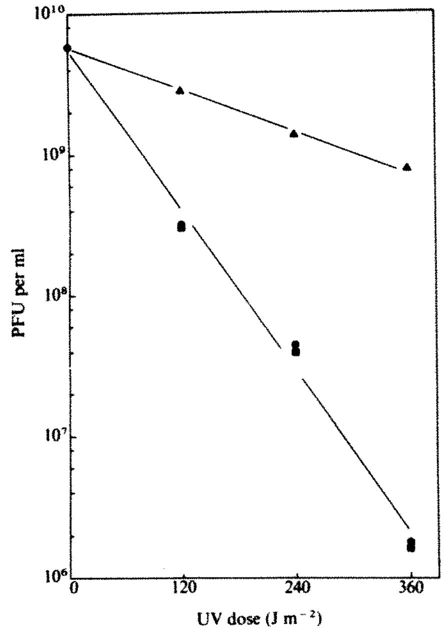

Fig. 2 Cultures of CON484, JC3890 and AB1157 were grown to saturation in T broth containing 0.2% maltose. A stock of λc_1857 in T broth[22] was irradiated in a watchglass with varied levels of 254 nm light. The phage were then appropriately diluted in 0.01 M Tris-HCl (*p*H 7.5) containing 0.01 M $MgSO_4$ and added to 0.1-ml cultures of one of the three strains to be tested. Plaques were scored after 16 h growth on T plates at 37 °C. ●, JC3890 (Δ*uvrB*); ▲, AB1157 (*uvrB*$^+$); ■, CON484 (*uvrB*::Mu(lac, amp)).

To establish finally that the Mu(lac, amp) insertion was located within the *uvrB* operon, strains were constructed in which a plasmid, derived from pBR322 and carrying the chromosomal region which includes the *uvrB* gene[23], was placed in cells carrying the Mu(lac, amp) insertion. This plasmid restored UV resistance to the multiply inserted CON48R as well as strains having only the single *uvrB* insertion. A similar plasmid carrying the same chromosomal segment but with an inactive *uvrB* gene left the insertion strains UV sensitive. We consider this to be very strong evidence that the Mu(lac, amp) insertion is within the *uvrB* operon.

The insertion of Mu(lac, amp) within the *uvrB* operon creates a situation where β-galactosidase is produced in response to stimuli which normally would cause increased synthesis of *uvrB* protein. Figure 3 shows that this operon is highly stimulated by exposure to UV light. During the 3 h following a 10 J m^{-2} exposure, β-galactosidase levels within the cell increase 20-fold (this represents a 5–6-fold increase in β-galactosidase synthesis relative to other proteins). This UV dose produced a near maximum extent of induction. Exposure to other DNA damaging agents, such as *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG), also induces the synthesis of this enzyme but to a lesser extent. Cells without the insertion produce no β-galactosidase and non-irradiated cells continue to produce basal levels of the enyzme throughout the experiment.

The basal level observed from experiment to experiment is rather variable, ranging from 40 to 110 units for strains CON481R and CON484. In contrast to these relatively low basal levels, the original isolate, CON48, has an uninduced level greater than 200 units. Despite this higher level of uninduced β-galactosidase synthesis, its induced level is only slightly higher than that of the strains shown in Fig. 3. This is again consistent with CON48 carrying multiple Mu(lac, amp) insertions—the one in or near *uvrB* is inducible, whereas the other insertion(s) produces 100–200 units of β-galactosidase constitutively.

During the course of this work, a report was published which identified five other gene functions that were induced by UV light[25]. One of these inducible operons was the *uvrA* gene, but no insertion into the *uvrB* gene was reported. All the UV-inducible genes isolated by Kenyon and Walker seem to comprise part of a regulon which is controlled by the *lexA* and *recA* gene products. In an attempt to determine if the *uvrB* gene also belongs to this regulon, *lexA* and *recA* strains carrying the *uvrB*::Mu(lac, amp) insertion were constructed. Both the *lexA*1 and *recA*1 mutations blocked the UV induction of β-galactosidase seen in *lexA*$^+$, *recA*$^+$ insertion strains. Thus, the *uvrB* gene is probably part of the *lexA*, *recA* regulon.

The biological impact of these results is substantial. If the *uvrA*,*uvrB*-mediated excision repair system is controlled by the *lexA*,*recA* regulatory system, and the amount of excision repair capacity increases significantly in response to DNA damage, this could explain the observations of increased survival of UV-ray irradiated phage in cells carrying the *tsl* mutation[14]. It may also be responsible for parts of Weigle-reactivation[16,17], and post-replication repair[6]. If this is the case it could provide a significant simplification to an otherwise bewilderingly complex picture of UV repair.

However, a note of caution must be added. We have presented here evidence consistent with the idea that the *uvrB* gene is

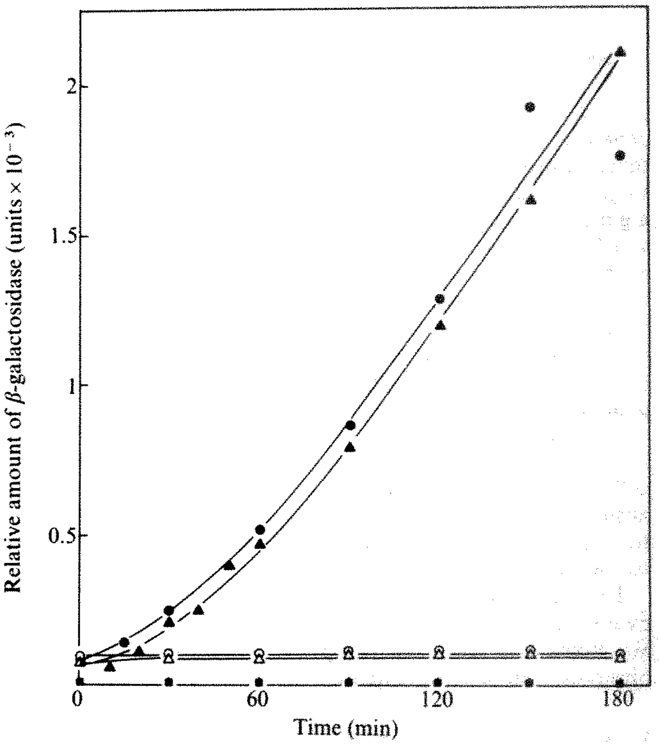

Fig. 3 Strains CON481R and CON484 were grown at 37 °C in M9 salts medium supplemented with 0.2% glucose, 2 μg ml^{-1} thiamine and 40 μg ml^{-1} Arg, Hist, Leu, Pro and Thr. When the cultures reached a cell density of 2–4 × 10^8 ml^{-1}, a 3-ml aliquot was irradiated with 10 J m^{-2} of 254 nm light. A 2-ml sample of these cells was diluted in 8 ml of pre-warmed medium and returned at 37 °C to incubate. The non-irradiated control cells were diluted similarly. Samples (0.5 ml) were withdrawn at various times and added to 0.5 ml of Zcm buffer[24] on ice. The cell density was monitored at 600 nm. Because irradiated cells stopped dividing, the optical density of the initial point was used throughout the outgrowth as an indication of relative cell number. The optical denisty at 600 nm of non-irradiated cultures was monitored at each time point. After completion of sampling, toluene was added to make the cells permeable; the toluene was then evaporated at 37 °C and 0.2 ml of *o*-nitrophenyl-β-D-galactopyranoside (4 mg per ml in 0.1 M sodium phosphate buffer, *p*H 7.0) was added to each sample and the reaction allowed to proceed at 28 °C. The reaction was stopped by addition of 0.5 ml of 1.0 M Na_2CO_3. Relative amount of β-galactosidase is expressed as standard units which have been defined[22] as $[(A_{420}-1.75\,A_{550})/(tvA_{600})]\times 1{,}000$. ○, Non-irradiated CON481R; ●, irradiated CON481R; △, non-irradiated CON484; ▲, irradiated CON484; ■, non-irradiated or irradiated AB1157.

Table 1 Genotypes and origins of strains used

* Ref. 18; † ref. 19; ‡ ref. 20; § this study.

part of an inducible regulon controlled by the *lexA* and *recA* gene products. This conclusion seems to make good biological sense. Unfortunately, it has been based on the analysis of a single insertion mutation. We cannot rule out the possibility that a genetic rearrangement could have occurred during insertion which fused the *uvrB* gene to a promoter other than the one normally used by *uvrB*. If this occurred, we have been analysing regulation at this promoter rather than the one normally used for synthesis of *uvrB* message. Although this is possible, it seems unlikely that a second extraneous promoter fortuitously fused to *uvrB* would be controlled by the *lexA* and *recA* gene products.

Another complication which could affect our conclusion arises from the fact that the Mu(lac, amp) insertion makes the cell UvrB^-. If the *uvrB* gene is in any way autoregulatory, the absence of an active *urvB* gene product could drastically alter the regulation of this operon. Experiments are being carried out to clarify this situation.

This work was supported in part by NCI grant CA 14733 and by the Institute of Materials Science, University of Connecticut. We thank Drs Kacinski, Rupp and Sancar for supplying the plasmids used in complementation analysis of our strains.

Chromatin fine structure of active and repressed genes

Abraham Levy & Markus Noll

Department of Cell Biology, Biocenter of the University,
Klingelbergstrasse 70, CH-4056 Basel, Switzerland

Study of the structural organization of chromatin during transcription and replication may reveal important aspects of these processes. At the lowest level of organization, chromatin consists of a repeating subunit, the nucleosome (for reviews see refs 1–3). Electron microscopy indicates that the nucleosomes are arranged helically[4–6] or form discrete superbeads[7], generating the familiar 250 Å–300-Å fibre[8]. It has been suggested that this fibre is further folded into loops containing up to several hundred nucleosomes[9,10]. Despite extensive study, the significance and fate of these nucleosomes remain obscure. We have used here micrococcal nuclease digestion to compare the structures of actively transcribing and inert chromatin of the genes coding for the major heat-shock protein of *Drosophila melanogaster*. The repressed *hsp 70* genes were considerably more resistant to cleavage by micrococcal nuclease than their flanking regions and the bulk of chromatin. The active genes, previously shown to be more sensitive than the repressed genes[11–13], are also more susceptible to the nuclease than their 3′-flanking regions and bulk chromatin.

The heat-shock genes of *D. melanogaster* provide an excellent system for studying different aspects of gene structure and regulation (reviewed in ref. 14). These genes are induced by transferring *Drosophila* tissues or cell cultures from their normal temperature at 25 °C to elevated temperatures above 30 °C. The major protein synthesized at 37 °C—*hsp 70*—has a molecular weight of 70,000. Six copies of the gene coding for this protein exist in the haploid genome of Kc cells[15]; each has been extensively characterized by cloning and whole-genome Southern analysis[15] (M.-E. Mirault, personal communication).

Nuclei of a *Drosophila* tissue-culture cell line were digested with micrococcal nuclease before or after heat shock. The DNA fragments obtained were separated according to size by agarose gel electrophoresis, denatured, transferred and bound covalently to diazobenzyloxymethyl (DBM)-paper[16]. By hybridization with radioactively labelled probes, the DNA sequences of interest were analysed selectively. Three different probes were used (Fig. 1)—the *Sal*–*Sal* fragment of 56H8 containing almost the entire coding region yet no flanking region, the *Sal*–*Bgl*II fragment of 56H8 adjacent to the 3′ end of the coding region and the *Bgl*II–*Bgl*II fragment to the left of the coding region in the genomic clone 132E3. The last probe contains moderately repetitive sequences[17] and was found to exhibit the same distribution of the nucleosomal repeat pattern (Fig. 2*C*) as bulk chromatin [revealed by staining the gel with ethidium bromide (Fig. 2*A*)] and hence is designated 'bulk'. Whenever the patterns revealed by these different probes are compared, they have been obtained by hybridizations with the same DBM-paper after release of the previous probe by denaturation.

The micrococcal nuclease pattern of the coding region (Fig. 2*B*) differs from that of bulk chromatin (Fig. 2*A*, *C*) in non-heat-shock conditions. The higher ratios of multimers to monomer in the lanes of the repressed gene (Fig. 2*B*) compared with the corresponding lanes representing bulk chromatin (control lanes in Fig. 2*A*, *C*) indicate that at least part of the coding region of the repressed gene is more resistant to micrococcal nuclease than bulk chromatin. This conclusion is corroborated by the observation that the average size of nick-translated DNA (bulk) obtained after nuclease digestion of

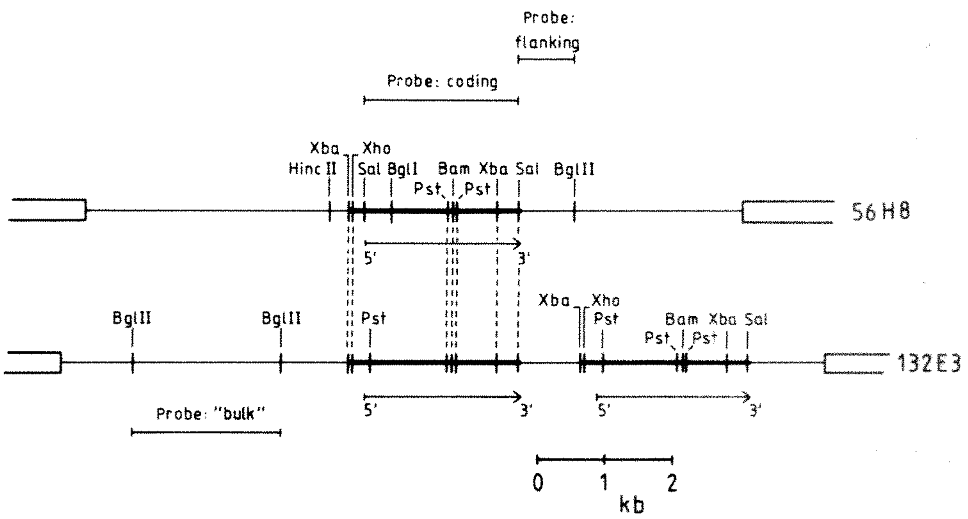

Fig. 1 Restriction map of *hsp 70* genes. Restriction maps of the *D. melanogaster* sequences in the hybrid plasmids 56H8 and 132E3 (ref. 26) have been published[27]. Only a few selected restriction sites are indicated here; the distances have been slightly corrected by calibration with additional low-molecular-weight markers (*Hae*III digest of PM2 DNA[28]). Sequences complementary to the *hsp 70* mRNA and the direction of transcription of these genes are indicated by arrows[18]. The protected domain of the repressed *hsp70* genes is represented by a thick bar comprising the coding region and most of the z_{nc} region[18]. The probes for the coding (*Sal–Sal*) and the flanking region (*Sal–Bgl*II), and the probe revealing a pattern similar to bulk chromatin (*Bgl*II–*Bgl*II) are shown above and below the maps. The names of the restriction enzymes have been abbreviated as follows: *Bam*, *Bam*HI; *Pst*, *Pst*I; *Sal*, *Sal*I; *Xba*, *Xba*I; *Xho*, *Xho*I. kb, Kilobases.

non-heat-shocked nuclei is much smaller than that of the pattern revealed by hybridization of the same DNA with the coding region. (Compare lanes labelled 'nt' and 'c' of 6% acid-soluble DNA in Fig. 3. Considering that the label incorporated into nick-translated DNA is proportional to its mass whereas the label of the hybridized DNA is proportional to the number of DNA molecules, the observed difference is even greater than apparent from a mere comparison of the patterns of the autoradiogram.)

After mild digestions, the DNA of the repressed gene hybridizing to the coding region exhibits a relatively narrow size distribution with an average of about 2.5 kilobases (control lane of *a* in Fig. 2*B*). In a more extensive digestion, three sharp bands at 2.52, 2.34 and 2.16 ± 0.05 kilobases appear above a background (control lane of *b* in Fig. 2*B*). These bands are more clearly visible when the background is reduced by a shorter exposure (lane *b* at far right in Fig. 2*B*). Therefore, a region of 2.5 kilobases, larger than the coding region[18] but which must contain at least part of the coding region, is more resistant to micrococcal nuclease digestion than its flanking regions when the gene is not expressed. To determine the right boundary of this protected domain, the *Sal–Bgl*II probe specific for the 3'-flanking region of one of the genes (Fig. 1) was used. As evident from Fig. 2*D*, the patterns resemble those of the bulk DNA (Fig. 2*A*, *C*) more closely than those of the coding region (Fig. 2*B*). The three bands between 2 and 2.5 kilobases are barely visible (control lane of *b* in Fig. 2*D*), and digestion is slightly inhibited in the repressed gene (ratio of monomer to oligomer DNA in lanes of control in Fig. 2*D*) compared with the bulk (Fig. 2*C*). This suggests that the protected domain and the *Sal–Bgl*II region overlap only slightly. In other words, the protected region of the repressed gene ends at a site close to the 3' end of the mRNA coding region[18] (Fig. 1).

From the size of the protected domain of about 2.5 kilobases, we predict that its left end reaches beyond the 5' end of the mRNA coding region and maps close to the left boundary of the z_{nc} region[18]. A more precise localization of the 5' limit by direct mapping is complicated by the presence of repetitive sequences in this region.

No bands are ever observed between 2 and 2.5 kilobases in heat-shock conditions, even when digestion is very mild ($<0.2\%$ acid-soluble DNA in Fig. 3), so that the DNA containing the coding region exhibits about the same average size as the protected domain of the repressed gene. (The size of the bulk DNA in such digests is on average 15 kilobases, as shown in the two lanes on the left in Fig. 3.)

During more extensive digestions, beyond 7% acid-soluble DNA, the protected domain of the inactive *hsp 70* genes is eventually degraded to smaller multiples of the nucleosomal repeat which are resolved significantly better than in bulk chromatin (control lane of *c* in Fig. 2*B*, and 11% acid-soluble DNA in Fig. 3). The largest fragments observed correspond to 12, 13 and 14 nucleosomes and co-migrate with the three bands of 2.16, 2.34 and 2.52 kilobases visible after milder digestions, whereas nucleosomal repeats larger than 10 are not resolved in bulk chromatin. It follows that the average spacing of nucleosomes is more uniform in the inactive gene than in bulk chromatin. Calibration with markers of known lengths shows that the nucleosomal repeat of the inactive gene is 180 ± 4 base pairs (Fig. 3).

The fragment sizes resulting from digestion of active genes are not distributed randomly, yet differ from those obtained after micrococcal nuclease digestion of bulk chromatin or of inactive genes. This results in bands ('hs' lanes of *b* and *c* in Figs 2*B* and 4) at positions between those of the familiar nucleosomal repeat. These bands are clearer in Fig. 4 where the DNA has been analysed in denaturing conditions. As the bands appear at roughly equivalent positions and intensities in denaturing (Fig. 4) and non-denaturing gels (Fig. 2*B*), the DNA fragments produced are largely double-stranded. These bands do not originate from the presence of preferential cleavage sites in the free DNA because digestion of free DNA of a mixture of 56H8 and 132E3 does not produce such bands after hybridization to the same *Sal–Sal* probe. Nor are they oligonucleosomes of which the DNA has been degraded from the ends because no such monosomes are observed. Moreover, in contrast to bulk chromatin, these structures do not show any metastable intermediates at any level of digestion but are readily degraded to very short pieces. This is demonstrated in Fig. 4 in which DNA fragments as short as 57 nucleotides have been transferred efficiently (shortest marker indicated on the left), yet very little hybridization is observed below 160 bases. The conditions of hybridization used permit detection of hybrids as short as 40 base pairs[19].

The observed changes in chromatin structure depend completely on the level of transcription. After returning heat-shocked cells to the normal temperature (25 °C), there is a gradual disappearance of the transcription-specific structures

Fig. 2 Chromatin structure of *hsp 70* genes: comparison with structure of bulk and flanking regions. Digests of control (labelled 'c') and heat-shocked nuclei ('hs') were compared pairwise in bulk chromatin (*A*), in the coding region of the *hsp 70* gene (*B*), in a region containing a middle-repetitive sequence (*C*) and in the 3′-flanking region of the *hsp 70* gene (*D*). Four levels of digestion are shown in each panel corresponding to about 2.3% (*a*), 7% (*b*), 12% (*c*) and 18% (*d*) acid-soluble DNA. For preparation of nuclei, *Drosophila* Kc cells (adapted to growth in low serum) were grown in suspension at 25 °C in Echalier's medium[29] supplemented with 1% fetal calf serum (Gibco). Cells heat-shocked for 35 min at 36 °C, or control cells not subjected to heat shock, were collected in mid-log phase at a density of about 8×10^6 cells ml^{-1}. The cells were quickly chilled by pouring them on to half a volume of frozen balanced salt solution (BSS), and all subsequent steps were carried out on ice or at 4 °C. The cells were pelleted, washed twice in BSS and resuspended in Mg^{2+}-buffer (0.33 M sucrose, 20 mM HEPES, *p*H 7.5, 80 mM NaCl, 1 mM $MgCl_2$) at 4×10^8 cells ml^{-1}. To lyse the cells, the cellular suspension was made 0.2% in Triton X–100, incubated for 15 min on ice and passed four times through a hypodermic needle (G-18). The nuclei were washed (1,400*g* for 10 min) two or three times in Mg^{2+}-buffer and finally resuspended at a concentration of 1.2×10^9 nuclei ml^{-1}. For digestion, $CaCl_2$ to 1 mM was added to the nuclear suspension, and 0.5-ml aliquots were incubated for 2 min at 37 °C with 20 (*a*), 60 (*b*), 180 (*c*) and 360 units (*d*) of micrococcal nuclease (Worthington). The DNA was extracted and treated with a mixture of RNase A and T_1 RNase. Samples containing 5 μg (*A*) or 50 μg of DNA (*B–D*) were subjected to electrophoresis in two 1.7% agarose slab gels in 50 mM KNa_2PO_4, *p*H 6.5, 4 mM NaAc, 0.5 mM EDTA. One gel was stained with ethidium bromide (*A*), while the DNA from the other gel was transferred to DBM-paper and analysed by hybridization with various probes (Fig. 1); *Sal–Sal* of 56H8 (obtained as subclone *Sal*-O; *B*), *Bgl*II–*Bgl*II of 132E3 (*C*) and *Sal–Bgl*II of 56H8 (*D*). Before transfer, the DNA was denatured by washing the gel twice for 15 min in 0.5 M NaOH, neutralized in 0.5 M Na-phosphate, *p*H 5.5, for 15 min, and washed twice for 10 min in 11.5 mM Na-phosphate-citrate, *p*H 4.0, first at room temperature, then at 4 °C. For preparation of DBM-paper, a published procedure[16] was modified to achieve an efficiency of DNA transfer of at least 40% over a size range of 40 bases to 21 kilobases. Using this modification, we can transfer at least twice as much DNA as was used in the experiments reported here before the binding capacity of the DBM-paper is reached[19]. Hybridization with the nick-translated[30], ^{32}P-labelled probe was carried out in 0.02% each of Ficoll, polyvinylpyrrolidone and bovine albumin[31], 5 × SSC, 1 mM EDTA, 0.1% SDS, 2 mg ml^{-1} salmon sperm DNA. After hybridization, the paper was washed four times for 1 h at 65 °C in 2 × SSC, 0.5% SDS, 17 mM Na-phosphate, *p*H 7.5, 0.05% $Na_4P_2O_7$, 1 mM EDTA and finally briefly in water at room temperature. For autoradiography, preflashed[32] Kodak XR-5 film was used with a Kyokko intensifying screen. All three autoradiograms have been obtained from one transfer of DNA to DBM-paper. After autoradiography, the hybridized probe was removed by four 30-min washes in 99% formamide at 80 °C, the DBM-paper was washed in water and the remaining ^{32}P-radioactivity (<3%) further reduced during 3–4 half lives to less than 0.3%. For calibration, the far-left lanes of each autoradiogram show *Hae*III fragments of PM2 DNA[28] and *Eco*RI fragments of λ DNA[33] labelled at their 3′ ends by 'Klenow' DNA polymerase I (Boehringer Mannheim). The lane on the far right in (*B*) represents a shorter exposure of the fourth lane from the left in (*B*). kb, kilobases.

(not shown). In some experiments (not shown), after micrococcal nuclease cleavage in the mRNA coding region of the active gene, we observed a smeared hybridization pattern initially which then gave way to a pattern reflecting the nucleosomal repeat. We could clearly correlate this smearing effect with a suboptimal heat-shock response. It thus seems crucial that transcription-specific structures be observed in heavily transcribed genes.

If the digestions after heat shock are relatively extensive ('hs' lanes of *d* in Figs 2*B*, 4), most of the hybridized DNA disappears, and only faint bands at the monomer and dimer positions of the inactive gene are visible. The residual monomer and dimer DNA can be explained if a few cells do not respond to heat shock or if a minor fraction of active genes contains small regions of a structure similar to that of inactive genes. Inactivity of one or more of the six *hsp 70* genes in all cells after heat shock is unlikely because, as the milder digestions show, the quantitative differences between the active and repressed genes exceed a ratio of 6 : 1 (compare, for example, the region between 2 and 2.5 kilobases in the two lanes of *b* in Fig. 2*B*).

As even bulk chromatin was more sensitive to micrococcal nuclease than the repressed gene, it was of interest to compare the sensitivity of the active gene with that of bulk chromatin. Comparison of the corresponding lanes of digests obtained after heat shock in Fig. 2*B* with *C* shows a smaller average DNA size and a reduced amount of hybridization in the former. Thus the DNA of active genes is more sensitive than the DNA of bulk chromatin.

We also compared the initial rates of digestion of the active and repressed genes. The average DNA size of the active gene after digestion to less than 0.2% acid-solubility is about the same as that of the repressed gene after digestion to 6% acid-solubility for which 30 times more enzyme is required (Fig. 3). Thus the active gene is degraded 30 times more rapidly.

In addition, we conclude from a comparison of the amounts of hybridizable material in denaturing conditions in control and heat-shock DNA (for example ~1.9 kilobases in lanes of *b* or ~1 kilobase in lanes of *c* in Fig. 4) that both DNA strands of the active gene are more sensitive to micrococcal nuclease than those of the repressed gene.

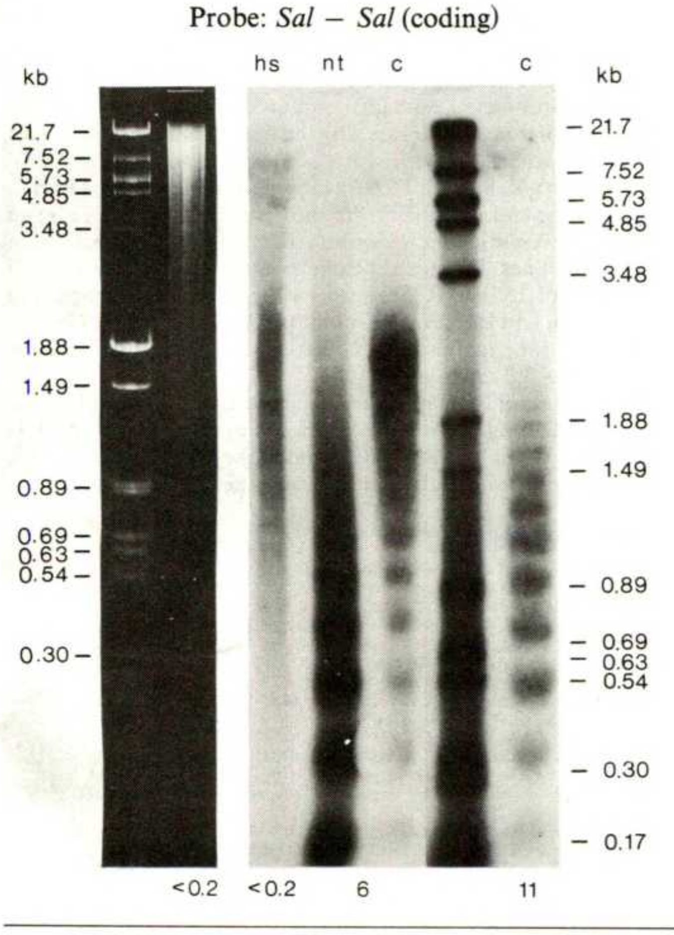

Fig. 3 Nucleosome spacing in repressed *hsp 70* genes and relative sensitivities of active and repressed *hsp 70* genes to micrococcal nuclease. On the left of the autoradiogram, the relative sensitivities to micrococcal nuclease of the active *hsp 70* gene ('hs'), of bulk chromatin ('nt') and of the repressed *hsp 70* gene ('c'; 6% acid-soluble DNA) are compared. At the far right, the uniform nucleosomal repeat of the repressed gene is shown ('c'; 11% acid-soluble DNA). Nuclei of heat-shocked ('hs') and control cells ('c') were prepared as in Fig. 2 except that the Mg^{2+}-buffer was replaced by spermine-spermidine buffer[34] (0.33 M sucrose, 15 mM Tris-HCl, *p*H 7.5, 60 mM KCl, 15 mM NaCl, 0.5 mM spermidine, 0.15 mM spermine) and the concentration of Triton X-100 was raised to 0.4%. Digestion of heat-shocked nuclei (1.2×10^9 ml^{-1}) with 4 U ml^{-1} of micrococcal nuclease and digestion of control nuclei with 120 or 360 U ml^{-1} rendered <0.2%, 6% and 11% of the DNA acid-soluble, as indicated below the corresponding lanes. The DNA was extracted, and 50-μg samples were subjected to electrophoresis in 1.7% agarose gels, transferred to DBM-paper and hybridized to labelled *Sal*-O DNA as described in Fig. 2. The 'nt' lane shows nick-translated DNA of the digest generating 6% acid-soluble DNA. The second lane from the right contains the same markers as in Fig. 2. The two lanes on the left show the same marker DNA and DNA of the digest of less than 0.2% acid-solubility after staining with ethidium bromide.

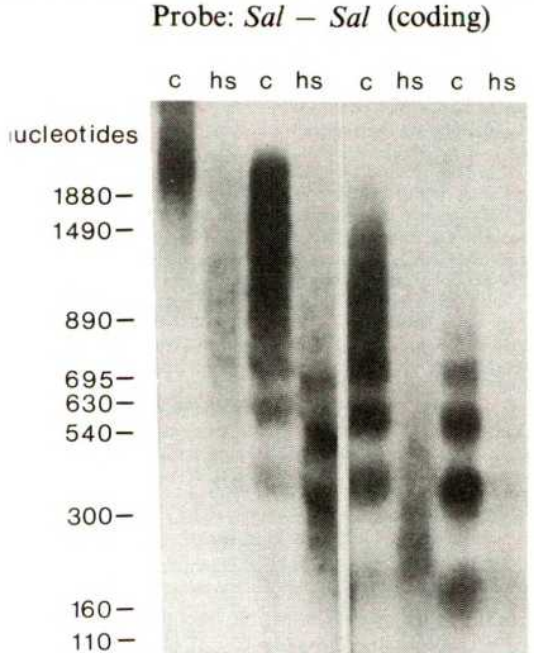

Fig. 4 Analysis of DNA fragments of the *hsp 70* gene in denaturing conditions. DNA samples (50 μg) of the same digests of control ('c') and heat-shocked nuclei ('hs') shown in Fig. 2 were subjected to electrophoresis in an alkaline 1.7% agarose gel[35]. After electrophoresis, the DNA was neutralized, transferred to DBM-paper, hybridized to *Sal*-O DNA and autoradiographed as described in Fig. 2 legend. On the left, the positions of *Hae*III fragments of PM2 DNA, used for calibration, are indicated.

As genes may be part of large loops of domains[9,10,20,21], it was interesting to examine whether the sensitive region of the active state extends beyond the coding region to include such larger domains. A comparison of the hybridization pattern of the 3'-flanking region (Fig. 2*D*) with that of the coding region (Fig. 2*B*) shows that the enhanced sensitivity does not extend much beyond the 3' end of at least one of the *hsp 70* genes (a similar study with the 5'-flanking region is complicated by the presence of repetitive sequences). The pattern obtained by hybridization to the 3'-flanking-region probe (Fig. 2*D*) is very similar to that of the bulk (Fig. 2*A*, *C*). Thus, for a first approximation, the region downstream from the right *Sal* site (Fig. 1) is organized similarly to bulk chromatin in heat-shock conditions. However, the patterns revealed by these two probes do differ slightly. First, the heat-shock lanes of *b* and *c* in Fig. 2*D* show more hybridization in the regions between monomer and dimer and between dimer and trimer DNA than the corresponding non-heat-shock controls or than the same lanes representing bulk chromatin (Fig. 2*A*, *C*). This suggests that the *Sal*–*Bgl*II probe overlapped slightly with the chromatin region containing the transcription-specific structure (Fig. 2*B*). Second, there is less hybridization after extensive digestion of the heat-shock-treated nuclei ('hs' lanes of *d*) in the flanking region (Fig. 2*D*) compared with bulk DNA (Fig. 2*C*) when normalized to the control. We infer that the sensitive portion of the gene ends close to the right-hand *Sal* site. As the 3' end of the mRNA coding region also maps close to this site[16], the 3' end of the mRNA coding region and the right boundary of the nuclease-sensitive chromatin region must be very close to each other.

Altered sensitivity to nuclease of actively transcribed genes may result from several structural changes: (1) changes in the higher structural orders, (2) changes in the structure of the nucleosomes, and (3) the absence of histones from transcribed DNA. Therefore, earlier suggestions made solely on the basis of DNase sensitivity that active genes contain structurally modified nucleosomes are invalid[22,23]. More detailed information with respect to the structure of active genes may be gained by analysing the size distribution of the DNA fragments produced by the action of DNase, and this study has revealed transcription-specific structures not previously observed. Micrococcal nuclease was found to discriminate between a gene, regardless of its state, and the rest of the chromatin. The repressed genes were protected and the active genes were highly sensitive compared with bulk chromatin or the neighbouring non-transcribed region. The levels of sensitivity of the gene are reversible and depend on its transcriptional activity. Hence, models of gene repression need not be based solely on the interaction of regulatory proteins with the 5' end. Similarly, the association of bulk-type nucleosomes with the gene seems, *in* itself, insufficient to keep the gene in the inactive form. Some mechanism seems to exist which, on repression, alters the chromatin structure of the gene so as to reduce its accessibility (and that of a region of about 1 nucleosome at its 5' end) to the nuclease considerably below that of the flanking, non-transcribed DNA sequence.

The mechanism of protection of the repressed genes could be explained on at least two structural levels. Each linker region joining adjacent nucleosomes could be modified in such a way as to reduce its sensitivity to micrococcal nuclease. The known sequence of the *hsp 70* gene[24,25] rules out the trivial explanation that all linker regions are less sensitive to micrococcal nuclease because of a high G+C content. In a more attractive model, all the linker regions of the entire domain become collectively resistant to the nuclease by some change in higher order of chromatin structure. The transition points between the protected domain of the repressed state and the flanking, bulk-like structure might then be sequences of regulatory significance. Specific nonhistone protein(s) interacting with these sequences may associate with each other to bring the two ends of this chromatin segment into tight proximity, producing a loop containing 14 nucleosomes. Such a loop may form a supercoiled, more compact and less accessible form of chromatin. In this model, activation of a gene would require at least two steps. First, the protected domain is unfolded, and only then does initiation of transcription start by the modification or removal of the nucleosomes.

We thank P. Schedl, S. Artavanis-Tsakonas, M.-E. Mirault, W. Gehring and A. Tissières for the hybrid plasmids 132E3 and 56H8, M. Goldschmidt-Clermont for the *Sal*-O subclone of 56H8, R. Jack for the subclone containing the *Bgl*II–*Bgl*II fragment of 132E3, R. Steward for the Kc cell line adapted to low serum, and E. Frei, M. Goldberg, R. White and H. Noll for criticism of the manuscript. This work was supported by Swiss NSF grants 3.719.76 and 3.466.79.

The results of this paper have been presented previously at the Annual Meeting of Swiss Societies of Experimental Biology in Basel, on March 13–14, 1980[36] and at the Gordon Conference on Chromatin and Nuclear Proteins (June 15–20, 1980).

Theory agrees with experimental thermal denaturation of short DNA restriction fragments

Albert S. Benight*, Roger M. Wartell*† & Dennis K. Howell*

Schools of Physics* and Biology†, Georgia Institute of Technology, Atlanta, Georgia 30332

Experimental melting transitions of several natural DNAs of known nucleotide sequences have recently been obtained. The differential melting curves of these DNAs—ΦX174 DNA[1–3], fd DNA[4] and SV40 DNA[5]—all show distinctive sets of peaks or fine structure. Theoretical melting curves calculated from the sequences and a few *a priori* parameters have not accurately predicted the experimental transitions[2,6,7]. Although calculated fine structure resembled experimental curves in some cases, the characteristic features of a DNA's differential melting curve could not generally be produced. Azbel[8,9] and Gabbarro-Arpa *et al.*[5] have recently obtained good agreement between calculated and experimental curves using a different theoretical approach—only ground-state configurations of DNA were considered for temperatures inside the transition region. Their results suggest that the basic model of DNA melting, common to all theoretical approaches, is accurate. We have used here an exact theoretical approach to calculate melting curves of four DNA restriction fragments of 95–301 base pairs containing the lactose promoter region (Fig. 1). Theoretical curves agree very well with the experimental transitions published by Hardies *et al.*[10] and obtained in this laboratory.

Figure 1 shows the four fragments relative to the *lac* promoter–operator region. The base sequence of this region was determined by Dickson *et al.*[11]. Figure 2 shows the comparison between theory and experiment for the *lac* fragments in 0.1 M Na^+. Theoretical curves predict the melting temperatures, T_ms, peak heights and widths at half height for the four fragments. Although short fragments do not have as much detail in their melting curves as long DNAs, the fine structure observed in Fig. 2 is predicted.

Theoretical curves were generated using the loop entropy model of the DNA helix–coil transition[12–14]. Poland's algorithm including the effects of final dissociation of duplex DNA to single strands was used[15]. Parameter values for T_{AT} and T_{GC}, the average melting temperatures of A·T and G·C base pairs, σ, the nearest-neighbour cooperativity factor, and other thermodynamic parameters are given in Fig. 2 legend. For the short DNAs examined, the melting of internal regions and the corresponding loop entropy contribution to the theory are not significant. Proper account of dissociation of duplex to single strands[16] is essential for accurate agreement with experimental results.

The total fraction of hydrogen-bonded base pairs, θ_{net}, depends on the DNA's external, as well as internal, degrees of freedom. θ_{net} may be written as $\theta_{net} = \theta_{int}\theta_{ext}$, where θ_{int} is the fraction of bonded base pairs among the duplex strands and θ_{ext} is the fraction of strands associated as a duplex with one or more intact base pairs. The equilibrium dissociation of the duplex to single strands may be represented by the reaction:

$$C_2 \rightleftarrows 2C_1 \qquad (1)$$

where C_2 is a duplex and C_1 is a single strand. It has been shown[13,16] that θ_{ext} depends on Z_{int}, the internal molecular partition function of the DNA, C_0, the total strand concentration, and β, the ratio of partition functions for the external degrees of freedom of duplex and single strands.

The mass dependence of rotational and translational partition functions of polyatomic molecules suggests that β varies with DNA length in base pairs, N, as

$$\beta = \frac{Z_{ext}(C_2)}{[Z_{ext}(C_1)]^2} = K\frac{N^{\alpha_2}}{N^{2\alpha_1}} = KN^{\alpha} \qquad (2)$$

where $\alpha = \alpha_2 - 2\alpha_1$ and K is a constant which includes all terms independent of N[13,17]. α_1 and α_2 combine the N dependence of the translational degrees of freedom, $N^{3/2}$, as well as the N dependence of the rotational degrees of freedom. The latter vary according to the molecule's principal moments of inertia, for example, for a rod $N^{7/2}$, for a sphere $N^{5/2}$. Our first attempts to fit theoretical curves to experiment modelled equation (1) as a rod dissociating to two spheres. This assumption yields $\alpha = -3$ for equation (2). A constant K value was selected to provide a

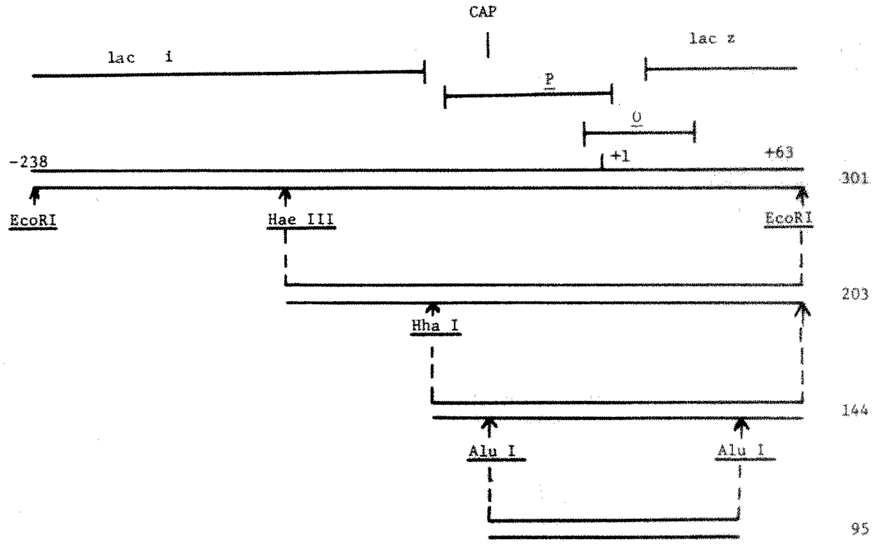

Fig. 1 The 95-, 144-, 203- and 301-base pair restriction fragments containing part of the lactose operon transcription initiation region. Each fragment is fully embodied within the next largest. A partial restriction map indicates location between restriction sites. *lac z* is the region coding for *β* galactosidase; *lac i* is the region coding for the *lac* repressor. The starting point of transcription for the *lac* operon mRNA is designated as +1. CAP, P and O indicate the binding sites for the CAP–cyclic AMP complex, RNA polymerase and *lac* repressor respectively. Each fragment was cloned into *Eco*RI sites[21,22]. Purified fragments thus had four-base *Eco*RI ends. The influence of these single-stranded ends on theoretical melting curves was negligible.

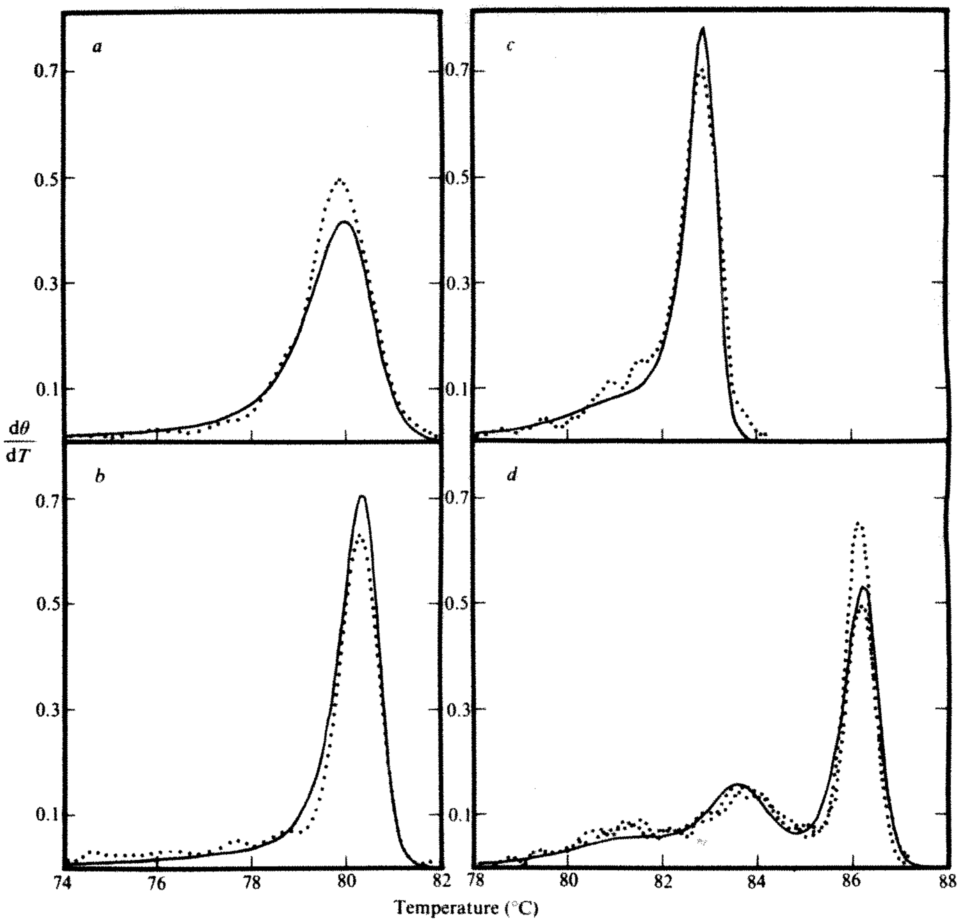

Fig. 2 Experimental differential melting curves of *lac* operon fragments (dotted lines) and theoretical curves (solid lines) are plotted. *a* Shows the 95-base pair DNA, *b*, the 144-base pair DNA, *c* the 203-base pair DNA and *d* the 301-base pair DNA. The solvent was 0.1 M NaCl, 1 mM potassium phosphate and 10 μM EDTA. Experimental data for the 95-, 203- and 301-base pair DNAs were from Hardies *et al.*[10]. The 144-base pair fragment was isolated in this laboratory using previously described methods[21,22]. Melting curves of the 144-base pair DNA were obtained in the same solvent as above. A double-beam spectrophotometer was used. A platinum resistance thermometer measured the sample temperature. The heating rate was 6 °C h^{-1} and absorbance readings at 260 nm were made at approximately 0.05 °C intervals. Data were collected on paper tape and then processed with a time-sharing computer facility. Detailed procedures will be described elsewhere (D.K.H. and R.M.W., unpublished). The data analysis is similar to that used by Vizard *et al.*[2]. The T_m values of the 95-, 203- and 301-base pair DNAs were reported in ref. 10. Reproducibility of these T_ms was within 1 °C. Duplicate experiments of the 144-base pair fragments gave a T_m of 80.9 ± 0.2 °C. *d* Shows the internal reproducibility of two melting curves of the 301-base pair fragment. The major peaks of the two dotted experimental curves have been aligned for comparison at the average T_m. Experimental error for the other three fragments was no greater than that shown in *d*. Calculated curves were shifted slightly in temperature (0.2–0.6 °C) to match the average T_ms of the major peaks. The small oscillatory peaks in the early part of the experimental transitions are probably due to the cubic fit smoothing of the raw absorbance data. We do not regard them as real intensity peaks. Melting curves of the 95- and 301-base pair fragments were also obtained at 282 nm. The 95-base pair curve was within the experimental error of melting transitions measured at 260 nm. The only significant difference between the 301-base pair curve at 282 nm and *d* was 20% decrease in the amplitude of the minor peak. Theoretical parameters used were $T_{AT} = 64.3$ °C, $T_{GC} = 107.2$ °C, $\sigma = 4.5 \times 10^{-5}$, $H_{AT} = -8.5$ kcal mol^{-1} and $H_{GC} = -9.4$ kcal mol^{-1}. The loop entropy term was that used by Wartell[23]. As expected, varying the loop entropy constant ($1.0 < k < 1.9$) did not alter the results. The dissociation parameter, β, is given in the text and Fig. 3 legend.

good fit to the melting curve of the 301-base pair DNA and β values for the other DNA fragments were determined from equation (2). This procedure provided very good agreement with the experimental T_m values and overall transition shape. However, the theoretical curves consistently predicted transition widths slightly broader than those observed experimentally. This discrepancy was removed by altering the simplified model to include dependence of the external partition functions on θ_{int}. The moments of inertia for various duplex configurations clearly depend on the amounts of base-paired and single-stranded regions. Figure 3 illustrates DNA configurations at different stages of melting. We assume that within the helix–coil transition region, DNA melting resembles a rod dissociating to two coiled spheres for the initial stages of melting and a sphere dissociating to two coiled spheres at the upper end of the transition. Thus α varies as $\alpha = a + b(1 - \theta_{\text{int}})$, where the constants a and b are chosen such that α decreases from -3 to -4 through the transition. This change removed the transition-width discrepancy.

Theoretical calculations can determine θ_i, the probability that the ith base pair of the sequence is intact at a given temperature[14,15]. Melting profiles—plots of $(1 - \theta_i)$ against i as a function of temperature—indicate the temperatures at which specific regions within the DNA sequence unwind. Note that θ_i depends only on a DNA's internal degrees of freedom, that is,

$$\left(\sum_{i=1}^{N} \theta_i\right) \Big/ N = \theta_{\text{int}}.$$

Figure 4 shows melting profiles of the 301-base pair fragment between 80 and 90 °C. Similar profiles have been obtained for the 95-, 144-, and 203-base pair fragments (not shown). The profiles indicate that denaturation initiates from the ends with regions of 60–80 base pairs melting over a 1–2 °C interval. These regions can sometimes be associated with peaks on experimental

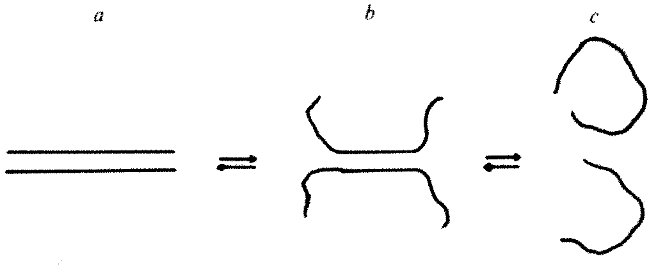

Fig. 3 Simple model for short DNA helix–coil dissociation. Three configurations are labelled *A* (helix rod), *B* (helix rod–sphere) and *C* (two coiled spheres). β, the ratio of partition functions for the external degrees of freedom, depends on fragment length N, and the fraction of bonded base pairs among duplexed strands, θ_{int}. $\beta = KN^{\alpha}$, where $\alpha = a + b(1 - \theta_{\text{int}})$. Constants K, a and b were 5×10^3, -2.8 and -3.2 respectively. a and b were chosen such that when combined with θ_{int}, α varied from -3 to -4 through the transition. In the early stages of the transition, $\theta_{\text{int}} \approx 0.9$, $\alpha \approx -3$ and dissociation is best described as $A \rightarrow C$. Base-pair unwinding with increasing temperature changes the configuration of the partially duplexed DNAs. Duplex dissociation resembles $B \rightarrow C$ as the temperature increases. For the last portion of the transition, $\theta_{\text{int}} \approx 0.6$ and $\alpha \approx -4$.

curves. Figure 4 shows the right-most 52 base pairs melting by 82 °C. This region corresponds to the slight increase from 80–82 °C in Fig. 2*d*. The small peak centred about 83.6 °C in Fig. 2*d* is associated with the melting of an 88-base pair block adjacent to the previously unwound region. These results are similar to those deduced by Hardies *et al.*[10] from analysis of the experimental curve and base-composition distribution of the 301-base pair fragment. One must be careful not to overinterpret melting profiles such as those in Fig. 4. As θ_i values do not consider strand dissociation, a meaningful comparison of melting profiles with differential melting curves is only possible when most strands are in the duplex state. Figure 4 shows an 80-base pair region largely intact at 88 °C, where the net fraction of intact base pairs, θ_{net}, is close to zero (Fig. 2*d*). At this temperature $\theta_{\text{int}} \approx 0.3$ but $\theta_{\text{ext}} \approx 10^{-5}$. Strand dissociation has reduced duplex DNAs to an insignificant fraction of total strands. Figure 4 would be valid throughout the transition if one could cross-link the complementary strands to prevent strand dissociation. Melting profiles of the 95-, 144- and 203-base pair fragments also show that melting initiates from the ends.

The agreement between theory and experiment indicates that the theoretical model is accurate for the conditions examined. Further studies on other short DNA restriction fragments also show good theory–experiment agreement (W. Hillen, T. C. Goodman, R. D. Wells, A.S.B. and R.M.W., unpublished results). It remains uncertain why exact calculations do not agree well with experimental curves of longer DNAs. The theory provides a method for examining the influence of base pair sequence on DNA melting of short fragments. Additional calculations show that single base pair changes in certain locations in the 203-base pair DNA can alter the overall melting temperature by 0.6 °C. This type of information may be relevant to understanding the interaction of RNA polymerase with promoter sites. Several results indicate that the thermal stability of promoters and their surrounding regions influence RNA polymerase–promoter interaction[18–20].

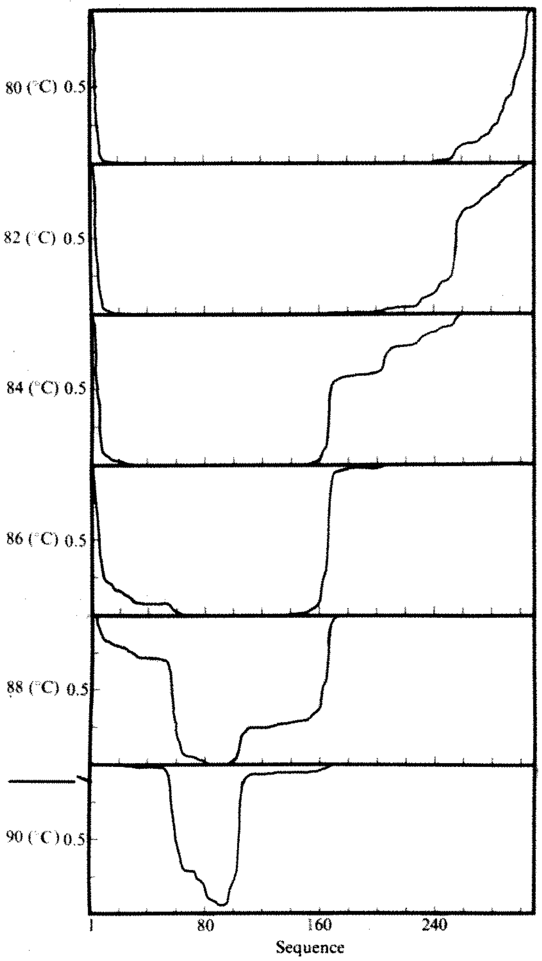

Fig. 4 Probability profile for the 301-base pair fragment. Probability of a base pair broken $(1-\theta_i)$ is plotted on the *y* ordinate against base pair (*i*) of the 301-base pair DNA sequence as a function of temperature.

We thank S. C. Hardies, W. Hillen, T. C. Goodman and R. D. Wells for providing us with their manuscript before publication, and for helpful discussions and supplementary information. Detection of the effects of asymmetric assortative mating

L. J. Eaves & A. C. Heath

Department of Experimental Psychology, South Parks Road,
Oxford OX1 3UD, UK

Assortative mating is clearly important in determining the genetic structure of a population but studies of assortative mating in man have been restricted mainly to the examination of correlations between spouses for single variables. It has been assumed that assortation is based directly on the measured phenotype or on components of the phenotype whose determination is similar in both sexes. Recently, such assumptions have been questioned (see, for example, refs 1–3) because males and females may regard different aspects of the phenotype as important for mate selection. The term 'asymmetric assortative mating' has been used to describe such situations. It has also been suggested that the study of the spouses and offspring of twins[1,2] may permit resolution of such components of the mating system. *Ad hoc* models have been proposed (for example, ref. 1) to specify the contribution of asymmetric assortment to the correlations between relatives, but these have not been internally consistent or sufficiently parsimonious. We show here how a simple model based on biological considerations offers a foundation for a consistent and economical theory of asymmetric mate selection which may be used for the analysis of patterns of familial similarity.

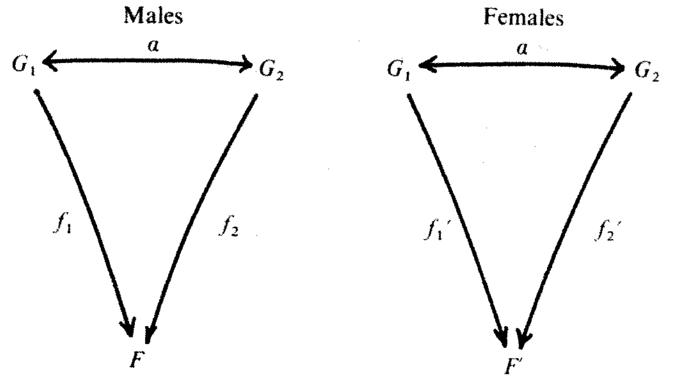

Fig. 1 The contributions of two genetic systems to variation in male and female fitness. See text for definition of symbols.

Table 1 The genetic correlation between MZ twins and their relatives in the presence of asymmetric assortative mating for fitness

Genetic correlation	Sex of twins	
	Male	Female
Twin	1	1
Twin–spouse	$\phi\phi'\mu$	$\phi\phi'\mu$
Spouse–spouse	$\phi'^2\mu^2$	$\phi^2\mu^2$
Sibling	$\frac{1}{2}(1+\phi\phi'\mu)$	$\frac{1}{2}(1+\phi\phi'\mu)$
Half-sibling	$\frac{1}{4}(1+2\phi\phi'\mu+\phi'^2\mu^2)$	$\frac{1}{4}(1+2\phi\phi'\mu+\phi^2\mu^2)$
Parent–offspring	$\frac{1}{2}(1+\phi\phi'\mu)$	$\frac{1}{2}(1+\phi\phi'\mu)$
Spouse–nephew/niece	$\frac{1}{2}(\phi'^2\mu^2+\phi\phi'\mu)$	$\frac{1}{2}(\phi^2\mu^2+\phi\phi'\mu)$

See text for definition of parameters.

The model assumes that assortative mating is based on a composite aspect of the phenotype, 'fitness', and is necessarily symmetric at this level. Asymmetry in mate selection arises because the sexes differ in the contribution of particular genetic effects to this composite phenotype, thus the determination of fitness is partly sex-limited. The principles are illustrated by a simple special case in which there is no environmental variation in fitness. The model can be extended to incorporate such additional subtleties as maternal effects and cultural transmission without altering its essential features.

For simplicity we postulate that fitness in males, F, and in females, F', is determined by two genetic systems, G_1 and G_2, which are correlated within individuals simply through the genetic consequences of the mating system. The contributions of G_1 and G_2 to variation in F and F' are represented by the standardized regression (path) coefficients f_1 and f_2 for males and f_1' and f_2' in females. The correlation between G_1 and G_2 is denoted by α. The possibility of asymmetry is represented by the fact that the paths in males and females, f_1 and f_1', f_2 and f_2' are not necessarily the same. Figure 1 represents the model in diagrammatic form.

It is assumed that assortation is based primarily on the phenotypic correlation (which is symmetric by definition) between F and F'. This is the marital correlation, μ, for fitness. The critical determinant of the distribution of genetic differences in the next generation is the genetic correlation between spouses. We consider that between the deviations in G_1 for males and females. The algebra is equivalent for any other component of F and F', whose effects may be measured directly or indirectly. Given α, μ, f_1, f_2, f_1' and f_2', the correlation between the G_1s of spouses is $\mu\phi\phi'$ where $\phi = f_1 + f_2\alpha$, and $\phi' = f_1' + f_2'\alpha$. As both ϕ and ϕ' are involved in this correlation, they will not be resolved by examining the phenotypic correlation between spouses for a single variable. Such resolution is possible, however, if we consider the spouses of relatives. Following Nance[1] and Eaves[2], we consider the spouses of identical (MZ) male and female twins. To explore the consequences of asymmetry for the next generation we also consider the genetic correlations between siblings and the biological half-siblings obtained by mating MZ twins to separate spouses. We consider only the effects of G_1, as shown in the model in Fig. 2. The coefficients of $\frac{1}{2}$ on the paths between parental and offspring genotypic deviations reflect an underlying assumption of genetic additivity. The diagram assumes that the twins are female. The figure for male twins would be similar except that ϕ would be replaced by ϕ' and vice versa.

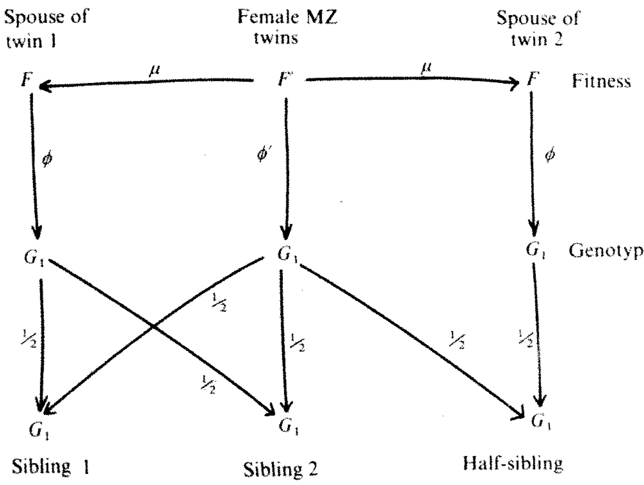

Fig. 2 The contribution of assortative mating to the genetic similarity of the relatives of female identical twins.

The expected genetic correlations between relatives are given in Table 1. These can be obtained by applying the rules of path analysis to the model in Fig. 2. The sex of the twins does not affect the sibling and parent–offspring correlations differently. The maternal and paternal half-sibling genetic correlations differ by $\mu^2(\phi - \phi')$ and that between the spouses of female and male twins by $\mu^2(\phi^2 - \phi'^2)$. As Nance[1] suggested, the effects of asymmetry may indeed simulate those of classical maternal effects in half-sibship data by making maternal half-siblings more alike than paternal half-siblings if $\phi > \phi'$. It is the comparison of the spouses of twins which may have a critical role in the resolution of direct maternal effects from those created or simulated by assymmetric mate selection. Environmental components in the determination of F and F' change the definition of ϕ and ϕ' without substantially altering these conclusions. Clearly, resolution of genetic and environmental determinants of mating preference requires data on the spouses of relatives in addition to MZ twins[2], but the model we propose may form the basis for the discussion of more complex systems of mating than those which are frequently considered by students of human differences.

BOOK REVIEWS

Anti-realist philosophy of science

Mary Hesse

The Scientific Image. By Bas C. van Fraassen. Pp.235. (Clarendon/Oxford University Press: 1980.) Hbk £15, $45; pbk £6.50, $18.95.

PHILOSOPHERS of science have recently been much exercised about the question "Do scientific theories describe the real world?". This is a question that arises from two sorts of problem. First, it has become a question within quantum physics, and has led to disputed interpretations such as those between the so-called Copenhagen school and the "hidden variables" theorists. Second, it has become a matter of particular concern to philosophers since the radical analyses of Kuhn and Feyerabend in the 1960s, in which it was suggested that the contents of particular scientific theories are culturally relative pictures of the world, not attempts at true objective explanation. The villagers of Salem believed in witches, modern scientists believe in atoms; both are unobservable, so why should the latter be considered to be nearer the truth? Even to raise such a question constituted an attack upon the rationality and progressiveness of science, and sent philosophers scurrying back to the defence of realism.

Van Fraassen's book marks a significant new stage in this debate. In it he defends an anti-realist position, but without falling into the extreme absurdities of relativism. He draws the lines of the debate in the following way. What he calls "minimal realism" holds that "science aims to give us, in its theories, a literally true story of what the world is like; and acceptance of a scientific theory involves the belief that it is true" (p. 8). What he calls "constructive empiricism", on the other hand, holds that "science aims to give us theories which are empirically adequate; and acceptance of a theory involves as belief only that it is empirically adequate" (p. 12). His arguments against the former view and for the latter are detailed and cogent, and range over the problematic relation of theory and observation, the nature of scientific explanation and scientific methodology, and the proper interpretation of "probability" in statistical science. I will pick out a few of the salient and more controversial points of the argument.

First, as van Fraassen construes the debate, it is about the aims of science, not about the nature of theories as such. He does not claim that theories are "nothing but" computing devices for processing and emitting predictions, nor that they are metaphorical fictions which speak only and misleadingly about observations. For van Fraassen, theories consist of meaningful propositions having truth value. They are given meaning in the same way that any descriptive language is given meaning (whatever that is). Van Fraassen does not consider it the job of philosophy of science to debate general theories of meaning, and here he reveals a belief that science and the philosophy of science do not fundamentally upset the *status quo* with regard to received theories of language, meaning and truth. Thus he does not follow those radical philosophers of science who consider that scientific concepts may so modify our commonsense picture of the world as to require changes also in the way we conceive natural language. van Fraassen does not believe that philosophy of science has implications for "deep" philosophical problems, or that philosophy of science is properly about "language" at all — it is about the world, just as science itself is about the world. Such conservative assumptions are controversial, but van Fraassen is certainly correct in seeing that if they were to be questioned, we would be led into issues far beyond the range of this book.

Theories, then, have truth value, but it is not the aim of science to discover true theories. Though it is not argued quite explicitly in the book, this rejection of theoretical "explanation" as the chief aim of science seems to be based on the belief that we can never know that we have arrived at exactly true theories. Most theories have turned or will turn out to be false as more evidence comes in, and even where they have not yet been refuted, there are always conceivable incompatible alternatives which are also empirically adequate. Thus the aim of discovery of true theories is one that we cannot ever know that we have attained, and it should be replaced by the realizable and often realized aim of empirical adequacy. To the currently fashionable argument that theories must be true of the real world because they are so successful in application, van Fraassen simply replies that they are successful because they incorporate accounts of real empirical regularities; it is these that make them successful, and only those theories that incorporate them survive. But we have no warrant to claim truth for what goes beyond empirical regularities, even though all interesting theories do undoubtedly go beyond them.

Other common arguments for and against realism have started from the so-called "theory-ladenness" of observation. On behalf of realism it is argued that since our theoretical view of the world reaches right down into the way we describe observations ("tracks of *electrons*", "*glacial* moraines") and into the expectations we form regarding possible future observations, therefore we are bound to presuppose that at least some of our background theories are true. On the other hand, the anti-realist replies that this all-pervasive character of theory simply shows that our theoretical world-views are cultural products, which can be seen in historical and social perspective to change from culture to culture, and are therefore culturally relative and not realist. Van Fraassen makes short work of all this argumentation. Our language, both theoretical and observational, is of course the language of *our* culture group. But this does not make observational *information* either theory- or culture-relative — only its *expression* as embodied in the current scientific language. Theories are not linguistic entities; they should rather be seen as families of models of possible worlds, whose empirical sub-structures represent phenomena.

Talk of models commits van Fraassen to a metatheoretical view of science in the sense that he presupposes that theories are ideally axiomatized, and that their empirical content is exhausted by the empirical interpretations of entailments of the axioms. This view results in what I would regard as a major limitation of the book, namely van Fraassen's treatment of scientific methodology. He sets out to show that accepted methodological principles such as simplicity, explanatory power, the unity of science and so on are explicable in terms of an anti-realist view. In some cases he succeeds, but in others he has to be content to regard the maxims of theory-choice as "merely pragmatic", that is to say not relevant to questions of truth or the empirical adequacy of predictions. In terms of his position he cannot answer questions such as: why should predictions from simpler theories be generally more reliable?; why should analogical arguments from theory to theory work as well as they do? I believe van Fraassen's comparatively cavalier dismissal of such problems of epistemology, induction and confirmation can be traced to his exclusively deductive (and sometimes statistical) construal of the formal character of theories. But theories are not treated in scientific practice as axiomatized entities; they have much fuzzier edges than that, and reliably support inferences that are not just deductive or formally statistical.

Such limitations apart, however, this book for the first time makes a clear statement of what is involved in scientific realism, and it will become the classic current argument against that philosophical position. It successfully debunks recent exaggerated attention to the concept of "explanation", and replaces it with a healthy concern with truth and empirical adequacy that does not give any hostages to relativism. Tactically, its relative conservatism about the general philosophical implications of philosophy of science will make it all the more influential among realist philosophers. Scientists, however, may well be ready for more radical investigation of the effects of changing scientific theories on our commonsense presuppositions, and particularly on our views of logic, natural language and scientific inference.

Mary Hesse is Professor of Philosophy of Science, University of Cambridge.

Archaeological jargon explained

A. F. Harding

A Dictionary of Terms and Techniques in Archaeology. By Sara Champion. Pp.144. (Phaidon/Facts on File: 1980.) Hbk £6.95, $15.95; pbk £4.95.

THE Introduction to this little volume tells us that the book "is not a general dictionary of archaeology: names of cultures and artefacts have been deliberately omitted". Instead, it "has been compiled with the aim of introducing to non-professional archaeologists the terms and techniques used in modern archaeology". The author disclaims personal expertise in most of the techniques described, and has generally provided brief (typically 30 to 300 word) entries with a reference to a standard work on the subject.

Despite its limited brief, professionals and students, as well as interested amateurs, will find much of practical use in this book, especially for checking up on those jargon terms one so frequently hears but secretly wonders about. The *Dictionary* contains only about 330 entries, many of them illustrated, so the scope is necessarily selective: most space is devoted to modern archaeological theory, scientific techniques in archaeology, archaeological techniques *per se,* terms from related disciplines and a certain number of technological terms — especially those relating to potting and metalworking. Stone and stone-working, to take a single example, are barely touched upon.

Each reader will undoubtedly find his own lacunae, and it is a pity that the author was not able to roam more freely. Yet the book is well-produced and within its self-imposed limits can be recommended.

A. F. Harding is a Lecturer in Archaeology at the University of Durham.

The biology of history

Hugh Thomas

The Human Condition. By W. H. McNeill. Pp.75. (Princeton University Press: 1980.) £4.75, $11.25.

UNIVERSAL histories are becoming alarmingly fashionable. This is understandable for three reasons. First, although we are a long way still from anything like a world state we are quite close to an interdependent world society. The slightest hiccup in southern Asia affects northern Europe. Oil, especially, is the great internationalizing force, causing all responsible people to remember statistics of production in countries whose very names were unknown to them ten years ago. Second, the concentration of such enormous power in the hands of two superpowers is, also, a development which has never occurred before in human history: until 1945, power was always far more widely dispersed. The third explanation is that the apparent long-term shortages in raw materials have persuaded human beings to reflect seriously over the springs of their predicament in a new way. There is no doubt but that this is a benefit. National revival is unilaterally possible (such as occurred in France in 1958) but it is unlikely to occur save in the climate of international prosperity.

W. H. McNeill is no newcomer to the grand approach. His *Rise of the West* (Chicago University Press, 1963) is rightly regarded as one of the best, probably the best, of the conventional outline general histories. His *Plagues and Peoples* (Blackwell, 1977) was an extremely interesting introduction to the role of disease in history. *The Human Condition* is more modest, being merely two (long) lectures given at Clark University. Or at first sight modest, because, after all, there is a sense in which any book with this title which seeks adequately to cope with such a subject-matter in 75 pages is magnificently ambitious.

The themes of Professor McNeill's essay (for such it is) derive from his earlier study of disease. The main concept is what he calls "parasitism", divided in its challenge to human beings into "macroparasites" and "microparasites". Microparasitism refers to the "metabolic activities of minute organisms" which compete with human beings for food: by getting there first, microparasites can forestall human efforts to capture energy from food. Macroparasitism is any "exploitative relations among groups and classes of human beings", such as when one man or group of men — armed raiders, tax collectors, rent collectors — seize goods or compel services from other groups.

This rather forbidding frame gives Professor McNeill a justification for what turns out to be an extremely lively and well-written short world history, with the use of little jargon other than that I have already quoted. The frame enables Professor McNeill to make some interesting and novel points: for example, he attributes the advance of our remotest ancestors to the "apex of the food chain" to the acquisition of language and to the superior co-ordination of human behaviour that language allowed. The next landmark was the use of clothes to "maintain a tropical microenvironment" next to the almost hairless skin we all inherit. A bearskin on the back enabled us to live in a cold climate. Agriculture, though a definite benefit, Professor McNeill somewhat grudgingly confirms, brought microparasites as well as harvests. Irrigation brought mosquitoes. The "first recorded conqueror" Sargon of Akkad (*c.*2250 BC) was the first macroparasite on an imperial scale. Civil servants were the consequence — a problem with which we are still wrestling. In the sixteenth century, a fundamental change occurred, worthy of greater attention than Professor McNeill gives it — businessmen succeeded in establishing real autonomy from their political superiors, with even the mightiest European rulers depending on traders and bankers to organize an efficient army. They had to solicit loans from private persons who were usually domiciled outside the ruler's own jurisdiction and so were safe from confiscatory taxation. This really began the modern age — despite Professor McNeill's encouragement to us to look at the Sung dynasty in China AD 960 – 1279 in this light. (Incidentally, there is a certain discrepancy between Professor McNeill's comments on mediaeval China — p.48 — and his comparison with Renaissance Europe — p.62; he seems really to stand by the latter interpretation where he says that private businessmen in China never won autonomy from their superiors nor accumulated capital on the scale that European entrepreneurs did.)

The last pages of Professor McNeill's book are provocative and interesting and end on a sensible note: "better hindsight deepens insight". Foresight also will be assisted by all sensible enough to get hold of this excellent little book.

Alternative energy: the biological option

C.R.W. Spedding

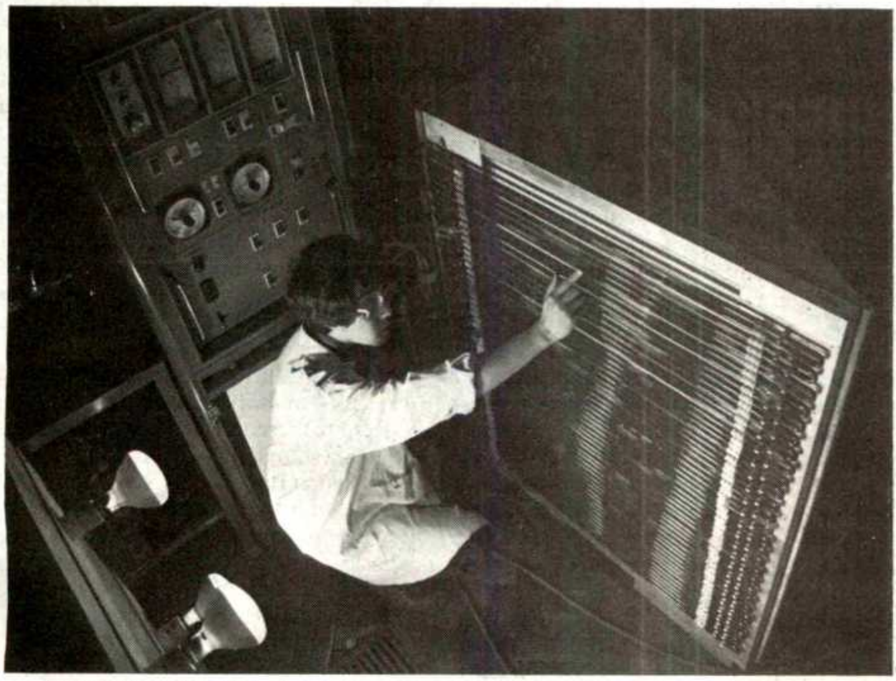
Biochemical and Photosynthetic Aspects of Energy Production. Edited by Anthony San Pietro. Pp.231. (Academic: 1980.) £15.80, $28.

AS THE editor of this book points out in his preface, photosynthesis is the only method of solar energy conversion currently practised on a large scale. Increasing dependence on fossil fuels is now an extremely vulnerable condition, and this volume explores the potential of biological processes that may serve in the future to provide alternative energy resources.

Eleven contributors discuss, in considerable detail, various aspects of this enormous subject. D.O. Hall provides an introductory overview and reviews the development of photobiological conversion systems and their long-term implications from the point of view of both energy and food. He stresses the need to consider all our energy options and not repeat the mistake of putting all our eggs in one basket.

Four chapters deal with different forms of energy from biomass production systems based on seaweed aquaculture, algal–bacterial systems, anaerobic fermentation of residues and biomass, and energy crops. All of these need further exploration; some are not yet established as technically feasible and all depend for their relevance on relative costs. This presents a major problem: how to estimate costs and prices for the future for technologies that are currently at a stage equivalent to the first motor car or aeroplane. The value and role of energy analysis is considered, but this cannot be a complete answer without regard to the fact that one joule of energy is not necessarily of the same value as another.

Several contributors emphasize the importance of non-energy products in our assessments. In some cases, such as glycerol production from the alga *Dunaliella* spp., the output is predominantly of one substance, but the economics of most processes will depend upon a use for all of the fractions produced.



Still small — photobiological conversion systems. An experimental tubular loop reactor which converts artificial solar energy into biomass.

Courtesy British Petroleum/Professor S.J. Pirt, Queen Elizabeth College

Other issues considered are the atmospheric consequences of various developments and the biological fixation of nitrogen. The latter is of key importance to greater and energetically more efficient production of biomass.

The book is well produced, has a useful index and comprehensive lists of references, and represents a valuable summary of the state of an important subject.

C.R.W. Spedding is Professor of Agricultural Systems and Head of the Department of Agriculture and Horticulture in the University of Reading.

Polyamines reviewed

Anthony E. Pegg
Hannu Pösö

Polyamines in Biomedical Research. Edited by Joseph M. Gaugas. Pp.474. (Wiley-Interscience: 1980.) £30, $90.

KNOWLEDGE of the importance of polyamines in cellular physiology has been greatly extended in recent years by studies of the control of polyamine biosynthesis, the development of drugs interfering with polyamine accumulation and improved technology for measurement of these compounds and derivatives. Many reviews on these subjects have appeared during the past few years and this book is the latest in the series. It contains a number of outstanding chapters and, though dated, will be of considerable interest to those working in the field.

The book is a collection of 27 review chapters by different authors. About one-third of these are concerned with the control of polyamine synthesis and the role of polyamines in cell growth. There are naturally substantial overlaps in which different authors describe results from the same publications but all of these articles are by experts in the field and are of interest. Chapters by Stevens and Stevens and by Mamont, Bey and Koch-Weser give comprehensive and well-written coverage of inhibitors of decarboxylases involved in polyamine biosynthesis. This provides excellent reference material, as does the contribution on regulation of ornithine

Erratum: see *Nature* **288**, 630. The title of the book written by Sandra Raphael and Wilfrid Blunt is *The Illustrated Herbal* (Frances Lincoln/Thames & Hudson, £12.50, $25).

decarboxylase by McCann. The possible importance of polyamines and ornithine decarboxylase in skin tumour promotion and as markers for compounds with anti-promoting actions are well described by O'Brien and by Verma and Boutwell who were pioneers in the field. There is also a first-rate and — at the time of writing — comprehensive evaluation of methods for polyamine measurement by Seiler who is responsible for much of the methodology now in routine use. Isolation and analysis of novel polyamines found in thermophiles are covered in a chapter by Zappia and colleagues. The remainder of the book contains a heterogeneous collection of contributions on carcinogenesis, polyamine degradation, their putative roles in macrophage function, relationship to chalones, suppression of lymphocyte function, excretion and conjugation, and value as tumour markers. These articles are often highly speculative and, while thought provoking, are much less rigorous.

Several important contributors to polyamine research are missing from this volume (for example it is unfortunate that there is no chapter from H. and C.W. Tabor on their polyamine-deficient mutants), and the two-year delay between writing and publication has meant there are a number of significant omissions in content. However, as a source book for scholars of a wide range of interests, it should prove valuable.

Anthony E. Pegg is Professor in the Department of Physiology at The Milton S. Hershey Medical Center, Hershey, Pennsylvania. Hannu Pösö is Docent in the Department of Biochemistry at the University of Helsinki.

Air of learning

Peter S. Liss

Air in Danger: Ecological Perspectives of the Atmosphere. By G. Breuer. Pp.189. (Cambridge University Press: 1980.) Hbk £10, $24.95; pbk £3.50, $7.95.

IMAGINE you are a scientist or scientific journalist invited to attend a research meeting on a topic which is not your speciality. You enjoy the meeting and become sufficiently interested in the topic to follow it up by reading, and visiting and writing to experts in the field. Then you decide to write up not only what you have learnt but also the various stages in the learning process, and persuade major publishers to issue the result in both German and English.

Although no biographical details of the author of *Air in Danger* are given (and, for once, I felt their absence to be a real loss), this would appear to be the way in which this book came into being. Georg Breuer attended, as an observer, the Dahlem Conference, "Global Chemical Cycles and Their Alterations by Man", held in Berlin in November, 1976. This spurred him to find out more about a major topic of the meeting, the way in which the major atmospheric gases — nitrogen, oxygen and carbon dioxide — are cycled in the environment. The chapters of the book chronicle the author's education as to how normal biological processes transfer these elements between the various environmental reservoirs and also how humans are influencing this cycling. Quite properly, considerable attention is given to the photosynthesis/respiration–decomposition reactions since these truly dominate the environmental chemistry of the gases considered, as well as that of many other substances.

Inevitably, this way of setting about writing a book has its disadvantages. Someone who is self-taught spends considerable time exploring what turn out to be blind alleys (for example, several pages in the first chapter deal with what is well known to be the "non-problem" of whether fossil fuel combustion can significantly deplete atmospheric oxygen) and also tends to over-detailed explanations.

On the plus side the approach adopted has the freshness inherent in knowledge newly acquired. What is not clear is what type of reader will want to share in the author's learning experience, since each of us learn in an individualistic and idiosyncratic manner. The book is certainly timely in that it presents in considerable detail much of the background behind the current debate over Lovelock's Gaia hypothesis, recently expounded in his book *Gaia: A New Look at Life on Earth* (Oxford University Press, 1979 — see *Nature* **282**, 154 for review).

The translation (by Peter Fabian) from the German original reads very well, but the English edition should never have been titled as it is. The main title gives the impression of a gloom and doom, pollution-orientated book which it certainly isn't. In fact, the author is to be commended for treading a very sensible line between natural and anthropogenic effects and the book's main title does his care a considerable injustice.

Peter S. Liss is Reader in the School of Environmental Sciences, University of East Anglia, and Scientific Advisor in the Environmental Studies Section at CEGB Headquarters.

Stimulating energy transfer

A.J. McCaffery

Introduction to Molecular Energy Transfer. By James T. Yardley. Pp.308. (Academic: 1980.) $34, £19.20.

THE microscopic processes of energy transfer — the molecular-level events in the gas, liquid and solid phases of matter — have been the subject of intense research interest for a number of years, and a book which attempts to draw together the wide-ranging strands of this field is most welcome. The topics covered in this volume reflect both the author's own research interests and the major thrusts of recent research, and thus the bulk of the book deals with vibrational energy transfer. Some of the modern experimental methods are reviewed in detail, as, more briefly, are the classical methods of ultrasonic dispersion and shock tube techniques. Gas phase vibration-to-translation and vibration-to-vibration transfer both receive detailed treatment and there is a short chapter on vibrational relaxation in liquids and inert materials. Included as a basis for the treatment of vibrational processes is a comprehensive theoretical development of the internal vibrational modes of molecules.

The remainder of the book is taken up with discussion of a diverse and interesting collection of topics. These range from radiationless electronic transfer in molecules, to the less known phenomena of collision-induced fine structure transitions in atoms and quenching of atomic excitation by curve crossing.

One interesting feature is a derivation of the Born approximation as early on as p. 8, and its subsequent usage runs like a thread through the wide range of fields covered in the later chapters, providing a useful physical insight into the individual transfer processes.

The difficulties of producing a completely up-to-date text are apparent, though references to work as late as 1978 are relatively frequent in some sections. Perhaps a more substantial criticism is that the book's purpose is not entirely clear. It is a mixture of pedagogy, in that it covers such basics as group theory, the hydrogen atom, LCAO-MO model and determinantal basis functions, and review. The coverage of rotational energy transfer is slightly disappointing by comparison to the treatment of its vibrational counterpart, as is the absence of discussion of scattering theoretic, semi-classical and classical trajectory studies of energy transfer.

Despite these small criticisms, Yardley's book is a stimulating and readable account of an important research topic with a number of interesting and novel features in its development. It should prove popular as a basic graduate text for North American universities and as a valuable source of methods and theory to research workers.

A.J. McCaffery is Reader in Molecular Sciences at Sussex University whose research interests are in the study of gas phase molecular dynamics using laser techniques.

nature

22 January 1981

Towards what shining city, which hill?

The American presidency is an impossible job which has an enlivening effect on those who do it. New encumbents embark on tasks widely held to be beyond the resources of one man with the zeal and enthusiasm of an army. Both Presidents Kennedy and Johnson, when new to office, offered the promise of a fresh start on old problems, domestic and international. Given the persistent importance of the United States in the affairs of most other communities, the promise of a change of direction echoes around the world. Some of the consequences are unsettling; changes of direction are disconcerting. Some are also enlivening, as for the new incumbent himself. It is too soon to know what will be the consequences of Mr Reagan's accession to the presidency, but a single inauguration speech is not a sufficient guide to what will follow in the months ahead. The safest assumption is that Mr Reagan, like all his predecessors, will be good at some things and less good, or even frankly bad, at others. There is no shame in that, given that the job is everywhere acknowledged to be impossible. After a spell in which the president seemed to be bad — but not for want of trying to be good — at most things, it is no wonder that Mr Reagan's coming has cheered even his political opponents. For a time, at least, people will be prepared to give President Reagan the benefit of the doubt. The vacillations and exaggerations of the election campaign will be forgotten. To that rule, there will be only one exception. In his acceptance speech in Detroit last summer, Mr Ronald Reagan promised that he would lead the American people to a "shining city on a hill". That phrase, redolent of Blake or Bunyan, is too arresting to forget.

President Reagan, no doubt less innocent than he seems, will not be starved of advice, solicited and otherwise. Politics being what it is, his presidency may well be made or broken in the next few months by almost accidental issues — the inflation rate, or the problems of Central America. In these connections, no new president would choose to start from where President Reagan must. One of the perils of the job is that he has no choice. Another is that the issues, although recently made clear, are by no means irrelevant to what may happen on the wider stage. If inflation continues as it has been in the past few years, American institutions will be weakened as surely as they have been undermined elsewhere, then the foundations of the shining city will be found not to exist. Already many of the new occupants of offices in the White House must be regretting that there had to be a campaign, and a promise of a tax-cut to go with it. If the problems of democracy in Latin America are ignored or, worse, supposed to be familiar problems susceptible to oldfashioned solutions, the roof could fall in. Even President Reagan's friends will be well aware of the seriousness of these dangers. Those who heard his acceptance speech may be forgiven for looking further ahead.

The Reagan position, so often defined in the past several months that it has become unclear, is ambiguous on two crucial issues — arms control and academics. In the parochial spirit in which trade magazines such as *Nature* grind their own axes on occasions such as the inauguration of a new president, special pleading may be excusable. On the face of things, for example, there is no reason why the new Adminstration should give an instant's thought to the special interest of the scientific community in the management of the arms race. Scientists, the argument might go, have (among other things) a special competence in military research and development. But only taxpayers have a right to say what should be done about relationships between the superpowers. President Reagan has in any case come a long way since the beginning of the election campaign, when he was bent on seeming a 1950s hawk. Now (the argument continues), he is for renegotiation of Salt II and other accommodations of that kind. The argument misses a point that will quickly become apparent, that the special but not exclusive interest of the scientific community in arms control is not merely academic. There is a sense in which J. Robert Oppenheimer was right in saying that "the physicists have known guilt" — hawks among them have persuaded doveish graduate students to work on unwelcome projects since time immemorial. The point has been reached at which both hawks and doves share with the general public the belief that it would be best if the consequences of the products of their joint endeavours could be contained within bounds, and that more or less any bounds would be better than none. This does not imply that all scientists share with the *Bulletin of the Atomic Scientists* the view that international tensions have worsened in the past few weeks — the *Bulletin* advanced its notorious minute hand one minute last week (and was mentioned on the British Broadcasting Corporation's morning news programme as a consequence) but did not convincingly explain why it had done so. Yet there is a great majority in the scientific community that would wish something sensible done about arms control, and which knows that such a course is not unattainable. The political question for the new president is whether he can see this as an opportunity.

Another issue for President Reagan, not too long to be left on the back burner, is that of the research community itself. Mr Carter (or, more probably, Dr Frank Press) has left the incumbent President with an awkward choice. Should an expansionary science budget be cut in the interests of financial prudence, or left as it is so as not to give offence? Neither of these questions should bother President Reagan in these early heady days. There is a simpler question he must answer. Since his early days as Governor of California, he has cut the figure of an adversary of the universities. At one stage, he forced Mr Clark Kerr out of his post as president of the University of California. Since then, he has made clear his disdain for academic preoccupations — decision is what matters. Such a position can be defended but is not defensible. The President needs urgently to build a bridge to the academics. To fail to do so will be to alienate some of those who might build a city, or find a hill.

Responsibility for trust in research

The public complaint, fashionable in the 1970s, that scientists could not be trusted when making statements about the hazards of pollution or of genetic manipulation, is now mercifully abating. Is the complaint now about to be replaced with the suspicion that scientists cannot trust each other? This will be some people's first reaction to the article by Harris *et al.* on page 228, and our Washington Correspondent's commentary on it (page 227). The reaction is understandable, even forgivable. For what has emerged is that three out of four laboratory cultures of cells originally described in 1977 as derived from the spleens of patients

0028-0836/81/040211-02$01.00

with Hodgkin's disease have nothing to do with human malignancy but are, instead, almost certainly derived from owl-monkey kidney tissue. This improbable conclusion has been established by means of as neat a piece of detective work as can be found in the recent literature. The fact remains that the four cell cultures have been the basis, in the past four years, for a spattering of spurious data in the scientific literature. Some of these unwarranted conclusions have been used by others in unrelated work towards the understanding of Hodgkin's disease. Elsewhere, laboratories have tried (usually without success) to establish their own analogous cell cultures from patients with the disease. But Dr John Long's apparent success with his supposedly authentic cultures appears to have led to the award of at least one substantial research grant (for $500,000 over three years), afterwards rescinded. Especially because the principal investigator had been accused of falsifying data in a different context, many will now be tempted to suppose that four years of work with Hodgkin's disease has been a kind of hoax.

To jump to that conclusion would be wrong. Those who work with cells in culture are continually aware of the risks of contamination. Especially in laboratories specializing in this work, one established cell culture may be contaminated with cells from another by a variety of means — contaminated glassware, people's hands or defects of laboratory plumbing. Almost by definition, the most esoteric kinds of cells, requiring the most elaborate mixture of nutrients to make them grow, are those which are the most susceptible to contamination. HeLa cells, the malignant cells derived from a single tumour half a century ago, and widely used as models of malignant cells, are frequent contaminants. Inevitably, when a cell culture that grows only with difficulty is contaminated by cells that grow more vigorously, like HeLa cells, it is a matter only of time, perhaps days, before the original cells disappear, swamped by their more strongly growing competitors. Naturally, people with cells at risk are constantly on the look-out for contamination. This is obviously easiest when the cells at risk can be easily recognized, perhaps because of some distinctive biochemical characteristic. Again, however, and almost by definition, novel types of cells are likely to be least easily recognizable. In other words, it is entirely possible that people may work for weeks or months with cells from a tissue culture without knowing that the originals have been supplanted. It is less easy to see how meaningful results can be wrung from such a culture, but nothing is impossible. The fact that Harris *et al.* have been able to say no more about the fourth of the cell lines than that it is of human origin emphasizes the difficulties of identification. There is therefore no reason to doubt Dr Long's assertion (see page 227) that he believed the cell lines to be authentic; but his response to the doubts raised within and from outside his laboratory seems to have been too casual.

The significance of the paper by Harris *et al.*, for all its interest, should therefore not be exaggerated. Almost certainly, this is not the first occasion on which research reports based on the mistaken identity of tissue culture cells have appeared in the scientific literature. Most of the articles concerned have probably disappeared from people's citation lists as their data have been recognized as spurious or simply puzzling. It would be foolish to ask that the scientific enterprise should be carried on in such a way that such unwanted and unrecognized noise is entirely eliminated. Would intending authors be required to submit with their manuscripts samples of their tissue culture cells for validation by the referees? Would those working with supposedly pure and authentic strains of laboratory mice be expected to follow suit? And how would the scientific journals cope with the problems that would follow? The only reasonable conclusion is that the ideal is probably unattainable, that the scientific literature is based to a very large extent on trust in what its authors say, that the system works surprisingly well and that its occasional failures can be accommodated without too much difficulty. If it follows that the scientific literature is not to be regarded as a collection of Mosaic tablets, nobody will be the loser.

The problems created for laboratories by such developments as those identified by Harris *et al.* are more immediate and in some ways more difficult. The necessarily close working relationship between people sharing the same facilities and even the same objectives in research is one of the most powerful safeguards of the authenticity of the scientific literature. However great may be the temptation for individuals to make too much of preliminary findings or to apply cosmetic treatments to otherwise untidy data, the knowledge that their most candid critics are likely to be their closest colleagues is constantly an influence towards sobriety. It is true, of course, that individuals who have misled themselves can usually succeed in misleading more junior colleagues as well, but even this is an unsure calculation now that many graduate students are zealous custodians of what is right and proper. The more certain safeguard, however, is that people in laboratories where all researchers are in the habit of talking freely with their immediate colleagues about their work, not merely at formal colloquia but over lunch, are imperceptibly persuaded to couch their interpretations of their work in moderate language. (The so-called sociologists of science, always on the look-out for subjects to study, could profitably pay some attention to the sociology of the laboratory as a formative influence on the pattern of science.) No doubt one of the reasons why the most successful laboratories are frequently large laboratories derives from the influence of these local invisible colleges.

Why, then, does this system of polite and imperceptible persuasion by colleagues not always function as it should? In the past few months, the grant-making system has frequently been blamed for departures from the path of strict propriety. The competition for grants, the argument goes, is now so fierce, and the consequences of failing to secure a grant can be so serious for the career of an individual, that people are tempted beyond endurance. This danger is more apparent than real. If the competition for grants is now more fierce, so is the scrutiny of the peer-review committees on whose recommendations most grants are awarded. A more likely explanation is that the grant-making system has disturbed the balance there would otherwise be among colleagues working within the same laboratory. A successful grant-holder tends, when grants are hard to come by, to acquire a status and a degree of autonomy that may not be entirely justified by his colleagues' estimate of his work. And people who are seen to enjoy the goodwill of the grant-making agencies are, if they so choose, to some extent immune from the necessarily searching scrutiny of their immediate colleagues. The Massachusetts General Hospital, one of the best known components of the Harvard medical complex, moved quickly after Dr Long's resignation last year to promise an audit of his work, and the paper by Harris *et al.* is one result. The hospital has probably for the time being done everything it can. But, in the long run, there and elsewhere, the objective should be to make sure that laboratory communities remain as rigorous as they should be in their internal assessment of all their members.

The responsibility lies fairly and squarely with heads of laboratories and heads of university departments. It is an unpalatable responsibility. But unless it is exercised diligently, the result will be unpalatable for the scientific community as a whole. One obvious danger is that of the emergence within the scientific profession of groups of zealous and often over-zealous people dedicated to rooting out what they consider to be dishonesty. Already there are signs of such developments. Some of the allegations of plagiarism in the past year or so appear to have had their roots as much in self-righteousness as in a concern for honesty in the literature. Some of the consequences of these allegations have been unfair to those accused. Yet there is no reason to suppose that the few cases of dishonesty that have come to light are in any sense the tip of an iceberg. On the contrary, as the day to day affairs of reputable scientific journals bear out, there is a general and quite remarkable concern for truth. Would-be authors are forever going back to their benches to check small points raised by referees, who in turn appear almost masochistically prepared to recommend the publication of data or arguments conflicting with their own positions. It would be tragic if these civilized habits were to be corrupted by the activities of self-appointed vigilantes.

More pressures on Rothschild system

Geology project threatened by more cuts

The Rothschild principle, whereby British government departments ("customers") commission research from research councils ("contractors"), already corrupted in medical and agricultural research, is now showing signs of strain elsewhere. The latest development is that two of the customers of the Natural Environment Research Council, the Department of the Environment and the Department of Industry, are threatening to cut the amount of geological research they are prepared to commission.

At stake are the Geological Survey and the mineral reconnaissance programme, both run by the council's Institute of Geological Sciences. The Department of the Environment, which currently contributes £1.5 million to the £4.5 million annual budget of the Geological Survey, is cutting its contribution to geological generally from £3.5 million in 1980–81 to £2.6 million in 1981–82. Although the department has not yet specified its priorities, it is expected that the cuts will be made in the Geological Survey and the engineering geology and bulk minerals resources programmes. The Department of Industry, which is the sole supporter of the mineral reconnaissance programme, is threatening to cut that budget from about £1.2 million in 1980–81 to £0.8 million in 1981–82.

Both departments say that they no longer want to fund research which is not directly relevant to their work. Thus the Department of the Environment will only fund those parts of the Geological Survey related to planning permission. Alternative funds for the survey are unlikely to be forthcoming and it will have to make do with less. Dr G. M. Brown, director of the Institute of Geological Sciences, finds his planning hampered by the Department of the Environment's delay in deciding its new priorities.

The Department of Industry is hoping that the mineral reconnaissance programme will find alternative funds from industry. Since 1972, this unit has been searching for metalliferous ores in Britain, especially in the Scottish Highlands, North Wales and Devon and Cornwall. Although deposits of several minerals — in particular copper and tungsten — have been found, only one, a barites deposit in Scotland, has led to an application for mining rights by private industry. Nevertheless, industry is interested. Companies consider that the results provide useful information for assessing mining profitability in the light of future market trends. But hitherto, there have been no direct commissions from industry.

The Natural Environment Research Council has been trying to establish whether it could act a contractor for private industry. Meetings with the mining houses have thrown up several problems such as that of confidentiality (reports have previously been publicly available) and the assignment of mining rights. Industry itself is keen that the programme should continue, but considers that financial support for it is properly the duty of central government.

Time is now running out. The new financial year begins in April, and twenty of the mineral reconnaissance staff have already moved to oil surveys of the North Sea, paid for by the Department of Energy. The Department of Industry has not finally decided to cut its support, but is thought by several observers to be in a mood to say that if private industry does not produce some cash, it will a sign that the programme has little practical relevance. **Judy Redfearn**

Carter's last budget asks for more

Washington

Determined to enter the history books on an optimistic note, the outgoing Carter Administration has proposed to Congress a budget for the next fiscal year that contains a 4.3 per cent real growth in support for basic research.

"This is the best budget for the past four years for science and engineering research", said Dr Frank Press, the President's Science Advisor and director of the Office of Science and Technology, commenting on the budget proposals last week. He added that it confirmed President Carter's commitment to the support of science and technology "as an investment in the future".

In addition to the intended growth above the expected level of inflation, Dr Press singled out several initiatives that were being proposed by the outgoing Administration "to solve problems that we have known about for a number of years".

One of these is the proposed inclusion in the budget of the National Science Foundation of a $75 million fund to improve university research equipment and laboratories. Their rapidly deteriorating state was highlighted in a recent report from the Association of American universities.

Two other proposals involve traineeships and other awards to avoid potential manpower shortages in fields such as computer science and energy engineering, and efforts to meet the present difficulties of engineering schools where, according to Dr Press, "faculty and equipment are not on a par with what one would expect in industry".

The big question, of course, is how much of this increase will escape the rapidly sharpening budget knife of the incoming Administration of President Ronald Reagan. For many social welfare programmes, the writing is already on the wall, but for science and technology the signals are mixed.

On the one hand, Mr Reagan's budget director, Mr David Stockman, has been talking about the need to rewrite the Carter budget "from top to bottom". Mr Stockman has previously placed the National Aeronautics and Space Administration (NASA) among his "low priority" agencies which might absorb significant cuts. In the same vein, a group known as the National Tax Limitation Committee put out a report last week suggesting, for example, reduced spending on the Galileo mission to Jupiter — already being delayed a year by NASA because of delays with the launch vehicles — on its list of "expenditure control opportunities". The group is also raising questions about the appropriateness of government support for the space shuttle, and suggesting a re-examination of the future cost-benefit ratio.

At the same time, however, members of the various transition teams which have been established by the Reagan Administration to look at research and development programmes have been making optimistic noises, insisting that the new president is committed to the support of "science, technology and productivity".

Part of the increase in defence spending supported by both the Carter and the Reagan Administrations, for example, is likely to have beneficial spin-offs for research support, particularly in areas where the large aerospace companies have a stake. "I have been looking in teacups for the past two months, and each time I look I see a different picture", said outgoing NASA director Dr Robert Frosch last week.

The details of the Carter budget proposals contain several proposed new scientific starts. The NASA budget, for example, contains funding for the development of the Venus Orbiting Imaging Radar — announced by President Carter shortly before the election — as well as a new Geological Applications Program (GAP) which will use remote sensing satellites to study geological resources which might contribute to the discovery of new oil and gas deposits.

Reflecting the delays in the space shuttle programme, the proposed commitment to start work on a fifth shuttle orbiter, the

0028-0836/81/040213-02$01.00

additional costs of science projects such as the space telescope, and the new projects described above, the total requested budget for NASA comes to $6,700 million. This would be a 20 per cent increase over the budget for the fiscal year 1981 which began last October, and if it is allowed to stand, would be the largest annual increase in the agency's budget since the early 1960s.

The National Science Foundation has also put in for a hefty 23.5 per cent increase, from $1,096 million in the current year to $1,353.5 million next year. Most of this reflects the Carter Administration's keenness to support both research and training in engineering fields. The new engineering directorate will receive a 20 per cent increase in its research budgets.

At the National Institutes of Health (NIH), the proposed increase for biomedical research is less spectacular. On the basis that whatever the president asks for is traditionally increased by Congress, Mr Carter is suggesting that the NIH budget for basic research be raised by 9.4 per cent. Allowing for inflation, this would result in a drop of 1.1 per cent between 1981 and 1982.

At the Department of Energy, increased support for research into synthetic fuels and nuclear power — particularly fusion energy — has resulted in a requested increase of 9.4 per cent in real terms for basic research, second only to that of NASA.

Many of these figures will remain only as indications of the "good intentions" with which the Carter Administration is leaving office. Perhaps of more lasting significance are the figures prepared by Dr Press to demonstrate the main trends of federal support for science during Mr Carter's four years in the White House.

These reveal, for example, that overall the biggest winner as far as support for basic research is concerned has been the Department of Defense. If the proposed 1982 budget figures are taken into account, the Pentagon's basic research efforts will have grown by almost a quarter — 22.6 per cent — between 1978 and 1982.

Next come NIH. Congressional enthusiasm has raised the NIH research budget by 13.3 per cent over the four years, compared with a growth of 12.8 per cent at the Department of Energy.

The National Science Foundation, even if it is granted this year's large increase, will still only have seen its basic research grow by 9.2 per cent. And at NASA, reflecting the pressures which the space shuttle has imposed on the space science programmes, the basic research budget actually fell, in real terms, by 0.6 per cent over the same four years.

Overall, the growth in basic research, including the 1982 proposals, would come to 10.8 per cent for the period of the Carter Administration. In current dollars, the budget would grow by 58.2 per cent. from $3,704 million to $5,801 million.

Ironically, the research and development budget shows an identical increase of 58.2 per cent from $26,388 million to $41,734 million.

"Anyone who says that we do not engage in long-term planning is proved wrong by these figures", quipped Dr Press — expected soon to be elected president of the National Academy of Sciences — although he added that the agreement was actually fortuitous and that "the figures just happened to fall our this way". In practice, he will not be required to explain why it should be otherwise.

David Dickson

Argentinian power

Soviets help

Argentina has bought five tonnes of heavy water from the Soviet Union under International Atomic Energy Agency safeguards, the Argentinian Comisión Nacional de Energia Atómica announced last week. It is intended for "topping up" the Atucha-1 nuclear station, which needs on the average an annual heavy-water replacement of 1.5 tonnes.

The sale is part of the growth of Soviet–Argentinian trade since January 1980, when Argentina refused to back President Carter's embargo of grain sales to the Soviet Union. The Soviet Union is now Argentina's main market for agricultural products. In July of last year, Argentina's Secretary of Commerce, Alejandro Estrado, signed an agreement to supply the Soviet Union with 20 million tonnes of feed grain and soya beans during the next five years. There are also persistent rumours that a major agreement to export meat to the Soviet Union is now being negotiated.

In return, the Soviet side has shown considerable interest in Argentina's nuclear programme. Argentina has been conspicuous among third world countries since the early 1950s for its nuclear programme aimed at ultimate autonomy in both research and technology. The commission has announced that the target will be for practical purposes attained by the end of 1981, when the Córdoba uranium processing plant will begin producing an estimated annual production of 150 tonnes. Rafael Coppa, the director of the plant, said last year that Argentina will then have full control of the primary uranium cycle, from prospecting for

---

Promises for President Reagan to deny

Specific proposals included in the budget are as follows.

- Major difficulties with the development of a vehicle to launch the two Galileo spacecraft on their journey to Jupiter from the space shuttle have caused NASA to propose delaying the Galileo project for one year and switching to a new launch vehicle, a converted Centaur rocket.
- The Carter Administration proposes that the National Institutes of Health should aim to stabilize support for both competitive research grants and research traineeships. Last year, the Administration promised to provide enough money to keep the number of new and renewing competitive research grants constant at about 5,000. Given general fiscal constraints, however, this meant cutting back severely on the number of traineeships, a move which brought strong protests from various sectors of NIH, and was subsequently overturned by Congress.
- Defense Department support for research on US campuses seems destined to continue to grow faster than support from any other federal agency. According to the budget request for the fiscal year 1982, military funding for research and development at US universities and colleges will be 21 per cent greater than in 1981, totalling $639 million.

The proposed figure, most of which will be spent on unclassified basic research projects, is part of a 16 per cent increase in all military-sponsored basic research expenditure.

- One major new start proposed by the National Science Foundation (NSF) is the detailed design and initial construction of a 25-metre millimetre-wavelength radio-telescope which is planned for installation at Mauna Kea in Hawaii.

Plans for the new telescope have generated widespread support in the radioastronomy community. NSF has asked Congress for funds as part of a 29 per cent increase in the NSF budget for astronomical sciences, rising from $58.5 million to $75.6 million.

- The Carter Administration is proposing to cut support for research and development in the Environmental Protection Agency (EPA) from $364 million to $345 million. At the same time, the outgoing Administration wants to earmark an extra $28 million to improve its review of the environmental impact of proposed major energy projects in the west of the country — particularly in connection with the synthetic fuels programme — and to launch a government-wide research programme on the effects of acid rain.
- The Carter Administration wants to give a major boost to research into magnetic fusion. The 1982 budget proposals include an increase of 28 per cent in fusion research, to a total of $520 million in budget obligations. $32.8 million of this would be spent on a new centre for magnetic fusion energy, as proposed by the Administration following a thorough review of the magnetic fusion programme last year. Research on magnetic confinement systems would increase from $119 million to $151 million.

David Dickson

0028-0836/81/040214-02$01.00

uranium to putting the fuel elements into the reactor.

Nevertheless, the search for self-sufficiency does not rule out cooperative projects. Indeed, on returning from the World Energy Conference in Munich last September, Admiral Carlos Castro Madero, the president of the Argentinian commission, openly attacked the "negative aspects" of restrictions of nuclear technology transfer, adopted first by the "London Club" of nuclear suppliers and then (at the end of 1979) by a wider circle of industrialized Western states.

Soviet interest has grown in the past year. Last April, during a visit to Buenos Aires, the Soviet foreign trade vice-minister Aleksandr Manzhelo suggested a major nuclear cooperation between the two countries, stating at the same time that he thought that Soviet–Argentinian trade could well double in the next few years. At the end of July, Yurii Fokin, Secretary of the Soviet Foreign Ministry, visited the Atucha-1 plant. **Vera Rich**

Large electron project

Swedish cloud

Sweden is having second thoughts about participating in LEP, the 500-cm 500-GeV electron–positron colliding machine which, at a cost of 900 million Swiss francs, is planned to be the next major project of the European centre for high energy physics research, CERN. At a meeting of the Swedish Natural Sciences Research Council last month, 90 per cent of those present expressed doubts about the arrangements for funding the project.

Delegates from CERN's member states are expected formally to approve the building of LEP at the next meeting of CERN council in June. The plan is to finance the project out of CERN's annual budget by reducing expenditure on other programmes such as the intersecting storage rings and the synchrocyclotron. How quickly LEP can be built will depend on how much of the budget — SwFr610 million this year — can be diverted to it each year. What seems to be worrying Sweden is that the CERN council, which requires a two-thirds majority vote to approve budgets, could demand that Sweden pay more if the cost of LEP rises above initial estimates.

One faction of the Swedish research council says that LEP is simply too expensive to be built now. Another would agree to the project with some concessions — either that Sweden be made exempt from budget increases approved by CERN council, or that the CERN budget be divided into LEP and other programmes, giving Sweden the option of leaving LEP while remaining a full member of CERN's other activities. Under the present arrangement, a decision not to participate in LEP would effectively be a decision to opt out of CERN altogether, An incidental factor which seems to have added weight to the arguments of LEP's Swedish opponents is the feeling that Swiss industry has reaped unfair benefit from contracts arising out of CERN's work.

Sweden's objections, which have come rather late in the negotiations (most of CERN's members have informally agreed to the LEP proposal), could delay official approval for the project. Although Sweden is not alone in wanting some guarantee that costs will not get out of hand, making it exempt from cost increases approved by CERN council is unlikely to be popular with other members: neither is splitting LEP from the rest of CERN's budget. Many see incorporating LEP into the annual budget as a way of controlling the rate at which money is spent on it.

At present Sweden contributes slightly less than 4.3 per cent of CERN's annual budget. If it decided to leave LEP, the other member states would have to decide how to redistribute the costs amongst themselves or whether to extend the time taken to build the machine. The chairman of the Natural Sciences Research Council, Mr Mats Lemner, expects that the council will shortly discuss the contribution with the Minister of Education. Depending on the outcome of this discussion, parliament may have to make the final decision. If it does, the Swedes would to be able to meet CERN's June deadline for a decision on the contribution. **Judy Redfearn**

Artificial hormones

European register?

Brussels

The European Commission is making heavy weather of its plan to ban the use of certain artificial hormones in animal farming. A meeting of agricultural ministers planned for last week was cancelled after the death of Mr F.O. Gundelach, the Danish agricultural commissioner. But the signs were that the meeting would have failed to reach an agreement.

The Commission decided last September that something should be done about hormones after the discovery that diethylstilboestrol was still being used for veal production in Italy. The hormone is banned in the United States and also in many European countries, but is so effective at increasing weight-gain in calves that, where its use is banned, black markets such as that in Belgium spring up.

The agricultural ministers were to have discussed two proposals elaborating on an original proposal made last December. The first calls for a register to keep track of all hormones used as medicinal products, whether for human or animal use, from manufacture and storage to distribution and final use. Veterinarians would be required to control all administration of hormones to animals. The proposed rules say that banned hormones can be used only for "therapeutic treatment" of pathological cases diagnosed by veterinarians, and not for chronic use in preventive treatments. The second proposal is that there should be a comprehensive sampling system for testing animals and carcasses

The proposals as drafted involve the "positive listing" of those hormones considered safe for use in meat production. This is opposed by Belgium and the United Kingdom. There is no dispute over banning compounds such as diethylstilboestrol, but it is held that a positive list would inhibit the development of new materials.

A system of "negative listing" would overcome some of these problems, but this would have to be continually revised as alternative hormones came on the market. Given the political need for action, the Commission favours the more cautious positive listing system. Whichever route is followed, the cost to European farmers of making the necessary adjustments will be substantial. **Jasper Becker**

Soviet chemical industry

Effective economy

The Soviet chemical industry is rapidly acquiring prestige status in the Soviet media and ranks, according to a *Pravda* article last week, together with nuclear energy, space research and electronics, as one of the hallmarks of twentieth century progress. The proximate source of this accolade is not hard to identify: almost every article cites, at some point, Mr Brezhnev's dictum that "there can be no effective economy today without a modern large-scale chemical industry".

When Mr Brezhnev made this pronouncement at last October's plenum of the Central Committee of the CPSU, however, he was not so much commending the industry as calling for a programme of "resolute measures" for overcoming major shortfalls in chemical production, ranging from chemical fertilizers and plant protection agents to synthetic fibres, dyes and household detergents. The 33 per cent production increase specified in the guidelines for the new Five Year Plan for the chemical and petrochemical industries (recently placed under separate ministries) is, say the planners, essential if the shortfall is to be eliminated.

The chemical industry does not shoulder full responsibility for the gap. At the end of December, a *Pravda* editorial shifted at least part of the blame to other sectors. Fertilizer plants, said *Pravda*, were held up by insufficient supplies of natural gas and "inaccurate" planning by the light metallurgy sector. Plants with processes requiring high temperatures and pressures often cannot obtain corrosion-proof equipment. In some cases new factories have been built, without the necessary equipment being forthcoming, while, on other occasions, expensive installations have been purchased before it has been

0028-0836/81/040215-02$01.00

finally decided just what the plant is to manufacture. The state supply board "Gossnab", *Pravda* concludes, must supervise the whole supply process more closely to eliminate such discrepancies.

Far more serious, however, are suggestions raised last week by a group of scientists from Byelorussia that the implementation of radical new technologies is being blocked by interdepartmental wrangles. In a major *Pravda* article they describe two such cases, in sectors which all planners consider to be of the highest priority — energy and agriculture. The first project, highly thought of by the Institute of High Temperatures of the Soviet Academy of Sciences, would have combined an electrolysis unit with a nuclear power plant so that hydrogen for fuel or industry could be produced during "off-peak" times. This combination of chemistry, electrochemistry and nuclear power engineering ran into the stumbling block of what the group describe as the "excessively rigid specialization of the branches of industry".

The second project, for the production of protein biomass for animal feed using hydrogen-consuming bacteria, was worked out jointly by teams from the Byelorussian and Moldavian academies as long ago as 1976. To be cost effective, however, the byproducts of the synthesis — oxygen, nitrogen and possibly ammonia — would also have been exploited. All these are prime requisites of the mineral fertilizer industry, which itself produces waste gas with a usable hydrogen content. Yet although plans have been drawn up for a pilot biomass plant to be run in conjunction with the "Azot" fertilizer plant in Grodno, neither the Ministry of Chemical Fertilizer Production nor *Glavmikrobioprom* — the body in charge of microbiological production — can see its way to go ahead. **Vera Rich**

European research

Counting costs

Brussels

The knotty problem of putting a value on the European Community's research and development programmes is the subject of new proposals which the European Commission has just put forward. The objective of this soul-searching is to define criteria and methods for both evaluating and exploiting research. The idea stems not from a fit of self-doubt but from the Council of "Research" Ministers in December 1979. There are no hard and fast ideas in the document, but areas of investigation are instead defined. Four pilot projects have been approved, which will give independent experts free rein to put certain programmes under scrutiny. The commission proposes then to use the experience of the experts to formulate a policy for exploiting and evaluating research results. This is to be ready by the end of the year but, before then, the first outlines of the policy will be presented at the International Congress for Research Evaluation in October.

One pilot project has already been completed by six independent experts, who looked into the Community's energy conservation and solar energy activities. Four other expert groups are to investigate programmes of research and development in fusion, radioactive waste management, the "Reference Bureau Programme" concerned with physical standards and critical data, and geothermal energy, the use of hydrogen as a fuel and work on the systems analysis of energy use.

The tightening of the European Community's budgetary belt is one motive for the new initiative, but another is the fear that the results of research are being ineffectively disseminated. The experts will be concentrating on the diffusion of information and in particular how to make the results available to the layman, requiring that more outlets should be found and language barriers overcome. Indeed, one member of the European Parliament has asked in a written question why the Commission does not publish the results of research in English as well as in the author's mother tongue. But the commission says that unless the results of research are first digested, readership is always restricted to specialist circles.

The stickiest part of the process on which the Community has embarked is the evaluation of research whose impact is likely to be long term or even unforeseen. Simplifying the results may help. Thus the report on solar energy and conservation says that the success of the programme cannot be measured in "tonnes of oil saved" and that the use made of research carried out may require further action and will take time. Even so, the chairman of the evaluation team, Ugo Forinelli, is confident that European research in this area is already competitive with that in the United States even though the European budget is much smaller than the American. Forinelli's team has made a number of recommendations about the management of the Community's programme, including the need for more explicit statements of objectives when putting contracts out to tender and some suggestions of areas where research might be concentrated or even discontinued.

The commission seems modestly aware of the inherent limitations of plans to evaluate research. The underlying objective is to strengthen the link between research and development and industrial innovation, and the commission acknowledges that its own research cannot be an important source of commercial inventions. But restrictions on Community expenditure outside the agricultural field are likely increasingly to stimulate the justifying of research. **Jasper Becker**

Swedish research

Lucky science

Stockholm

Research is one of the very few areas to be given more money in the budget bill for the fiscal year 1981–82, presented this week in Stockholm. Against the background of a budget deficit amounting to about $15,000 million, cutbacks in social services and mounting economic gloom, research received an extra $28 million.

Considering that this money is to be divided between the projects of eight ministries, individual increases will not be very great, and in real terms may well be eaten up by inflation, which was 14 per cent in 1980. One staff member at the Natural Sciences Research Council estimated that the net results of the council's $2 million increase will be an unchanged level of activity. But this is better than a cutback, the fate of nearly all other sectors.

The government sees research strengthening Sweden's industrial competitiveness in the long term. The Minister of Industry, Nils Aasling, wants to develop sophisticated chemical and mechanical products, and is to make specific allocations for this purpose in the spring. One sign of this policy is the changing proportions of the space budget being allocated between international and national programmes. In the 1980–81 fiscal year, the Swedish Space Corporation's budget of about $44 million was equally divided between international and national activities, but in future the accent will be on national programmes. The corporation's budget has been increased overall to about $58 million — a real increase in spite of inflation — about half of this will be used to build the country's first space satellite, Viking, which is to be launched from the European rocket Ariane in May 1984. It is hoped to produce the Viking at half the cost of comparable satellites from other European countries, and the project is planned to give Sweden a profitable national space industry. Another project being planned is an experimental telecommunications satellite.

The lion's share of the increase in research expenditure — about $16 million — is to be disbursed by the Education Minister, Jan-Erik Wickstroem, who wants to increase research capacity across the board. He is proposing an increase of about 12 per cent for mathematics and natural science faculties, an average of about 9 per cent for the four research councils as well as 90 new PhD places to be spread over all subjects, $2 million for particularly expensive equipment, $2 million to subsidize lecturers who want to take time off for research and $1 million for research libraries. Fifteen new chairs will be set up, among them molecular genetics (Karolinska Institute), medicine (Uppsala) and astrophysics (Gothenburg).

0028-0836/81/040216-01$01.00

Graduate education

Too many laggards

The Science Research Council, the chief source of public support for British graduate students, is alarmed at the lengthening time taken to complete PhD courses. A preliminary survey of 25 higher education institutions has shown that on average only 60 per cent of those holding SRC studentships complete their PhDs within four years. According to Sir Geoffrey Allen, chairman of the council, a figure of 80 per cent would be respectable, but 90 per cent would be the ideal.

The issue has come to the surface after an investigation by a working party of the Advisory Board for the Research Councils, which has been looking into the broader question of postgraduate education and manpower needs. That in turn was stimulated by the revelation of Sir Michael Posner, chairman of the Social Science Research Council, to the Public Accounts Committee of the House of Commons last summer that fewer than 30 per cent of his council's graduate students complete their PhDs within four years.

Given pause by that statistic, the Science Research Council made a rapid survey of five institutions where it supports students and arrived at the figure of 60 per cent, which a subsequent survey of 25 institutions has upheld. The advisory board's working party, which is also concerned with the performance of postgraduates supported by the Social Science, Medical and Agricultural Research Councils, has commissioned a more detailed study intended to throw some light on why so many students take so long to complete their theses, or even fail to complete them at all.

Particular attention is likely to be paid to the performance of the Science Research Council's students, if only because there are more of them than of the other councils — on the average, 2,350 new science studentships are awarded each year. Most of these are in the gift of university departments, to which studentships are allocated on a quota basis. Studentships are worth about £3,500 a year, and are tenable for three years, the estimated time for completing a research project.

The reasons for these delays are still obscure. The Science Research Council expects to find marked differences of performance in different institutions and subject areas. PhDs in pure science may more often be completed than those in applied science — applied scientists and engineers are more likely to find jobs in industry, where writing a thesis may seem irrelevant and where there is little time for writing up anyway. It is also suspected that institutions and departments with a large number of PhD students will have a better track record than those with relatively few.

The issue also, however, raises questions concerning the meaning and purpose of a PhD, which the advisory board's working party is looking into under its broader remit. Should a PhD for example, be a thorough and lengthy investigation of a detailed scientific problem, or more simply a means of training a student in the techniques of research? The approach is bound to have implications for the completion time.

As yet, no reliable pecking order of institutions has been established, but the early surveys do suggest that the Universities of Birmingham, Cambridge, East Anglia and Bristol, and King's College in the University of London, have the best completion records and that the Universities of Newcastle upon Tyne, Sussex and Bradford, together with Imperial College, London, and most of the polytechnics, have the worst.

The poor track record of Imperial College, regarded as a highly prestigious scientific and technological institution, may seem surprising. Lord Flowers, rector of the college, says that the explanation may be that large numbers of its postgraduates rapidly find employment in industry, leaving them little time for writing up.

The advisory board's working party has yet to decide what should be done. Sanctions against departments with poor track records have been mentioned. Cutting quotas of studentships is an obvious device. Sir Geoffrey Allen, however, hopes to avoid such heavy-handed treatment. Most academics, he says, are willing to accept genuine criticism and put their houses in order. The peer review system should take care of that.

Judy Redfearn

British universities

More confusion

Confusion among British universities about their financial prospects appears to have been further deepened by the letter from the chairman of the University Grants Committee, Dr E. S. Parkes, circulated to vice-chancellors on 30 December. The letter contained a warning that the resources available for the 1981–82 academic year may be reduced by between 5½ and 6 per cent compared with the amounts advertised in the Public Expenditure estimates a year ago. The committee's latest estimate of the shortfall next year is an amalgam of a 3½ per cent cut estimated to be the universities' share of the £30 million cut for higher education announced last November and the still incalculable effect on university finances of the partial disappearance of overseas students, some of whom have been frightened away by "economic" fees.

Some universities regard Dr Parkes's warning as a signal for drastic belt-tightening. Last week, for example, Lord Annan, Vice-Chancellor of the University of London, told the university senate that the total budget of £200 million might be reduced by between £15 and £20 million in 1982. Other universities appear to be taking a more phlegmatic line, believing that they cannot know the worst until the individual allocations of funds for 1981–82 are made in April or soon thereafter.

Between now and then, the committee itself will have several difficult questions to decide. One possibility raised in the letter from Dr Parkes is that the committee may keep back until later in the academic year a proportion of the funds made available by the Department of Education and Science, using the reserve to make good deficiencies that have by then appeared. There are precedents for such a reserve, but no decision has yet been made, nor have criteria for deciding how to use the money been defined.

The Parkes letter also promises explicit guidance in the spring on the numbers of home students at which British universities should aim in the coming academic year, and on their desired distribution among different kinds of courses. Although such "guidance" has accompanied previous financial allocations to British universities, some universities now apparently fear that the committee intends to be more *"dirigiste"* than in the past — while others remark that Dr Parkes's letter is a good deal less so than his speech to a closed meeting of the Committee of Vice-Chancellors at the beginning of December. It does however seem clear that the University Grants Committee will take steps to ensure that universities do not earn their way out of trouble by recruiting more home students than at present for the sake of the extra fee income that would bring.

Planning for the year ahead has been further confused by reports that Mr Mark Carlisle, Secretary of State for Education and Science, told a conference in the north of England on 6 January that he saw no reason why the cuts now proposed should be matched by "a reduced provision". Universities, on the other hand, say that there will have to be a reduction of student entry this October if they are to live within their straitened budgets.

The future constitution of the University Grants Committee itself also appears to be in question. Taking its cue from a recommendation of the House of Commons Select Committee on Education towards the end of last year that the committee should cultivate more independence, the department has raised the possibility that the committee's staff (at present seconded from the Civil Service) should become direct employees. Some of those concerned wryly reflect that this is not quite the independence that the House of Commons committee had in mind, but they acknowledge that such a step would reduce the size of the Civil Service and transfer part of its cost away from central government. The fine print in the proposal, which is said to be "very small", is being read carefully.

0028-0836/81/040217-01$01.00

CORRESPONDENCE

Badgers guilty

SIR — In his letter published on 11 December 1980 (page 532), Stephen Harris, among many other misleading and biased remarks, stated that the rate of decline in the incidence of tuberculosis (TB) in badgers in the South West was "paralleled" by a decline in the incidence of reactors in cattle herds not only in the South West but also in the rest of England. This statement was based on a graph which was attached to a copy of the letter sent to Lord Zuckerman and which is now reproduced (Fig.1). It was deduced from this that there might well be some common cause unconnected with the gassing campaign that was reducing the incidence of TB both in cattle and badgers throughout the country.

This "parallelism", however, was only secured by expressing all plotted values as percentages of the corresponding 1974 values. In Fig.2 I have plotted the breakdowns for the South West and for the rest of England on the same scale, subdividing the South West into (*a*) Gloucester, Avon and Wiltshire; (*b*) Cornwall; and (*c*) Devon, Dorset and Somerset. The radical differences between the counties that have a high incidence of herd breakdowns, (*a*) and (*b*), and the rest of England (*d*) is immediately apparent.

Table 10 of the report (*Badgers, Cattle and Tuberculosis,* Lord Zuckerman; HMSO, London, 1980) shows that the sources of infection are indeed different in the South West and in the rest of England. In groups (*a*) and (*c*) three-quarters of the infections are attributed to badgers, but only 1 per cent to imported Irish cattle, whereas in the rest of Great Britain one half are attributed to imported Irish cattle and none to badgers.

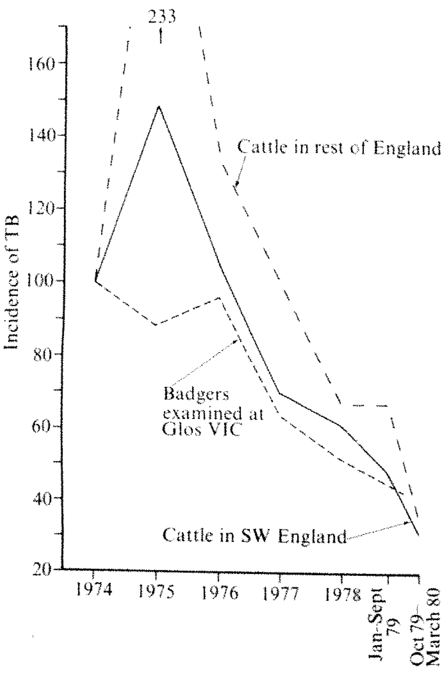

Fig.1 Annual changes in the incidence of TB in badgers sampled at the Gloucester Veterinary Investigation Centre (page 62 of the report) and herds of cattle in South-West England and herds of cattle in the rest of England (page 64). The first year for which data were available in the report from all three samples (1974) was taken as 100 per cent; for subsequent years, the level of TB was expressed as a percentage of the incidence in 1974.

In Cornwall (*b*), as Harris observes, only 15 per cent were definitely attributed to badgers, but as almost three-quarters of the causes of Cornish breakdown were recorded as "unknown" and the remainder were either from purchased cattle or contiguous premises, it may be presumed that infection from badgers was much greater than this.

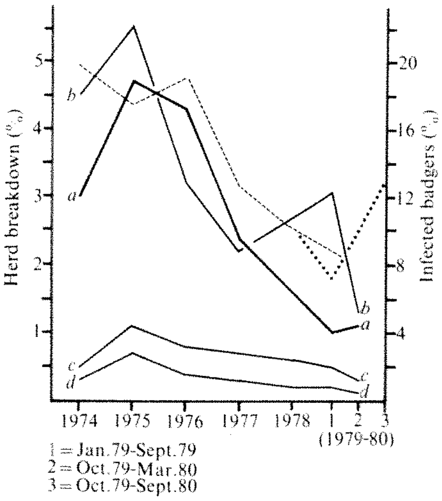

Fig.2 The percentages of herd breakdown are shown by full lines (from Table 19 of the report). The percentages of badgers found to be infected are shown by the broken line (Table 15). The dotted line gives some supplementary information from Table 18 (updated).

The fall in the incidence of herd breakdowns following the introduction of the gassing campaign in Gloucester/Avon agrees well with the reduction in the incidence of TB in badgers (broken line), bearing in mind that in addition to the reduction in the percentage incidence in badgers the numbers of badgers in close contact with herds must have been substantially reduced by the gassing.

The dotted line is derived from the latter part of Table 18, updated to September 1980, and indicates the rise in TB incidence in badgers following the cessation of gassing. (Updated figures for herd breakdowns in Gloucester/Avon and Wiltshire are not yet available).

The only support that Fig.2 gives to the suggestion that there was a common cause, other than appropriate action by ministry officials, affecting the decline in TB operating throughout the country is the substantial rise between 1974 and 1975. This cannot be related to infection from badgers. It may possibly have been due to climatic factors or to some improvement in the tuberculin test.

Figure 1 is a sad illustration of the way in which distorted and partial graphical presentation can be used for propaganda purposes.

FRANK YATES
Rothamsted Experimental Station,
Harpenden, UK

Rothschild retreat

SIR — It is not clear from your leading article in the January 1/8 issue (page 2) whether you regret the government's "retreat from Rothschild" or just the manner in which it is happening.

One of the difficulties for the Medical Research Council (MRC) at the time of the Rothschild report was the uncertainty as to the failures in the then current system which it was intended to correct. The Ministry of Health did not identify any omissions on the part of the MRC in their contribution to improving the health of the nation, nor did they subsequently propose contracts in fields of work outside the previous commitment of the MRC. Rothschild, in a thoughtless comment, referred to the very low expenditure on research into ageing, one of the fundamental aspects of all living things, but the understanding of which is nowhere in sight. He failed to ask the practical question as to how much of the MRC budget was spent on investigating diseases most common in old age. The answer would have been a major part.

There are, at present, three developments in medical research on which great hopes of practical gain are based: interferon, antibody production by hybridomas and DNA technology. How far the expectations will be justified remains to be seen, but the heavy investments of pharmaceutical companies throughout the world in these fields is evidence that the hopes are held widely. MRC laboratories were responsible for the first two discoveries and made a very big contribution to the third. None came from planned research but from "Dr Gowans' doctrine of investment in good ideas and good people".

It has been argued strongly that much more attention should be given to public health and preventive medicine and that the MRC's expenditure has the wrong emphasis. But one of the major advances in this field, the correlation of the incidence of lung cancer with cigarette smoking, came from work in an MRC unit.

No doubt governmental administration of civil science could be improved substantially, but the next enquiry which you appear to be advocating must surely start by identifying the omissions and failures of the present system whether in medical, agricultural or any other field of research before recommending changes to overcome them. Your generalized denigration of a system which has achieved obvious successes is not enough.

Deep-ocean hydrothermal vent communities

from J.T. Enright, W.A. Newman, R.R. Hessler & J.A. McGowan

THE theory of plate tectonics has led to a completely unexpected bonanza of research problems for marine biologists. The theory predicted major heat input to the ocean in areas where the sea floor is spreading, and in the search for those sources, geophysicists discovered not only deep-ocean hydrothermal vents, where warm water emerges from subterranean sources, but also extraordinary concentrations of large and unusual animals surrounding the vents[1,2]. The bottom of the deep sea typically has a sparse fauna dominated by tiny worms and crustaceans, with an even sparser distribution of macrofauna, including clams, crabs and echinoderms. Near the hydrothermal vents, however, are bizarre ensembles of abundant large animals — communities which resemble nothing ever before encountered by marine biologists. The most conspicuous and unusual animals around the warm-water vents (∽ 20°C) are huge gutless tube-worms (Vestimentifera), some of which are over 3m long and up to 10 cm in circumference; but there are also remarkable densities of huge clams (25cm length is typical), blind crabs, fish and polychaetes (see figure). More than 100 species have been collected[2], many of which are elsewhere unknown.

How do the animals in these deep-sea communities find enough to eat? Elsewhere, the deep benthic fauna relies on particulate matter, ultimately derived from photosynthesis, falling from above. The food supplies necessary to sustain the vent communities, however, must be many times that ordinary fallout. In the first report which described the vent fauna, Lonsdale[1] proposed two possible sources of nutrition: advection of food materials from surrounding regions and bacterial chemosynthesis. Shortly thereafter three kinds of evidence were presented[3] which support the idea of intense local chemosynthesis: (1) hydrogen sulphide, as a potential basis for fixation of CO_2, was found in vent water; (2) some of the bacteria isolated from a vent site were found to be capable of chemosynthesis on a thiosulphate medium; and (3) bacterial concentrations of 10^8 to 10^9 cells per ml were found in samples thought to be pure vent water. This final observation seems decisive: if such astonishing concentrations of bacteria — difficult to achieve even under optimal laboratory conditions (D.M. Karl, personal communication) — are indeed typical of steady-state vent outflow, then food from within the vent would be dwarfed by any contribution from advection. Hence, the widely quoted conclusion was reached, that bacterial chemosynthesis provides the foundation for hydrothermal-vent food chains[2-5] — an exciting prospect because nowhere else on Earth is a major community of diverse organisms known which does not depend, at least indirectly, on photosynthesis.

There are, however, certain difficulties with this interpretation. Some of the large sedentary organisms associated with vents are found at ordinary deep-sea temperatures many metres from the nearest hydrothermal sources[6], and therefore would not directly encounter any bacteria from within the vent. It is conceivable, however, that bacterial aggregates, which have grown subterraneanly, in the rising plume of vent water might rain back out in the peripheral areas to nourish these filter-feeders. Another difficulty is that similarly dense populations of large animals have been found[2,7] in the proximity of 'smokers' — hot-water vents where the dominant, conspicuous flow emerges at temperatures up to 350°C. No bacteria can be expected to multiply or even survive such heat, and none was found in the hot vent water[7]. Unless the smokers are consistently associated with smaller but more hospitable warm-water vents[2] — a distribution that has not actually been observed (F.N. Speiss, personal communication) — the chemosynthesis hypothesis could at best account for only a fraction of the vent faunas.

The food resource question has been further complicated by a recent and more extensive investigation[5] of the microorganisms associated with one of the warm-water vents in the Galápagos Rift region. Bacterial concentrations were measured in near-vent water which were approximately three orders of magnitude lower than those initially reported (5×10^5–10^6 cells per ml). These values were confirmed by replicate estimates of biomass based on ATP concentrations in the water[5] (100–250 µg of microbial carbon per litre, compared with the previous estimate[3] of 100–1,000 mg of bacteria per litre). Although the authors of that report still endorsed the chemosynthesis hypothesis[5], the available data suggest that Lonsdale's first alternative[1] deserves more attention than it has received. Could advection conceivably supply the near-vent fauna with enough food organic matter ultimately derived from photosynthesis?

Because of its temperature, water from a vent is very buoyant, densities as low as 0.62 gm cm^{-3} having been reported for a 'black smoker'[8]. The rising plumes of vent water are, however, rapidly diluted. Spiess *et al.*[7] report that a vent discharging at 23°C into water at 1.8°C produced a temperature only 0.3°C warmer than ambient at a height of 10 m above the vent. These values indicate that within 10 m of the bottom, the advected diluting water was about 70-fold the discharge volume $[(\Delta T_1-\Delta T_2)/\Delta T_2]$. Stability considerations dictate that such advective flow into the vent area would originate near the water–substratum interface, where suspended organic matter accumulates and epibenthic animals are concentrated. Typical values for suspended particulate matter in deep-sea waters within a few metres of the bottom[9,10] are of the order of 50–500 mg m^{-3}, of which several per cent is organic matter. Taking a conservative estimate of 5 mg of particulate organic carbon per cubic metre and the calculated dilution factor of 70, we find that for every cubic metre of vent discharge, 350 mg of particulate organic carbon would be advected into the vent area. If discharge volume were to be, say, 1 m^3 s^{-1}, advection could provide more than 30 kg per day of potential food. In addition, there is a good chance that small live animals in the advected water might be killed or stunned by thermal and/or

Examples of hydrothermal-vent fauna from Galápagos Rift area. Left, vestimentiferan worms, about 3 cm in diameter. Middle, dense group of encrusting serpulid polychaetes, about 5 cm long, some with tentacular crown extended. Right, vesicomyid (white) and mytilid (grayish) bivalves adjacent to an aggregation of anemones. The tip of the probe is 1 cm in diameter.

chemical shock, and subsequently rain down, thereby contributing to the vent food supply. Hence, it appears that an input of non-photosynthetic food might not, at least in principle, be required by the vent animals.

Such input calculations, however, ignore what may be the most important aspect of advective processes, that the near-vent area should accumulate and concentrate most advected organic matter. Entrained food particles which are not consumed in their initial passage through the vent area would be wafted upwards, but ought thereafter (given a density greater than ambient seawater) to rain out predominantly on the near-vent substratum. Once on the bottom, this food material would not be lost to the vent ecosystem because of resuspension. Sediment-trap data[11] indicate that the particulates suspended in near-bottom water of the deep sea must, on the average, be resuspended every few days. Because of such resuspension, the initially advected material would be subject to repetitive re-entrainment, thereby enriching the advected waters. Hence, filter-feeding animals near a vent should experience not only increased flow rate of waters bearing organic nutrients, as suggested by Lonsdale[1], but also experience unusually high concentrations of suspended particulates from non-vent sources, food which is ultimately derived from sea-surface photosynthesis. The nutrition of filter-feeding animals is even more dependent on food concentrations than on the flow rate of surrounding waters. At any new vent site, even if chemosynthesis were to be negligible, this sort of accumulation should progress until catabolic degradation, by both micro- and macroorganisms, balances the net rate of advective input.

Both Lonsdale's suggestion that food materials would be advected from extensive areas surrounding deep-water hydrothermal vents, and the enhancement of the local density of these food materials due to gravitational fallout and recirculation, appear to be reasonable, if not logically inescapable, expectations. The as yet unresolved issue is the quantitative one — what proportion of the food supply for macroorganisms is provided by such advective input and what proportion by vent-related chemosynthesis? The suggestion that advective input alone might provide an adequate nutritional basis for near-vent food chains implies that animals relying on advected biomass ought to do well around any intense persistent deep-water source of heat — an idea which may be worthy of direct experimental test.

By similar reasoning, the near-vent area should also represent a zone of accumulation for any organic materials which might be produced by chemosynthesis, and therefore it may prove to be extremely difficult to distinguish between a predominantly photosynthetic and a predominantly chemosynthetic basis for the near-vent food chains by measuring the local density of organic matter and associated bacteria, or by examining the spatial gradients in those densities. Even samples thought to be pure vent water[3] are not easy to interpret; the possibility of dilution or contamination by materials of non-vent origin will remain troublesome, because of the intense mixing around the vent[5].

Some of these uncertainties and paradoxes may soon be resolved by carbon-isotope data. The stable isotope ratio, ^{13}C to ^{12}C, depends on the nature of an organism's carbon sources, and is also a sensitive indicator of alternative metabolic pathways involved in photosynthesis and of heterotrophic fractionation. In the tissues of some of the vent fauna, the $^{13}C/^{12}C$ ratio differs significantly from values typical for other deep-sea animals[12–14], suggesting that some sort of unusual carbon sources or metabolic processes — perhaps chemosynthesis — may be important in near-vent areas. The finding that the ^{13}C ratios differ between vent bivalves and vestimentiferan worms in the direction of this anomaly (H. Craig, personal communication) is so far unexplained, the one group having smaller and the other larger values than expected. Also of great interest are data on the ratios of ^{14}C to ^{12}C in the tissues of near-vent animals, which ought to reflect their food resources, and which indicate[14] an apparent age of about 2,500 yr. Intra-vent chemosynthesis would incorporate the dissolved inorganic carbon of vent water, 80% or more of which apparently comes from magmatic sources (H. Craig, personal communication). If one assumes that magmatic CO_2 is very old and contains negligible amounts of ^{14}C, then in-vent chemosynthesis should lead to ^{14}C ages (>15,000 yr) very different from those obtained for the tissues of vent macrofauna ($\backsim$2,500 yr). So far, however, no actual measurements of ^{14}C in vent water are available, and other interpretations about its probable ^{14}C age have been proposed[14]. The apparent age of 2,500 yr of the circumvent fauna is clearly much older than concurrent sea-surface photosynthetic production (expected age $\backsim$0), and much younger than the available data for organic carbon incorporated into the top few millimetres of deep-ocean

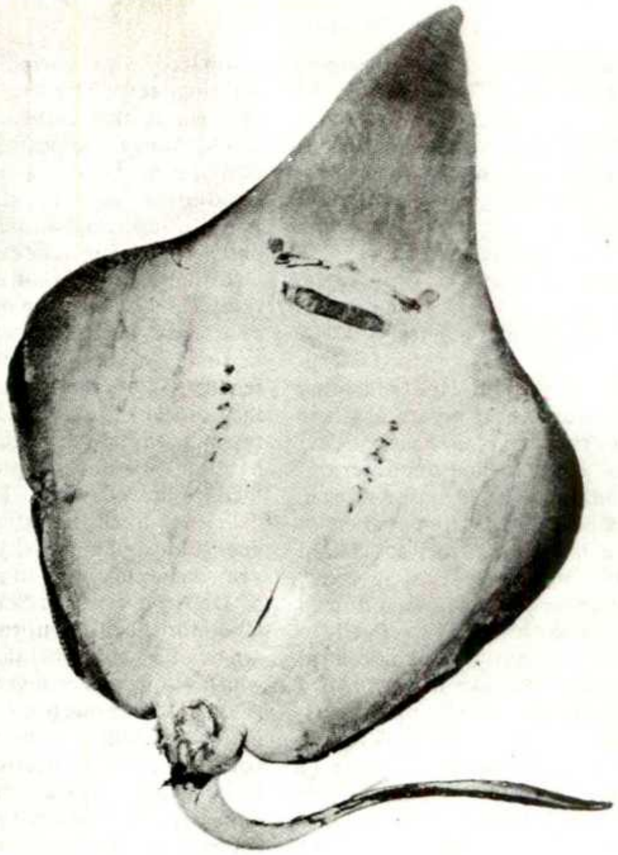
A new stingray from South Africa

from Alwyne Wheeler

ICHTHYOLOGISTS are accustomed to the regular description of previously unrecognized species of fishes, which if not a daily event at least happens so frequently as not to cause great comment. Previously undescribed genera are likewise not infrequently published, but higher categories are increasingly less common. The discovery of a new stingray, which is so different from all known rays as to require both a new family and a new suborder to accommodate its distinctive characters, is therefore a remarkable event.

A recent paper by P.C. Heemstra and M.M. Smith (*Ichthyological Bulletin of the J.L.B. Smith Institute of Ichthyology* **43,** 1; 1980) describes this most striking ray as *Hexatrygon bickelli* and discusses its differences from other batoid fishes. Surprisingly, this remarkable fish was not the result of some organized deep-sea fishing programme, but was found lying on the beach at Port Elizabeth. It was fresh but had suffered some loss of skin by sand abrasion on the beach, and the margins of its fins appeared desiccated in places. The way it was discovered leaves a tantalising question as to its normal habitat, but Heemstra and Smith suggest that it may live in moderately deep water of 400–1,000 m. This suggestion is supported by its general appearance (small eyes, thin black dorsal skin, flacid snout) and the chemistry of its liver-oil.



Ventral view of *Hexatrygon bickelli*

The classification of *Hexatrygon* presents some problems, the most obvious of which is that it has six pairs of gill openings, whereas all other batoid fishes (sawfishes, rays, skates, stingrays and electric rays) have only five paired gill openings. Another striking feature is that the spiracular openings behind the eyes are closed dorsally by a cartilage-supported flap to form an oblique slit. It seems that *Hexatrygon* may be able to shut its spiracles down externally, something that other batoids cannot do. Internal features are as strikingly different from its relatives, and the shape and structure of the snout are also unique. The snout is elongate, of uniform thickness (16–18 mm deep in the fish of 103 cm total length) and flaccid. Internally it is supported by lightly calcified rostral cartilages and filled with an acellular jelly, while the underside is richly supplied with well developed ampullae of Lorenzini. These ampullae are known to be electroreceptors and assist in finding buried food organisms in shallow-water rays. The combination of characters persuade Heemstra and Smith to erect a new suborder (Hexatrygonoidei) within the order Myliobatiformes to contain this fish. The order contains the other stingrays, eagle rays and mantas, most of which, like *Hexatrygon*, have one or more serrated dagger-like spines on the back of the tail.

The interest of this fish is not just that it represents a novel group within a well known order, but that all the other myliobatiformes are shallow-water bottom-living species or surface-living fish. *Hexatrygon* seems to be the first deep-water stingray known. Its elongate, jelly-filled snout richly supplied with electroreceptors is similar to the deep-water chimaeroids *Rhinochimaera* and *Harriota*, and there can be little doubt that it is an adaptation for finding food in the soft-bottom ooze of deep water.

One final point that Heemstra and Smith note is the remarkably small brain of *Hexatrygon* (it is about 3% of the cranial volume); in shallow-water stingrays it is about 80%. As they point out the coelacanth, *Latimeria chalumnae,* has a similarly small brain (as does the basking shark, *Cetorhinus maximus,* according to Scott *J. Fish Biol.* **16,** 665; 1980). This may also be an adaptation to deep-water life.

If nothing else the discovery of *Hexatrygon* off South Africa, as with the first coelacanth, reminds one of the tag — *ex Africa semper aliquid novi.*

Alwyne Wheeler is in the Department of Zoology, British Museum (Natural History), London.

sediment (apparent age $\sim$8,000 yr)[15]. For the advective contribution to vent nutrition, however, the appropriate comparison would be with the ^{14}C content of suspended particulate organic matter ordinarily present in near-bottom waters, which ought to be somewhere between these extremes, but again, appropriate measurements are not yet available.

In addition to the uncertainties associated with the two initial hypotheses for vent nutrition considered here, a third hypothesis has now entered the scene. Recent evidence (G.N. Somero and H. Felbeck, personal communication) indicates that significant bacterial chemosynthesis may be taking place *outside* the warm-water vents, by symbiotic microorganisms within the tissues of some of the macro-fauna. Hence, the basic problem of how the hydrothermal-vent fauna gets enough to eat remains an open and challenging question.

We are most grateful to the many colleagues who have shared their ideas with us, as well as those who have given us access to their unpublished data. □

Untangling ataxia-telangiectasia

from Bryn A. Bridges and David G. Harnden

THE rare autosomal recessive disorder, ataxia-telangiectasia (AT), has attracted attention because it is associated with an unusual sensitivity to ionizing radiations and an increased susceptibility to cancer, particularly of the lymphoid tissues. Patients also have a variety of other problems, including a progressive neurological disorder, a substantial immunological deficiency, spontaneous chromosome instability, a defect of DNA repair, premature ageing, raised serum alpha fetoprotein(AFP) levels and other less regular features. How are all these diverse manifestations of the genetic defect interrelated? In an attempt to answer this question and to resolve inconsistencies in reported results, workers from a variety of different fields came together at a recent conference* at the University of Sussex.

Many laboratories have now confirmed the cellular radiosensitivity of AT cells to ionizing radiation and there was agreement that AT cells are also unusually sensitive to the chromosomally radiomimetic anti-tumour agent, bleomycin. Not all agreed that AT cells are sensitive to a range of other chemical mutagens, suggesting that increased sensitivity to any of these agents cannot be very marked although some of the disagreements may be due to differences between AT lines. Three different groups (Paterson, Chalk River; Inoue, Mishima; Jaspers, Rotterdam) all reported complementation between different AT lines for some radiosensitive function and agreed that AT3BI could be distinguished from AT4BI and AT5BI. Attempts to elucidate the molecular basis of the radiosensitivity failed to detect differences between AT cells and normals in the repair of single-strand or double-strand breaks in the DNA using presently available techniques. Two different types of abnormal molecular response were described, a failure to inhibit DNA replication after γ- or X-irradiation, and a defect in one or more repair pathways. A possibly analagous situation exists in *Escherichia coli* where mutations at the *rec A* gene block both inhibition of DNA replication after UV exposure and several pathways of DNA repair. The existence of a repair defect was demonstrated in different ways by several different groups. Cox (Harwell) showed a failure to repair potentially lethal damage in AT cells following X-irradiation. Indirect evidence of a repair defect comes from cytogenetic studies following G_0 irradiation of AT lymphocytes which reveal a large increase in fragments and chromatid aberrations as compared with normal cells (Taylor, Birmingham). This, together with the observation that caffeine can potentiate DNA damage to visible chromosome damage at least 24 hours after G_0 irradiation of AT cells (Natarajan, Leiden), suggests that there are long-lived unrepaired lesions. The exact nature of the DNA repair defect is still not clear and it is possible that more than one pathway may be affected. Paterson detected a reduction, in some AT cell lines,of γ ray-induced repair replication,and also a deficiency in their capacity to excise and repair specific γ ray-induced base damage, although there has been difficulty in reproducing some of these results elsewhere. Inoue reported a deficiency in cell-free extracts of all AT cell lines studied of an activity which modifies γ ray-damaged $3'$ sites to permit the action of DNA polymerase. Some, but not all, laboratories could confirm these results.

The other abnormal radiation response which was agreed by several groups is that AT cells show a much less marked decrease in DNA synthesis than do normal cells following γ-irradiation (Edwards, Birmingham; Lehmann, Sussex; Jaspers). Similarly, Scott (Manchester) finds that AT cells do not show the normal post-irradiation mitotic delay. It is not clear how these defects relate to the repair defect.

Unlike the other cancer-prone DNA repair deficiency syndrome, xeroderma pigmentosum, where there is a hypersensitivity of the cultured cells for mutagenesis by UV light, there is no evidence for any spontaneous or radiation-induced hypersensitivity for the induction of gene mutations in AT (Cox; Simons, Leiden). Furthermore, Arlett (Sussex) was unable to detect any radiation-induced gene mutation in AT cells. One of the most interesting features of AT patients is the high level of spontaneous chromosome aberrations in circulating lymphocytes and particularly the tendency of cytogenetically abnormal clones to proliferate in the absence of any haematological abnormality. The formation of these clones following breakage at specific points on chromosome 14 was emphasized and it was suggested (Hecht and McCaw, Tempe, Arizona) that aberrations involving the breakpoint at or near 14q32 may have particular neoplastic potential.

There is definite evidence for a profound immunological defect in AT patients. All have a defect of cell-mediated immunity and some have a deficiency of IgA and IgE. Waldmann (Bethesda) showed that the IgA deficiency is due to lack of synthesis rather than abnormal metabolic rates. There is diminished helper T-cell function, but even stimuli which do not require a helper T function fail to provoke an IgA response, suggesting a defect of B-cell maturation. Waldmann also presented evidence to suggest that the DNA sequences necessary for IgA production are present in AT patients and there was some speculation about the possibility that the cutting and splicing of DNA required to produce the specific immunoglobulin genes may be impaired. The *rec A* gene of *E. coli* also controls the cutting and splicing involved in genetic recombination. The relationship betwen the immune defect and the occurrence of lymphoid cancers was considered. Unlike the other immunodeficiency syndromes AT patients show a range of epithelial cell tumours in addition to the preponderance of lymphoid cancers (Spector, Minneapolis). The pattern is also different from that seen in irradiated populations, where there is a preponderance of leukaemias rather than lymphomas. No conclusion was reached, but it seems likely that the cancers in AT are not related in a simple way to either the radiosensitivity or the disordered immune system, but rather to some combination of the two.

The neurological defects in AT patients, particularly progressive cerebellar ataxia, could not at present be readily linked with the biochemical or immune defects. There was, however, evidence that differentiation may be imperfect in many tissues and organs especially gonads, liver, the immune system and the central nervous system and this may in some way be related to the repair defect. The uniformly raised AFP levels in these patients may represent some immaturity of the liver. The deficient thymus appears embryonic rather than atrophic. Kidson (Brisbane) suggested that failure of the nervous system to differentiate properly might in time lead to progressive loss of neurones.

There was a great deal of interest in the possibility of detecting individuals heterozygous for the AT gene. This stems at least in part from the observation that heterozygotes had an increased risk for largely the same spectrum of tumours as the homozygotes (Swift, North Carolina). If current estimates of the AT gene frequency are correct, heterozygotes would comprise one per cent or so of the general population and this would have profound implications. It could be, for example, that AT gene carriers may account for a substantial proportion of early cancers of the lymphoid system. Suggested methods of detecting heterozygotes were low-dose chromosomal radiosensitivity (Kidson) and cell survival under hypoxic conditions (Paterson). The differences between obligate heterozygotes and normals were small, but may be significant in some cases. However, overlap between these two groups means that those tests would not be suitable for the recognition of heterozygotes in the general population.

Bryn Bridges is Director of the MRC Cell Mutation Unit and a Professor at the University of Sussex. David Harnden is Professor of Cancer Studies at the University of Birmingham.

---

*The workshop was held from November 6th to 7th, 1980, and was organized jointly by the MRC Cell Mutation Unit and the Department of Cancer Studies, University of Birmingham. Sponsorship was provided by the MRC, the Cancer Research Campaign and the International Cancer Research Workshops programme (ICREW) of the UICC.

0028-0836/81/040222-02$01.00

The emphasis of recent research on AT has been on the sensitivity of these cells to various agents and their effect on DNA synthesis and repair and progress in these areas has been substantial. While these are undoubtedly important, more effort could in future be directed towards relating these areas to the defect of the immune system and the neurological disorder. Such a relationship, though surprising, must exist since the evidence that AT is due to a single autosomal recessive gene is good. ☐

The spruce invasion

from Peter D. Moore

ONE of the greatest weaknesses of palaeoecology is its necessary reliance upon circumstantial rather than experimental evidence. Yet it is this weakness which also opens the way to interminable speculation on the basis of the temporal correlation of events in the past. A very good example is the debate concerning the expansion of spruce (*Picea abies*) in Europe since the last glaciation.

Pollen analysis shows that, following the final glacial retreat, *Picea* immigrated into the eastern Alps very rapidly, accompanied by deciduous tree genera such as alder (*Alnus*), hazel (*Corylus*), oak (*Quercus*) and elm (*Ulmus*). It was preceded by birch (*Betula*), pine (*Pinus*) and larch (*Larix*). In Austria, for example, this deciduous forest type expanded into the south-east around 10,200 BP (Fritz *Carinthia* II **83**, 277; 1973) and by 9,500 BP it had expanded westwards in the Tyrol (Bortenschlager *Ber. naturw.-med. Ver. Innsbruck* **63**, 105; 1976). Although *Picea* was a member of the early post-glacial forests of Austria, even in the upper valley of the Inn, it is interesting to note that its immigration into Switzerland was considerably later; and it is here that scope for speculation begins.

Markgraf (*Nature* **288**, 249; 1970) collated the Swiss data concerning the movement of *Picea* into Switzerland and she found that its expansion was not very regular. Only in the south-east had it arrived by about 6,000 BP, but between that date and about 4,500 BP *Picea* pollen increased very markedly in a series of sites scattered all over the country, extending right to the western borders, north of Zurich. There remained some sites, however, even in the south of the country, in which the expansion was delayed until about 3,000 BP or even later. The expansion of spruce was often accompanied by a decrease in other tree species, including fir (*Abies*), pine and the deciduous forest genera. Also there was a simultaneous increase in herbaceous pollen, largely grasses, which suggested that the forests had been disturbed by human activity and that this provided spruce with an opportunity to establish itself where previously it had been excluded by competitive pressures. The combination of these pieces of circumstantial evidence led Markgraf to reject the earlier theories of a climatic change which provided the right conditions for *Picea* invasion into Switzerland and to propose that the tree followed in the wake of Neolithic agricultural progress.

One still needs to explain the delay in expansion between Austria and Switzerland. Here Markgraf suggested that the early invasion of *Abies*, *Larix* and *Pinus cembra* (the only central European member of the *Haploxylon* subgenus of *Pinus* and therefore distinguishable on the basis of its pollen) may have formed a dense canopy forest into which *Picea* could not immigrate. All three of these species were present in Austria, but either arrived later or were in lower frequency. It is claimed that such a forest may have a certain degree of inertia which renders it resistant to invasion by new species and also resilient in the face of climatic fluctuations (Smith *Proc. R. Soc.* **B161**, 331; 1965).

Spruce has also moved westwards in Fennoscandia in the latter half of the post-glacial, but here alternative explanations have been proposed. Moe (*Bot. Notiser* **123**, 61; 1970) collected the dates for the rise in *Picea* pollen in this area and showed that its expansion began in eastern Finland by 5,000 BP, reached the Baltic coast of Finland by 3,500 BP and subsequently spread through Sweden and into Norway. It has an unbroken distribution, reaching the west coast of Norway only in the central

New vistas in soil research

from Hamish Anderson

FRANCIS BACON'S assertion, that "there is nothing makes a man suspect much, more than to know little", gives an adequate summary of the present state of soil organic chemistry. Soils produce a [illegible] array of organic and [illegible], long [illegible] ultimate basis of [illegible] proof. There remain few separation techniques or analytical methods which have not been used in humic substance research, and the structural chemistry of soil extractives has uncertainly advanced, mainly by degradative techniques (see Schnitzer and Khan *Soil Organic Matter* Elsevier, 1978).

Proton magnetic resonance spectroscopy is an obvious tool but initial results were beset with line-broadening problems arising from chemical shift anisotropy, even in the rare cases where samples were sufficiently soluble for examination. The advance in NMR capability has now led to the threshold of the soil organic chemist's dream, the possibility of examining humic substances *in situ* (Barron *et al.* this issue of *Nature*, page 275). The Antipodean researchers have shown that the use of cross-polarization ^{13}C NMR techniques has allowed the [illegible] of useful spectra from whole [illegible]. Conventional ^{13}C spectra of amorphous solids usually give no useful structural clues, mainly due to large dipolar interactions. The ^{13}C cross-polarization technique leads to increased sensitivity by the elimination of heteronuclear dipolar broadening, this being achieved by transferring polarization from ^1H to ^{13}C (Mehring *High Resolution NMR Spectroscopy in Solids* Springer-Verlag, 1976). The transfer from the more abundant and more polarized ^1H spins leads to a possible quadrupling of the ^{13}C spins and, more importantly, the ^{13}C spin-lattice relaxation rate now occurs at that of the proton population. Since this is usually an order of magnitude faster than the conventional ^{13}C rate, the data accumulation frequency can be greatly increased. Even allowing for this 'speeding-up' process, it is sobering to realize that the number of free induction decays collected by Barron *et al.* during whole soil spectrometry ranged from 2×10^4 to 2×10^5. One major defect of the present system is that the chemical shift anisotropies of aromatic and carboxylic carbon lead to signal broadening and loss of resolution. However Barron *et al.* are confident that the combination of the present high-field cross-polarization technique with 'magic-angle' sample spinning will resolve this problem, as has been demonstrated with isolated humic substances (Hatcher *et al. Org. Geochem.* **2**, 87; 1980).

Humic substances research has long been dogged by the uncertainty of structural alterations occurring during extraction, and the proposed techniques offer answers to this problem. Indeed, the fact that modern NMR spectroscopy offers an ever-widening scope for examining a variety of nuclei instils hope that whole soils and their physical separates can be studied, resolving the interactions between humic substances and silicates, along with the involvement of nutrients such as nitrogen, sulphur and phosphorus.

Hamish Anderson is in the Department of Soil Organic Chemistry, Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen.

0028-0836/81/040223-02$01.00

region. There are some similarities to the Swiss data in that the expansion is non-synchronous, but in this case there is a more distinct pattern of progressive westward movement.

Tallantire (*Norw. J. Bot.* **19**, 1; 1972) assessed the possible courses of the late post-glacial movements of spruce in Fennoscandia and he regarded the expansion as a step-wise development with phases of expansion, and plots them in this form on his maps. He quotes in full the dates upon which he bases this idea but, if the dates are considered in conjunction with their errors, it cannot be fully supported; it is possible to interpret the spread of spruce as a gradual process. Tallantire considers the expansion a consequence of climatic changes and bases this partly upon his assumption of phased movements, but also upon the inconclusive nature of the palynological evidence for coincident human activity. Further analysis of the climatic requirements of spruce (*J. Biogeogr.* **4**, 219; 1977) led Tallantire to regard the critical parameters as ample early-summer water supply and stable, low winter temperatures. In the absence of either of these factors, the young spruce (2–3 years) is selected against. He concludes "the conformable arrangement of the dates of spruce spread in southwestern Finland and its relationship to present winter climatic data is surely too marked to be due to a chance distribution of the investigated sites."

Since we are dealing with correlations, however, it is worth pointing out that correlation between pollen evidence for human activity and the spread of the spruce is becoming increasingly convincing as more detailed data accumulate, particularly from Finland. In the Kuusamo district of the north-east, *Picea* expanded at the time when tree pollen was falling and increasing Gramineae, *Calluna*, *Vaccinium* and *Empetrum* indicate ground flora changes (Hicks *Trans. Inst. Br. Geogr.* NS1, 362; 1976 and *Commentat. Biol.* **80**, 1; 1975). Although Hicks does not place such an interpretation upon the data, it is possible to support the idea of human agency in *Picea* spread.

Similarly in southern Finland, Tolonen (*Ann. Bot. Fenn.* **15**, 4; 1978 and **17**, 15; 1980) produces pollen stratigraphic curves in which the indications of human activity at the times of *Picea* expansion are strong. Many weed species, in addition to cereals, show short-duration peaks at precisely the time of the *Picea* rise at Lake Lammijärvi. At Lake Ahvenainen, *Picea* pollen rises in a series of episodes at each of which there are also cultural indicators. It is also noteworthy that considerable increases of charcoal are found in the latter site following the horizon at which *Picea* begins its spread.

Tallantire has claimed that the ecological conditions in Fennoscandia were essentially different from those in central and southern Europe in that *Abies, Fagus* and *Carpinus* were not found in the pre-*Picea* woodlands, whch consisted largely of *Betula, Pinus* and *Sorbus*. These forests would therefore have offered little competitive resistance to *Picea*, it may be supposed. The correlation between forest disturbance and spruce invasion certainly exists, however, and it may be that nutrient release from litter caused by disturbance and especially burning was influential in allowing spruce to invade. In the current management of Fennoscandian spruce forest, for example, Viro (in *Fire and* Ecosystems (eds T.T. Kozlowski & C.E. Ahlgren), Academic Press, New York, p.7; 1974) recommends the use of fire for rejuvenating old stands.

We are thus faced with the task of balancing alternative correlations, bearing in mind that a strong probability exists that both processes were operative. In the absence of any possibility of experimental confirmation of either hypothesis, the ground is well prepared for lengthy debate and speculation. ☐

Inclusion compounds

from J.E.D. Davies

COMPOUNDS which show unusual properties, such as a preference for methanol rather than for ethanol, for the *para* rather than for the *ortho* or *meta* isomers of $C_6H_4Cl_2$, for the axial rather than for the equatorial conformer of $C_6H_{11}Cl$, for the *trans* rather than for the *gauche* rotamer of 1-chlorooctane, and even a preference of $C_6D_4(CD_3)_2$ rather than for $C_6H_4(CH_3)_2$, were the subject of a recent symposium* in Poland.

These interesting compounds are the inclusion compounds, which are two-component solid-state systems where the 'guest molecule' is accommodated in voids formed in the crystal structure of the 'host lattice'. These host–guest complexes (for which the term 'hogiplexes' was suggested [J.E.D. Davies, Lancaster]) can be classified according to the type of void available for the guest molecule. The guest species is accommodated in interlayer spaces in the intercalates; in the clathrate compounds the guest species is completely enclosed in a cavity; and the term inclusion compound is usually used where the guest species is accommodated in any other type of void, such as long channels (see figure).

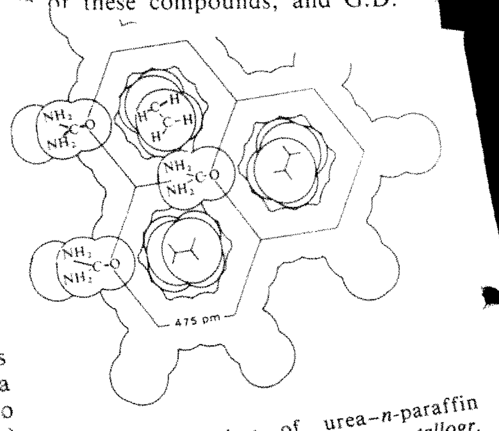
After a historical introduction [illegible] Kemula (Warsaw) and a general survey of the different types of host–guest complexes by J.E.D. Davies (Lancaster), the symposium heard about current work using a variety of host lattices.

The greatest number of papers was devoted to the Werner-type host lattices, M(X-py)$_4$ (NCS)$_2$, where M = Mn(II), Co(II), Ni(II), Fe(II) and X=3-Me, 4-Me, 4-Et, whose selectivity towards isomeric disubstituted benzenes has long been known (Schaeffer *et al. J. Am. Chem. Soc.* **79**, 5870; 1957) and recent selectivity studies were reported by S. Brzozowski (Warsaw), J.E.D. Davies (Lancaster) and A. Lewartowska (Warsaw). This selectivity can be put to good use, and D. Sybilska (Warsaw) showed how it is possible to separate isomers chromatographically on columns consisting of the Werner complexes. The chromatographic use of a wider range of inclusion compounds was reviewed by E. Smolkova-Keulemansova (Prague).

Undoubtedly the most unexpected selectivity shown by these host lattices is towards isotopic molecules. N.O. Smith (New York) described his careful work in this area and was able to show that when Ni(4-Mepy)$_4$(NCS)$_2$ is equilibrated with a mixture of the protonated and deuterated guest, there is a definite selectivity towards the deuterated species with benzene, xylene and naphthalene.

The related compounds, Ni(NCS)$_2$-(α-arylalkylamine)$_4$, also show remarkable selectivities and P. de Radzitzky (Brussels) described the work of the Labofina group on these compounds and illustrated a plant using these compounds to separate the dimethylnaphthalenes on an industrial scale.

Crystallography has been an important technique in the study of inclusion compounds, particularly since it was the pioneering crystallographic studies of H.M. Powell which first elucidated the [illegible] of these compounds, and G.D.



Cross-sectional view of urea–*n*-paraffin complex. (Fig.11 from Smith *Acta crystallogr.* **5**, 224; 1952. Reproduced by permission of *Acta crystallographica.*)

The source of meteorites in time and space

from Robert Hutchison

VARIOUS false alarms have occurred in the past over alleged discoveries of fossil meteorites. For example, a squarish piece of iron weighing 785g from Tertiary lignite mined at Wolfsegg, Austria, was originally reported as meteoritic (*C.r. hebd. Séanc. Acad. Sci., Paris* **103**, 702; 1886; *Nature* **35**, 36; 1887). More recently, in 1930, a fist-sized piece of iron-nickel metal was said to have been recovered from a borehole at a depth of 1,525 feet in Eocene sediments; this 'Zapata County', Texas, iron has since been lost (Lovering *Nature* **183**, 1664; 1959). Until the discovery of the remains of a chondrite in Ordovician limestone in Sweden by Thorslund and Wickman (see this issue of *Nature*, p. 285), the only probable fossil meteorite material known to the writer was the occurrence of chondrule-like structures in Mesozoic sediment from the Urals (Yudin *Meteoritics* **6**, 99; 1971). The Ordovician chondrite has been reasonably (but not conclusively) identified as a member of the high-iron or H-group of the ordinary chondrites. Its fall to Earth some 460 Myr ago has considerable significance.

There are compelling arguments that most meteorites come from asteroids. But although it now seems probable that there are sufficient numbers of the Earth-crossing Apollo asteroids and the related Mars-crossing Amor asteroids to account for the observed flux of meteorites, a steady state can only be maintained if these groups are fed from some source beyond Mars (Wetherill *Geochim. cosmochim. Acta* **40**, 1297; 1976). The small Apollo objects have a mean lifetime of only a few tens of millions of years before they are either captured by a planet or ejected from the Solar System by Jupiter. About 30% of observed meteorite falls are H-group chondrites. Most of these meteorites have cosmic-ray exposure ages close to 4 Myr (see, for example, Zähringer *Geochim. cosmochim. Acta* **32**, 209; 1968), which is taken to mean that they were released as metre-sized objects from some larger body some 4 Myr ago. Release was presumably the result of a collision involving the parent body. No stony meteorite has an exposure age greater than 100 Myr. Thorslund and Wickman's discovery indicates that there was H-group chondrite material among Apollo asteroids some 460 Myr ago, and the possibility then arises that the meteorite flux has not changed significantly in composition with time.

If this is so there appears to be a problem. From spectral reflectance data Gaffey and McCord (*Proc. 8th lunar Sci. Conf.* **1**, 113; 1977) found that belt asteroids rarely have surfaces with the mineralogy of ordinary chondrites; such surfaces are common among Apollo and Amor objects. Wetherill concludes that to maintain a steady-state population of these bodies, belt asteroids and, dominantly, comets must have orbits which can evolve into Earth- or Mars-crossing orbits. However, belt asteroids appear to have surfaces which are almost exclusively not ordinary chondritic, and Anders (*Icarus* **24**, 363; 1975) has argued, on the basis of the ancient bombardment undergone by meteorites of different types by particles emitted by solar flares, that most stony meteorites cannot have come from the outer Solar System. The problem of the maintenance of the meteoritic flux was recently discussed by Napier and Clube (*Nature* **282**, 455; 1979), who proposed that a proportion of meteorites come from outside the Solar System, but the meteorites themselves have no major chemical or isotopic anomalies consistent with different regimes of nucleosynthesis; so we are left with a Solar System origin. The question of where in the Solar System that might be has, if anything, been aggravated by the new discovery.

Robert Hutchison is at the British Museum (Natural History), where he is responsible for the curation of the national collection of meteorites.

Andreetti (Parma) dealt with crystallographic studies of a whole range of inclusion compounds. It was therefore surprising to learn of the lack of crystallographic studies on Werner inclusion compounds and J. Lipkowski (Warsaw) reported his recent studies which aimed at trying to understand the factors governing host lattice selectivity. A knowledge of the crystal structure is also necessary to understand the energy-transfer processes between host and guest using UV and γ-ray radiation reported by the group from the Institute of Nuclear Chemistry, Rome. Another new term suggested at the meeting was 'excitrate' (A. Guarino, Rome) to denote a clathrate with either the host or guest, or both, in an excited state.

The Hofmann inclusion compound, $Ni(NH_3)_2Ni(CN)_4 . 2C_6H_6$, has been known since 1897, but its properties have only been recently studied extensively. The most prominent worker in this field, T. Iwamoto (Tokyo), described his work on modifying these host lattices by replacing the ammonia by bidentate bridging ligands, and by replacing the square planar $Ni(CN)_4{}^{2-}$ group by tetrahedral $M(CN)_4{}^{2-}$ groups. These modified host lattices show interesting properties such as the ability of $CdenHg(CN)_4$ to stabilize the cyclohexadienyl free radical, produced by the γ-ray irradiation of the benzene guest molecule. This free radical is stabilized up to the thermal decomposition temperature of the host lattice, 423K. Vibrational spectroscopic studies of these systems were reported by J.E.D. Davies (Lancaster) and stability studies were reported by A. Sopková (Košice).

It is true to say that the majority of inclusion compounds known have been discovered by accident, but D.D. MacNicol (Glasgow) gave a fascinating talk outlining his strategy for the synthesis of a variety of compouds which should be expected to act as host lattices. Equally fascinating was the talk by J.L. Atwood (Alabama) describing his work on 'liquid clathrate' systems. These are non-stoichiometric compounds which form in the liquid phase on the interaction of aromatic molecules and $M[Al_2R_6X]$ moieties. The mole ratio of aromatic to anion can vary enormously, the present record being $[N(C_6H_{13})_4][Al_2Et_6I].39.6$ *o*-xylene. A few of these liquid-phase systems have yielded crystalline products, for example $Cs[Al_2Me_6N_3]$ .2*p*-xylene, in which the *p*-xylene molecules sandwich the caesium ion.

A recent interesting application of inclusion compounds is the realization that a chiral host lattice might show enantiomer selectivity, and G. Tsoucaris (Chatenay-Malabry) gave examples of the enantiomeric selectivity of the tri-*o*-thymotide host lattice. Another recent development is the application of solid-state NMR spectroscopy to the study of inclusion compounds. J.A. Ripmeester and D.W. Davidson (Ottawa) illustrated the use of ^{129}Xe NMR in the study of the Structure I xenon clathrate deuterohydrate, where it was possible to observe well separated resonances from the atoms in the two types of cavity.

In conclusion, this was a well timed symposium, as it is apparent that the field of inclusion chemistry has advanced considerably in the 33 years since H.M. Powell first characterized this type of compound, and it is equally apparent that further advances remain to be made. Some of the papers presented at this meeting will be published in a special issue of the *Journal of Molecular Structure*, and it is hoped to hold another symposium in Parma in about two years time. ☐

J.E.D. Davies is in the Department of Chemistry, University of Lancaster, UK.

Holographic bubble chambers

from David J. Miller

THE new particles have tantalisingly short lifetimes. Even the D^+, the longest-lived charmed particle, lasts for only about 10^{-12} seconds — time to travel 300 μm at the velocity of light, or a few millimetres with relativistic time dilation. But the D°, the Δ_{charm}, the F meson, the τ lepton and the 'beauty' mesons are predicted to travel only some tens of microns before decay. Nuclear emulsions have come back into popularity in the past five years because they gave the only chance of studying such short tracks, and now a new generation of tiny bubble chambers is developing which can resolve bubbles of less than 25 μm in diameter. Each technique has shortcomings — the emulsion requires many scanner-years of work to find the interesting events; a bubble chamber with conventional cameras has such a poor depth of field when the resolution drops below 25 μm that it becomes impossible to focus all of the beam particles into the sensitive volume.

At the Fermilab workshop* Le Coq (CERN) presented impressive pictures and videotapes that had been reconstructed from holograms made with a 6.5 cm diameter by 3.5 cm deep heavy liquid bubble chamber ('BIBC', the Berne Infinitessimal Bubble Chamber). The holographic technique gave clearly resolved images of bubbles only 8 μm in diameter over the whole depth of the chamber. This work has inspired a number of other developments. Pless (MIT) presented scaling rules for the change of resolution when Le Coq's 'straight-through' holographic layout is modified to medium-sized bubble chambers with $\sim$ 1 m diameter. His collaboration is now presenting a proposal to Fermilab for a study of the τ neutrino in such a chamber, using a neutrino beam from a beam dump. A proposal by a European collaboration for a small holographic hydrogen bubble chamber was discussed by Fisher (Rutherford). This would be a continuation of the work being done with conventional optics in proton and pion beams at CERN. He warned that, although the desired resolution can almost certainly be achieved over a useful volume, and although there are techniques available for detecting, measuring and identifying the secondary particles outside the chamber, one serious problem remains for the exploitation of holographic bubble chambers — a very similar problem to that faced by nuclear emulsions. The new particles are produced very rarely — in less than one event in a thousand. To make an emulsion, or a hologram, really useful, an electronic trigger must be devised which will identify the subsample of events which might contain the short-lived particle. The tracks from these events must then be extrapolated back into the emulsion or the chamber so that the scanner knows where to look. With a bubble chamber it should be possible, in principle, to pulse a laser and make the hologram only when a good event has been detected, but Fisher warned that no technique yet exists which can separate the rare particles cleanly from the background within the few microseconds that it takes for bubbles to grow to the desired size.

Some people think that an alternative approach might bring good results. Instead of looking for a 'needle in a haystack', using small chambers with fine resolution in proton, pion or photon beams, where the backgrounds are enormous, it is perhaps more sensible to work in a neutrino beam where charmed particles occur in 10 per cent of events. To have a reasonable number of neutrino interactions a large bubble chamber must be used, such as BEBC at CERN or the 15 foot chamber at Fermilab. At present these chambers grow their bubbles to around 600 μm in diameter in order to give a clear conventional image from more than 10 m^3 of sensitive volume. A few D^+ tracks have been resolved — the very furthest tail of the length distribution — but many more could be seen if 50 μm resolution were possible. Very little work has been done on the possibilities of using holography in the large bubble chambers but no one has demonstrated that it cannot be done. A number of methods were suggested: bright field 'Scotchlite' illumination, though work at Imperial College has shown that speckle may be a problem; dark field with Scotchlite, but can sufficiently powerful lasers be found; retrodirecting mirrors, if a suitable reference beam can be set up. Peterson (Hawaii) drew attention to the relevance of these ideas to proposals his collaboration is making for a new chamber at Fermilab. Its primary purpose is to allow secondary particles from neutrino interactions to leave the bubble chamber and be identified, but such a new device could also be designed to incorporate whatever is found to be the most favourable holographic layout.

We were reminded by Lederman, the Fermilab director, that finer resolution means smaller equipment which costs less to build. Fine electronic counters would enable experiments of all kinds to be scaled-down proportionally to the resolution, giving more than proportional reductions in magnet, material and building costs. Such counters were outside the scope of the workshop, but more than one group is convinced that the solution to the 'needle in a haystack' problem will depend on an emulsion or small holographic bubble chamber being followed by electronic counters with a resolution of 20 μm which will both improve the trigger and allow very precise predictions to be passed on to the scanners.

The workshop ended with a theorist's checklist of the effects that could be studied at high resolution. Bjorken (Fermilab) stressed that once the new particles can be collected in reasonable numbers they should show as complex and instructive a phenomenology as did the strange particles. □

D.J. Miller is a lecturer in the Department of Physics and Astronomy at University College London, at present on sabbatical leave in Fermilab.

*A workshop on holographic bubble and streamer chamber techniques was organized by L. Voyvodic at Fermilab, Batavia, Illinois on 11–12 November 1980.

100 years ago

Mr E. T. Sachs sends us some interesting notes from Batavia: — "Within the past month I have been so lucky as to make what I hope is a very interesting if not remarkable discovery. On the Island of Biliton, 200 miles from here, I found a fresh water fish which produces its young *living from its mouth.* I am quite prepared for the cry of incredulity that will be raised; but I conducted my observations with living fish and closed doors, and what I assert is undeniable: the eggs are hatched in the lower portion of the head of the fish, and are projected out at the mouth and from nowhere else. I have secured several specimens, which I shall send to Dr. Günther, who will of course at once set the matter at rest."

A "Natural" Experiment in Polarised Light

Break off a plate of ice and hold it between the sky and a pool of water. Its reflected image will show the beautiful colours due to polarised light. The incident rays should come from a part of the sky about 90° from the sun, and reflection should take place at the polarising angle for water, and the plate will probably require adjusting to bring out the maximum effect. Water, vaporous, solid, and liquid, thus furnishes us with polariser, crystal, and analyser. I do not remember to have read any account of this very simple experiment, for which Nature provides all the materials.

Chas. T. Whitmell

Contaminated cell lines

from David Dickson, Washington

YET another corruption of the scientific literature has been uncovered with the discovery that several cell lines widely quoted in the scientific literature as originating from patients with Hodgkin's disease have now been shown not to be human cells at all, but to come from a strain of owl monkey (see the accompanying article, pages 228–230).

The cells were grown in culture by Dr John C. Long, who resigned a year ago as assistant pathologist at the Massachusetts General Hospital and associate professor of pathology at Harvard Medical School, after admitting to having faked data in a research paper published in the *Journal of the National Cancer Institute* in 1979.

On resigning Dr Long admitted having misled colleagues about carrying out experiments to produce revised data on the molecular weights of immune complexes. The alterations were included in the paper after it had been rejected by the referees of another journal.

Dr Long said on the telephone last week that during his time at the Massachusetts General Hospital, he had no reason to suspect that his cell lines were contaminated and welcomed the work of Harris *et al.* However, when he resigned, he did not reveal that six months earlier he had received data from the National Cancer Institute (NCI) casting doubt on the identity of the cells.

The first successful long-term cultivation of cells from patients with Hodgkin's disease was claimed by Dr Long and colleagues from the hospital and the medical school in *Proceedings of the National Academy of Sciences (PNAS)* in 1973. Other groups have encountered considerable difficulty in establishing permanent lines from diseased spleen cells.

The procedures used to grow the original cells through over 200 passages were described in a 1977 paper in *Journal of Experimental Medicine* as well as *PNAS*. (*Science Citation Index* lists 30 citations of this paper in 1979 and 1980, which its compilers say means the paper is "highly cited".) In total four papers have appeared in *PNAS* — three naming Dr Long as the first author. Experiments using these cells have also been described in other publications (see page 228).

All the papers referring directly to the now-challenged cell cultures will have to be reassessed to see if any data of scientific value can be salvaged, since there is now evidence that the cell lines were contaminated from an early stage.

Dr Long was awarded a three-year grant for more than $200,000 in 1976 to continue his study of the Hodgkin's disease tissue cultures. This was renewed in 1979 — based on an application said to include the data which he later admitted forging — and he received $96,000 in that year, as the first part of a three-year grant of almost $500,000.

This grant was terminated by the NCI at the request of the hospital, after Dr Long admitted falsifying data in the 1979 paper in *Journal of the National Cancer Institute*. According to the hospital, Dr Long claimed at the time that "competition for federal research grants" was a major factor in causing him to lie about experiments he had not carried out.

However, he did not admit to any other impropriety and the hospital put out a statement saying that the data he had admitted falsifying was "obscure, and of no known significance. . . no known harm has resulted even in the field of science".

The hospital also said that further suspicions about his research were being followed up. There was already evidence of contamination of the cell lines — early in 1979 one of Dr Long's research associates had grown suspicious about the true nature of the cells, and sent samples to Dr Stephen O'Brien at the NCI Laboratory of Viral Carcinogenesis for genotypic evaluation.

The NCI scientists told Dr Long that three of the cell lines carried the enzymatic signature of the same individual. And they also pointed out an unusual characteristic they could not explain — a peculiarly fast mobility in a key enzyme system.

Dr Long did not follow up this comment with the NCI. And he told his research workers that the NCI check had shown that the cells were genuine — indeed that in one case the signature of the cultured cells corresponded directly with that of the red blood cells of the patient from whom the cells were said to have been taken (another claim subsequently shown to be false).

Nothing further happened at the time. But after Dr Long's resignation, Dr Robert T. McCluskey, head of the hospital's pathology department, considered further investigations necessary. Karyotypes and cell samples were sent to the cell culture laboratory at the University of California's School of Public Health, where chromosomal analysis revealed that the cells were not human. Several other laboratories were subsequently sent samples to complete the identification. And the karyotype was recognized as that of the owl monkey by Dr Bharati Hukku of the Child Research Center of Michigan, Detroit.

The cells were then confirmed by the New England Regional Primate Center as coming from a Northern Columbian brown foot owl monkey. Indirect evidence that this was the likely source of contamination was the fact that this cell line had been used for virus research in the early 1970s in the laboratory in which Dr Long was then working.

The fourth suspected cell line, started later than the other three, has turned out to be human. But there is no evidence of a link with Hodgkin's disease tumours.

The full impact of Dr Long's publications remains unclear. His results have been quoted as supporting a particular view of the pathogenesis of Hodgkin's disease which may now be questioned, in particular suggesting a macrophage origin of the peculiarly large Reed–Sternberg cells found in Hodgkin's patients.

Other research workers have been careful not to put too much weight on Dr Long's results, remaining sceptical in the light of their own failure to culture the same cells. And Dr Henry Kaplan of Stanford University feels that the main impact may have been to reduce the incentive for others to tackle the problem of growing the cells *in vitro*, since Dr Long had already claimed success.

Investigators for the Department of Health and Human Services in Boston must now decide whether there is any evidence that should be passed to the Department of Justice to charge Dr Long with fraud against the federal government. Under the US Code, consciously providing false information when applying for federal assistance is a criminal offence.

The journals which published Dr Long's papers now have to decide what action to take. A representative of the National Academy of Sciences has said that the situation was "unique" for *PNAS*, which has never previously had to disown any paper it has published.

Papers submitted to *PNAS* are not formally reviewed if a member of the academy is a co-author. In Dr Long's case, each of the four papers that he published was written with academy member Dr Paul Zamecnik, who recently retired as professor of oncological medicine and director of the J.C. Warren Laboratories at Harvard Medical School, where Dr Long was a research student.

The National Institutes of Health are already discussing how to tighten up on evaluating the scientific content of research funded by federal grants. An audit of Dr Long's grant revealed no fiscal irregularities in the way that the money had been used, but did not go into the legitimacy of the research.

Ironically, the recently created President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research is now considering another Boston case, in which a research worker at the Boston University Medical School was shown to have faked data in a cancer survey.

Research administrators admit that cases of fraud — usually relatively minor — are not unusual, although few reach the public eye. "Whatever you see is probably only a small fraction of what actually goes on," according to Dr Donald Kennedy, president of Stanford University.

Contamination of Hodgkin's disease cell cultures

Nancy L. Harris*, David L. Gang*, Steven C. Quay*, Sibrand Poppema*, Paul C. Zamecnik†, Walter A. Nelson-Rees‡ & Stephen J. O'Brien§

* Department of Pathology, Harvard Medical School, Immunopathology Unit, Massachusetts General Hospital, Boston, Massachusetts 02114
† Worcester Foundation for Experimental Biology, Shrewsbury, Massachusetts 01545
‡ Cell Culture Laboratory, University of California School of Public Health, Naval Biosciences Laboratory, Oakland, California 94625
§ Laboratory of Viral Carcinogenesis, National Cancer Institute, Bethesda, Maryland 20014

Several laboratories have recently reported the establishment and characterization of long-term cell lines thought to be related to the neoplastic cell of Hodgkin's disease. Here, Harris et al. discuss evidence that some of these lines are, in fact, not related to Hodgkin's disease but are non-human contaminants.

IN an effort to determine the origin of the malignant cell of Hodgkin's disease, many investigators have attempted to establish permanent cell lines from tissues involved with the disease. Early attempts to culture tissues involved with Hodgkin's disease yielded either mixed cultures which could not be maintained *in vitro*, or Epstein-Barr virus-infected lymphoblastoid cell lines (see ref. 1 for a review). Recently, several laboratories have reported the establishment and characterization of long-term cell lines thought to be related to the neoplastic cell of Hodgkin's disease[2–7]. Our studies indicate that several of these cell lines are not related to Hodgkin's disease, but are non-human contaminants.

Long *et al.* reported the establishment of four permanent monolayer cell lines, designated FQ, RB, SpR, and RY, from tumour nodules in spleens of patients with Hodgkin's disease[7]. These four cell lines were considered to be neoplastic by virtue of their capacity for indefinite replication *in vitro*, aneuploidy and the production of invasive tumours on subcutaneous injection into nude mice[8]. Although the cells had no surface markers demonstrable by standard immunological techniques, several features, namely the production of lysozyme and esterases, the ability to phagocytose iron particles[9] and the ultrastructural morphology of the cells in culture[10], were felt to be consistent with a macrophage origin of the cultured cells. The establishment of these permanent cell lines, which seemed to be neoplastic and had features of macrophages, supported the

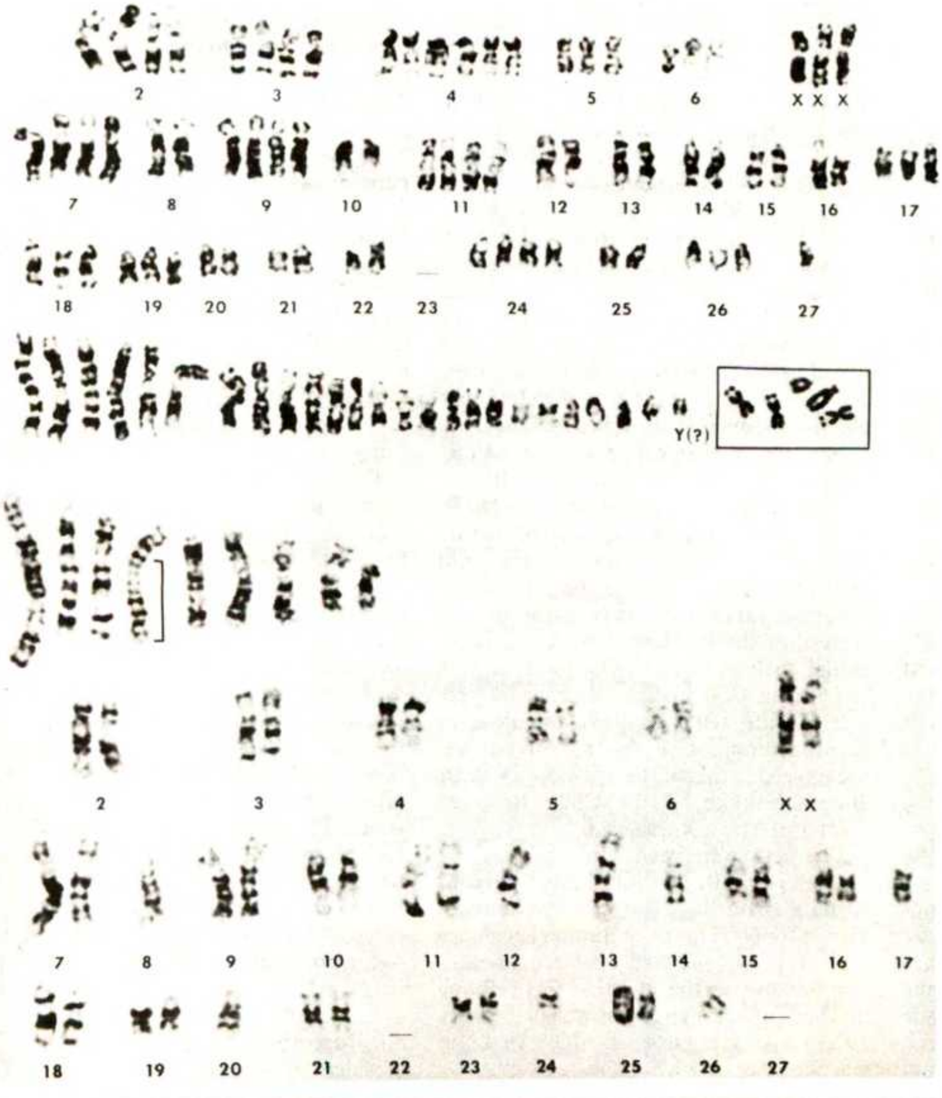

Fig. 1 Three marker chromosomes, conventional staining (insert). Trypsin-Giemsa banded metaphase chromosomes of an FQ (top four rows) and an OMK-210 cell (bottom four). The FQ culture exhibited polysomy for many chromosomes including, in some instances, duplicate marker chromosomes. OMK-210 cells (kindly provided by Dr M. Daniel) were near-diploid. Identical marker chromosomes in both cells are indicated by arrows. Most noticeable are isochromosomes for 13q. A small, altered chromosome which resembles the Y chromosome was noted among the markers in the FQ cells [designated Y(?)]. As the karyotype of OMK-210 is female, and the presence of multiple identical markers in the two cell lines indicates a common origin, it is unlikely that the small FQ chromosome is a true Y chromosome. The FQ karyotype was kindly constructed by Dr N. S. F. Ma; its pattern was followed for the OMK-210 cell.

0028-0836/81/040228—03$01.00

concept that the malignant-appearing cells observed by pathologists in Hodgkin's disease tumours are neoplastic macrophages[1,9,10].

Further studies of these cell lines appeared to offer a new insight into the pathogenesis of Hodgkin's disease. It was reported that two of these cell lines (FQ and RB) specifically bound immune complexes from the sera of patients with Hodgkin's disease[11,12]. As the cells lacked receptors for immunoglobulins and complement and did not bind immune complexes from sera of patients with other disorders, it was concluded that the antibody portion of the immune complex was reacting with an antigen on the cultured cells. This observation not only provided the first direct evidence that the cells cultured *in vitro* were related to the human disorder, but also suggested that some patients with Hodgkin's disease were reacting immunologically to a tumour-associated antigen.

A recurring problem associated with the use of long-term, established cell lines in the study of human tumours is the risk of contamination and overgrowth of cultures by unrelated cell lines[13]. Previous publications have shown that the techniques of trypsin-Giemsa-banded karyotyping[14] and isoenzyme (allozyme) analysis[15,16] can detect both intra- and interspecies contamination of cell lines. In addition to these methods of genetic characterization of cell lines, the technique of subcutaneous transplantation into nude (athymic) mice can also be used to investigate the origin of a cell line. When noncultured tumour cells or established cell lines are injected into nude mice, the tumours which form may be more differentiated than either the original tumour or the *in vitro* cultured cells, thus permitting determination of the histogenesis of an apparently undifferentiated cell[17].

Using these three techniques, we have found that three of the four cell lines (FQ, RB and SpR) reported by Long *et al.*[7] are identical to each other and are of owl monkey rather than human origin. Furthermore, they have morphological features of epithelial cells rather than macrophages. The fourth cell line (RY) is of human origin, but its relationship to Hodgkin's disease has not been established.

Cultures of FQ, RB, SpR and RY cells maintained by Dr J. Long, (Immunopathology Laboratory, Massachusetts General Hospital) were studied, as were the earliest available cultures from the laboratory of Dr P. Zamecnik (spanning passages 14-500 of FQ, 300-380 of RB, 21-220 of SPR, and 5-130 of RY). In FQ, RB and SpR cells the chromosome numbers ranged from 75 to 100, with a modal number between 83 and 100 chromosomes. Conventional chromosome preparations of FQ, RB and SpR metaphases revealed three to four copies of a medium-size submetacentric chromosome with a pronounced near-terminal secondary constriction; a chromosome peculiar to normal owl monkey cells (Fig. 1, insert). Trypsin-Giemsa-banded karyotopes of FQ, RB, and SpR exhibited non-human chromosomes, singly or in multiples, and were recognized as polyploid derivatives of cells of the owl monkey, *Aotus trivirgatus* ($2n = 54$)[18,19]. Cells at both early and late passages in culture contained many normal chromosomes of the owl monkey karyotype, as well as highly altered, marker chromosomes. Most notable among the latter were one or two isochromosomes involving the long arm of chromosome number 13 (Fig. 1). A search for an owl monkey cell line that was well adapted to *in vitro* culture led to the study of OMK-210 cells, an established cell line derived from owl monkey kidney[20]. Comparison of FQ, RB and SpR with OMK-210 cells showed that identical marker chromosomes, as well as normal chromosomes, existed in all lines.

Despite the presence of identical marker chromosomes, further chromosomal alterations had clearly taken place following the separation of FQ, RB and SpR from OMK-210 cells, leading to differences in their individual karyotypes. For example, although OMK-210 contained near-diploid numbers of chromosomes, the FQ, RB and SpR cells were all near-tetraploid. Such chromosomal alterations are common occurrences in cultured cell lines[21].

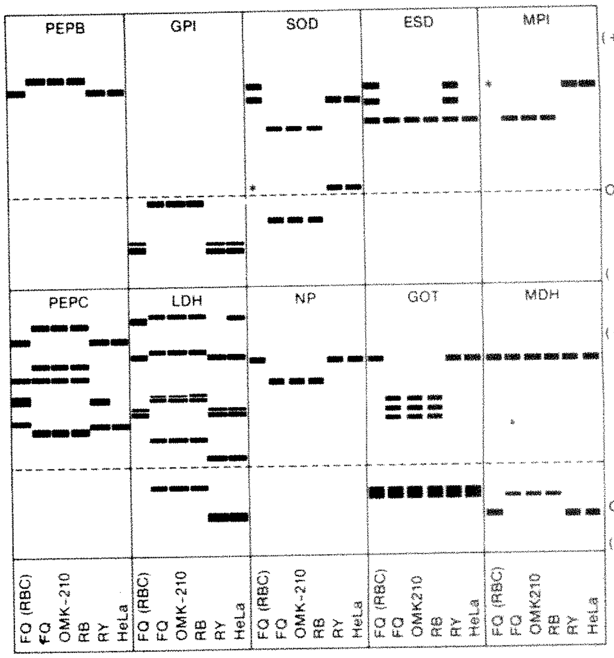

Fig. 2 Composite electropherograms of 10 gene–enzyme systems diagnostic for interspecies cell identification (refs 15, 16). The columns represent: 1, FQ patient's red blood cells; 2, FQ cell line; 3, OMK-210 cells; 4, RB cells; 5, RY cells; 6, HeLa cells. The 10 diagnostic enzymes were: PEPB, peptidase-B (EC 3.4.11.); GPI, glucose phosphate isomerase (EC 5.3.1.9); SOD, superoxide dismutase (EC 1.15.1.1); ESD, esterase-D (EC 3.1.1.1); MPI, mannose phosphate isomerase (EC 5.3.1.8); PEPC, peptidase-C (EC 3.4.11); LDH, lactate dehydrogenase (EC 1.1.1.27); NP, purine nucleoside phosphorylase (EC 2.4.2.1); GOT, glutamate oxaloacetate transaminase (EC 2.6.1.1); and MDH, malate dehydrogenase (EC 1.1.1.37). * Indicates that no activity was observed in that extract for the enzyme. All the systems except ESD vary between man (HeLa) and owl monkey (OMK-210). In man ESD is polymorphic for two alleles *ESD*-1 and *ESD*-2. The RY line is heterozygous for *ESD*-1-2. The FQ red cell extract shows that the FQ patient is heterozygous for *ESD*-1-2 while the FQ cell has an ESD with a mobility of *ESD*-1, which is identical to that of OMK-210. The OMK-210 isozymes were each identical to those observed in extracts of OMT-1, an owl monkey lymphoid cell line derived by Drs Louis Qualtiere and Gary Pearson (data not shown).

The identity of the FQ, RB and SpR cell lines with OMK-210 cells was further established by determining the electrophoretic mobilities of a panel of 10 isoenzymes selected to detect interspecies contamination (Fig. 2). The FQ, RB and SpR cell lines, at the passages examined, were identical to each other and to OMK-210 cells at each locus, and distinct from the human cell line, HeLa, and the red blood cells of the patient from whose spleen the FQ cell line purportedly arose.

Together, the chromosome and isoenzyme analyses indicated that the three supposed Hodgkin's disease cell lines had been cross-contaminated by OMK-210 cells. OMK-210 cells had, in fact, been carried in the laboratory of Drs Long and Zamecnik at the time when the FQ, RB and SpR cell lines were initiated. In the original description of the cell lines, it was reported that the Hodgkin's disease monolayer cultures underwent a morphological alteration *in vitro* after 3–10 months' propagation in culture, with the appearance of polygonal cells that replicate in a mosaic pattern[8]. This appearance of cells with different morphology from that first noted in the primary cultures or early passages is a characteristic occurrence in the course of contamination of cell lines[14].

Subcutaneous tumours formed by the FQ, RB and SpR cells in nude mice contained acinar structures with microvilli and intercellular junctions (Fig. 3*a*). These features indicated that the cultured cells were epithelial, and not of monocyte-macrophage or lymphoid origin[22]. The ultrastructural features of the nude mouse tumours contrasted with those of the cells when examined in monolayer culture[10], and indicated that additional differentiation had occurred in the nude mouse. Surface microvilli were present on the monolayer cells, but acinus formation and intercellular junctions were not seen *in vitro*[10]. Although a previous report on the transplantation of the FQ, RB and SpR

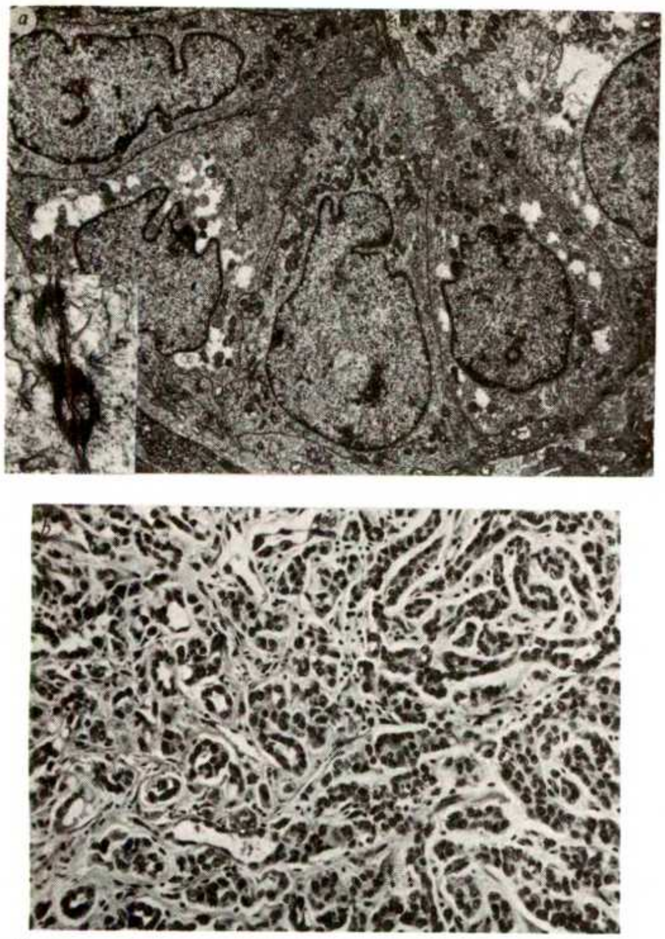

Fig. 3 *a*, Electron micrograph of tumour formed 3 weeks after subcutaneous injection of 5×10^6 FQ cells into a 6-week-old nude mouse (CRL:*nu*/*nu* (CD-1) BR, Charles River), fixed in Karnovsky-II and stained by the OCUB method[9]. ×2,750. Insert: intercellular junctions. ×27,500. *b*, Paraffin-embedded section of subcutaneous tumour formed in nude mouse by FQ cells (from J. C. Long, as described in ref. 7) showing gland and tubule formation (haematoxylin-eosin, ×185).

cell lines into nude mice stated that the morphology was that of 'reticulum cell sarcoma'[8], review of the original slides from that study revealed that tubular and acinar structures indicative of epithelial differentiation were present in the tumours formed by these three cell lines (Fig. 3*b*). This observation indicates that contamination of these cell lines had already occurred by then.

The origin of the fourth cell line, RY, could not be established with certainty. The cells had approximately 60 chromosomes. Conventional chromosome preparations did not contain the characteristic owl monkey chromosome with the near-terminal secondary constriction which was seen in the other three cell lines. Trypsin-Giemsa banding revealed an abnormal human karyotype, which was distinct from HeLa or any other established cell line known to us. The isoenzyme genetic signature likewise indicated that the cell line was human (Fig. 2); analysis of a different panel of isoenzymes, selected for their polymorphism within human populations[15,16], confirmed that RY differed from HeLa or any other known cell line (not shown). Tumours formed in the nude mouse by the RY cells, in contrast to the other cell lines, did not have epithelial features; the histogenesis of this cell line could not be determined from the morphology of the nude mouse tumours. As previously described[7], the RY cell line did not have surface receptors characteristic of macrophages. We were unable to confirm the initial report of lysozyme production by this cell line (S. Quay and S. Poppema, unpublished data). A review of the donor patient's hospital record revealed that the spleen from which the RY cell line originated contained no grossly or microscopically identifiable tumour. As this cell line fails to meet a basic criterion for a tumour cell line—namely, that it be cultured from a specimen known to contain tumour cells[23]—its relationship to the malignant cell of Hodgkin's disease remains in doubt.

Although a few other laboratories have reported the establishment of permanent cell lines from patients with Hodgkin's disease, no conclusions regarding the nature of the malignant cell have been drawn from them[2-4]. Although there are indications from other sources that the malignant cell of Hodgkin's disease is of macrophage origin, the evidence is not conclusive (for a review, see ref. 24). As the only permanently established Hodgkin's disease cell lines with macrophage characteristics, the cell lines reported by Long *et al.* were thought to provide substantial evidence for the macrophage origin of the Reed–Sternberg cell. Our findings, therefore, remove some of the support for the theory that the malignant cell of Hodgkin's disease is a macrophage. Furthermore, results obtained with these cell lines cast doubt on the specificity of the properties which were considered to indicate that these cultured cells were macrophages. Recently, the RY cell line was found to produce endogenous pyrogen, an observation which it was thought might explain the tendency of some patients with Hodgkin's disease to develop fever[25]. The significance of this observation must be re-evaluated in the light of our findings.

Our results also indicate that the establishment of permanent cell lines from tissues involved with Hodgkin's disease may be more difficult than had been previously suggested[6-9]. Several major laboratories have experienced repeated failure in their attempts to establish permanent cell lines from tissues involved with Hodgkin's disease[24,26,27]. The inability of these other workers to establish permanent lines *in vitro*, despite numerous attempts, may mean that appropriate methods for culture of these cells have not yet been found. On the other hand, it is possible that their very resistance to *in vitro* propagation has some biological significance which has not yet been recognized.

We specially thank Dr Bharati Hukku of the Child Research Center of Michigan, Detroit, who first noted the similarity between certain chromosomes in FQ and *Aotus trivirgatus*. Dr Ward D. Peterson Jr provided additional immunological and serological proof of contamination. Messrs R. R. Flandermeyer and D. W. Daniels and Dr L. Atkins assisted with karyology as did Dr N. S. F. Ma, whose classification of *Aotus* karyotypes was followed. We also thank Drs Robert T. McCluskey, Sigmund A. Weitzman, C. Alan Brown and Clive L. Hall for their support.

Multiple asperity model for earthquake prediction

M. Wyss*, A. C. Johnston† & F. W. Klein‡

* Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, Colorado 80309

‡ Hawaiian Volcano Observatory, US Geological Survey, Hawaii 96718

Large earthquakes often occur as multiple ruptures reflecting strong variations of stress level along faults. Dense instrument networks with which the volcano Kilauea is monitored provided detailed data on changes of seismic velocity, strain accumulation and earthquake occurrence rate before the 1975 Hawaii 7.2-mag earthquake. During the ~4 yr of preparation time the mainshock source volume had separated into crustal volumes of high stress levels embedded in a larger low-stress volume, showing respectively high- and low-stress precursory anomalies.

OBSERVATIONS of seismic velocity anomalies by Russian seismologists[1,2] and the development of the dilatancy–diffusion model of earthquake precursors[3,4], have encouraged research into earthquake prediction. The simplicity of the microcrack–pore fluid mechanism[5], its foundation in repeatable observations from laboratory rock mechanics and the absence of contradictory evidence led many seismologists to anticipate in vain that definite prediction of earthquakes would soon be possible. For many medium-size earthquakes ($5<M<6$), mostly strike-slip events along the San Andreas fault, the expected precursors could not be detected[7–9]. These negative findings bring into question the universal applicability of dilatancy to the Earth's crust.

A new model of the preparatory process leading to earthquake ruptures is needed. However, field data for such a model cannot be gathered rapidly and in abundance because we do not know where and when large earthquakes will occur. Without an earthquake prediction capability we may have to wait several decades for large shocks to occur in a location where we can measure in detail the phenomena associated with their preparation process.

The Hawaii earthquake of 1975 occurred within a dense network of geophysical observations. Geodetic and seismological measurements had been carried on systematically for many years to monitor the volcano Kilauea. These data indicate that earthquake precursory changes do occur, but that they show contrasting behaviour in different parts of the earthquake source volume. We interpret this as meaning that the stress level throughout the source volume varies strongly—in small sub-volumes dilatancy-related precursory changes may occur, while strain-softening phenomena (due to stress unloading by creep) occur in other parts of the source volume.

The Hawaii (Kalapana) earthquake

The Hawaii earthquake of 29 November 1975 of 7.2 mag. occurred in the south-east coast of the island of Hawaii on Kilauea's south flank. The rupture occurred along a near-horizontal plane in the Earth's crust at a depth of 8 ± 1 km. Its length was 40–50 km and its width 10–20 km (Fig. 1). Along the south coast subsidence of up to 3.5 m occurred and tsunami heights reached 14.6 m (ref. 6). Damage from the earthquake and related catastrophic events was estimated at $4.1 million, and two people were killed.

The source of stress in Kilauea's south flank is the intrusion of magma into the volcano and its rifts[10,11]. The last earthquake of similar size to the 1975 rupture seems to have occurred in 1868. Since then repeated episodic intrusions of magma along the rifts (dotted in Fig. 1) have provided the 'pushing hand' compressing the south flank. The Hawaii earthquake was a rupture of the crust under stress, not a volcanic quake caused directly by an intrusion. While the stress loading process was different we believe that the rupture process was the same as that in other tectonic earthquakes.

Seismic waves emanating from this rupture were recorded by instruments on Hawaii which are designed to produce on-scale records for the strong ground motions of large, local earthquakes. The seismic energy was radiated in a sequence of high-amplitude pulses separated by comparatively long periods of low-amplitude radiation (Fig. 2). Such records are often observed for large earthquakes and are thought to represent multiple rupture sources[12–14]. As the rupture propagates along a heterogeneous faulting surface, or through a heterogeneous crust, it encounters high- and low-stress volumes. The rupture may speed up and slow down, or stop temporarily, with little radiation emitted from low-stress portions of the fault and large pulses emitted from zones of high stress. The latter may form around asperities on the fault surface, a term which we will use loosely as meaning a strong segment of the fault along which stresses will accumulate.

We conclude that the Hawaii earthquake source volume contained high- and low-stress sub-volumes, based on the strong

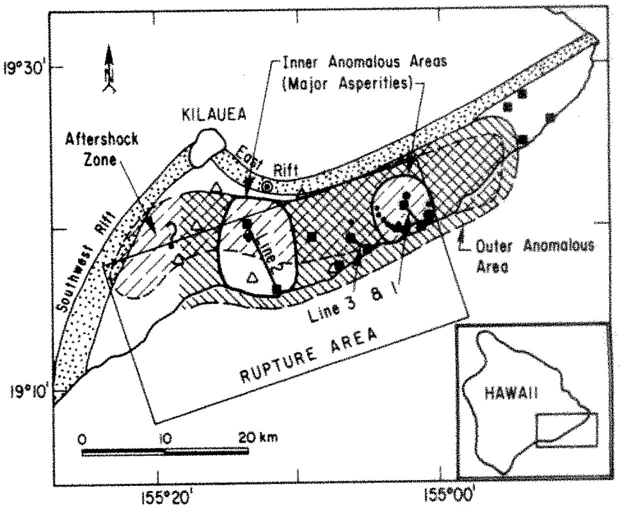

Fig. 1 Map of the south flank of Kilauea volcano showing major geological features, the aftershock zone of the Kalapana earthquake (dashed diagonal hatching), the outer precursor volume (solid hatching), the areas designated as 'major asperities', and the rupture area inferred from surface wave and tsunami data. △, Seismograph stations where constant seismic velocities were observed; ▲, the station showing the velocity anomaly; ■, geodetic line benchmarks; ⊙, the site of the 1972 Mauna Ulu eruption. ●, Immediate foreshocks; the 5.9-mag foreshock is the larger circle and the 7.2-mag main shock is the largest circle. Some seismic and geodetic stations are omitted for clarity.

0028–0836/81/040231—04$01.00

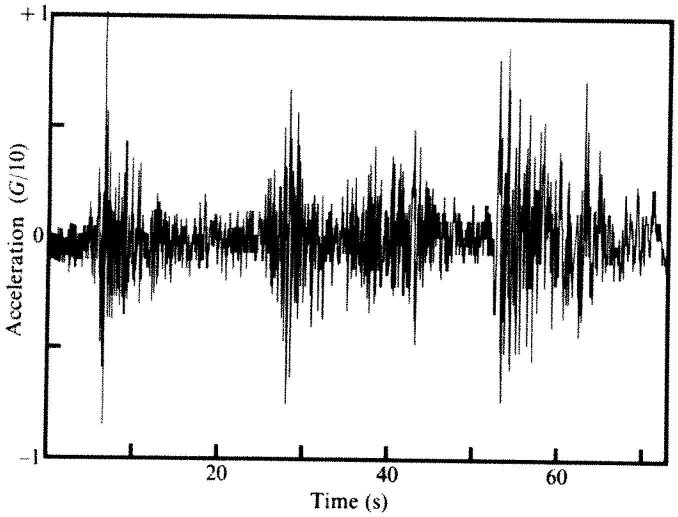

Fig. 2 Strong-motion seismogram of the Hawaii main shock of 29 November 1975, recorded at Hilo. Note that the main rupture seems to be made up of several events emanating energy pulses roughly comparable in amplitude and duration with that of the foreshock[22].

motion records (Fig. 2). It is therefore not surprising that in different regions of the source area we found contrasting precursory changes which we interpret as reflecting high- and low-stress regimes respectively.

Precursors to the Hawaii earthquake

The first documented precursor to the Hawaii earthquake was a delay of teleseismic P-wave travel times by 0.2 s lasting from 3.8 yr to several months before the main shock[15] (curve *b* of Fig. 6). According to Student's *t*-test this anomaly is significant at the 99.9% confidence level. Only the station nearest to the epicentre (▲ Fig. 1) exhibited delayed arrivals; six other stations (△, Fig. 1) within 3 km of the rupture area showed no significant change. Nearly horizontal rays from local earthquake sources also showed constant travel times at all stations, indicating that the anomalous volume did not extend to the surface[16].

These observations indicate that the Hawaii earthquake was preceded by a velocity decrease in a volume of ~10-km horizontal extent centred on the hypocentre, while the rest of the source volume remained nondilatant.

The rate of earthquake occurrence may contain information on the state of stress of a crustal volume. If the seismicity rate changes significantly as a function of time, the stress or the strength of the rock in the volume must have changed. Since 1968 all shocks with magnitude 2.0 or more are located routinely. During the 8 yr before the main shock ~1,600 such earthquakes occurred within the main rupture volume. This abundance enabled us to examine separately the rate in sub-volumes of roughly 10-km dimensions. Two types of seismicity behaviour were found. In some volumes the seismicity rate remained approximately constant. An example of this consistency is the seismicity rate of the foreshock volume (eastern major asperity in Fig. 1) as shown in curve 2 in Fig. 3. In other sub-volumes the seismicity rate dropped dramatically around the year 1971 ± 1 (see curve 1 in Fig. 3).

The combined seismicity of the volumes with approximately constant rate (inner anomalous areas of Fig. 1) contrasts sharply with that in the outer anomalous region (Fig. 4) where the rate dropped in early 1972 by ~50% from 120 events yr^{-1} to 55 events yr^{-1}.

The normal rate in the outer anomalous region is defined by data for the period 1968–71. A longer observation period can be opened if we raise the minimum magnitude in the data set. The seismicity rate in the outer anomalous region for magnitudes 2.4 or more is shown in Fig. 3 (curve 3) for the period 1962–75. Again we see that a highly significant decrease by about 50% occurred. The time of the change in this data set seems to be late 1970. We conclude that a 50% seismicity rate reduction occurred in the outer anomalous volume in 1971 ± 1 yr and lasted up to the time of the main shock.

Summarizing the geodetic data from 1914 to 1971, Swanson *et al.*[11] showed that the south flank was displaced several metres to the south-east with respect to observation points to the north and west of Kilauea's rifts. They also noted that the south flank accumulated compressive strain in the NW-SE direction in steps which coincided with volcanic eruptions and intrusions (Fig. 5). They concluded that shallow (depth <5 km), forceful magma intrusions under Kilauea and its rifts provided the 'pushing hand' which strained and dislocated the south flank away from Kilauea and the rest of the island. Based on these geodetic data, Swanson *et al.*[11] wrote that a large earthquake might be expected on the south flank.

All geodetic observation lines on the south flank showed compression up to 1970. In late 1971 and late 1974 respectively some lines reversed their behaviour, showing extension, that is they indicated strain was released[17]. The data for the past eight years are shown in more detail in Fig. 6*a*. Open circles indicate the average strain registered by lines 1 and 3 (defined in Fig. 1); solid squares show the strain measured on line 2. The strain data interpretation after 1972 is debatable because of the absence of measurements until late 1974. During this period a major phase of the east rift Mauna Ulu eruption commenced (large arrow in Fig. 6; ⦿ in Fig. 1). If the associated intrusive activity of this extrusive event compressed the south flank as observed for previous eruptions[11], it could account for the approximate 30-bar increase of line 2 observed in late 1974. Because no data are available for 1972–74, we show in Fig. 6 the uncertainty of the strain (stress) behaviour of this period with both a solid (preferred) and dotted line, depicting two alternative strain histories.

After the late-1974 survey, only line 2 in the western inner region was resurveyed before the 1975 main shock. It revealed a massive, pre-main shock strain relaxation, corresponding to a stress drop of ~30 bar. The earthquakes which occurred during this time could not account for this stress release because they were far too small. We conclude that the strain was released aseismically by some kind of creep process, perhaps along the future fault plane, and at a rate $>10^{-12}\ \mathrm{s}^{-1}$. Significantly, line 2, which accumulated stress up to the end of 1974, was located on a volume of constant seismicity rate, supporting the idea that high seismicity indicates high stress accumulation.

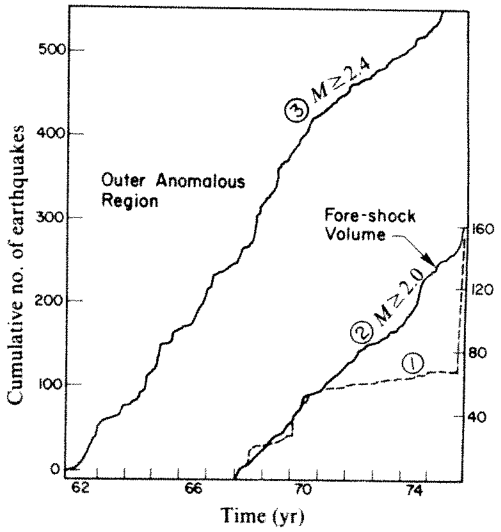

Fig. 3 Cumulative number of earthquakes as a function of time for three subregions of Kilauea's south flank. The slope of the curves equals the seismicity rate. The lower two curves (scale to the right) starting in 1968 are based on earthquakes with magnitudes >1.9. Curve 1 represents the south flank volume east of longitude 154.9° E, curve 2 the foreshock volume. For a better definition of the normal seismicity rate, the magnitude >2.3 seismicity from 1962–75 is shown as curve 3 (scale to the left) for the entire, outer anomalous region as defined in Fig. 1.

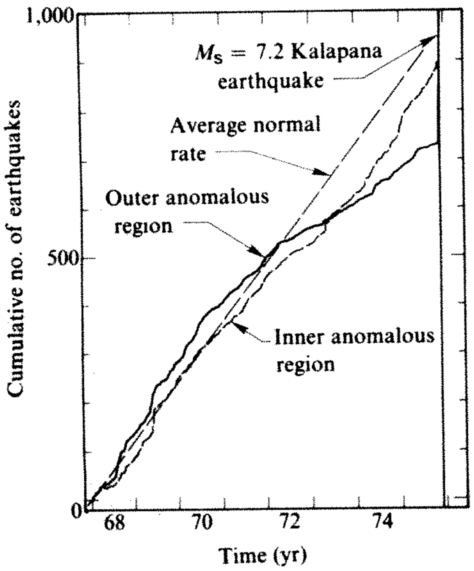

Fig. 4 Cumulative number of earthquakes ($M \geq 2.0$) in the south flank of Kilauea volcano, Hawaii, as a function of time. The solid curve, representing seismicity in the outer precursor volume (see Fig. 1), shows a sharp (≈50%) decrease in 1972. The dashed curve indicates roughly constant seismicity rate in the inner precursor volumes.

The strain release along line 1 (1971) and line 2 (1974) is interpreted to indicate that the respective southeastern end points of these lines were then located above the outer anomalous volume. Therefore the outer anomalous volume was apparently expanding at the expense of the inner anomalous volume.

The asperity model

The model for the preparatory process for the Kalapana earthquake must be complex, because different precursory patterns existed in subregions of the future rupture area. The characteristics of the outer anomalous zone are: decreased seismicity rate, strain relaxation and the absence of a travel time anomaly. One or both of the eastern (E) or western (W) inner anomalous zones, exhibited: constant seismicity rate until shortly before the main shock when the rate increased (E and W), a significant P-wave velocity decrease (E), the largest surface displacements during the main shock[6] (W) and an increase of compressive stress at least up to the fall of 1974 (W).

The decrease of seismicity in the outer volume seems to be directly related to the stress decrease observed there geodetically. Because the microearthquake activity in this region could not have accumulated the 10-bar stress drop throughout the outer anomalous volume, we hypothesize that a seismic fault creep along the nearly horizontal fault plane at 9-km depth caused the strain relaxation and the relative seismic quiescence. The stress decrease also explains the absence of travel time anomalies in the outer volume. The two inner anomalous volumes both have a constant and high seismicity rate. As this contrasts with the observations in the strain-softening outer anomalous volume, we suggest that the high seismicity rate indicates high stress in the inner anomalous zones. This interpretation is supported by different observations in the eastern and western volumes. In the eastern volume, near the point of initial rupture, the travel time anomaly indicates the presence of dilatancy, which requires high, deviatoric stresses. In the western volume, the stress increase of 30 bar between 1971 and 1974 shows that elevated stresses were present at that time. Thus, our observations indicate that two areas of high stress accumulation exist surrounded by a larger area where aseismic slip is occurring on the future rupture plane. By analogy with rock mechanics studies, we term these small volumes of high-stress concentrations 'major asperities'.

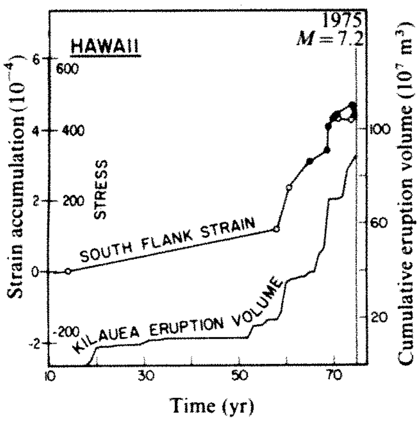

Fig. 5 Strain accumulation on Kilauea's south flank from 1914 to 1975 (upper curve). ○, Averages from the geodetic line 1 and 2 (Fig. 1); ●, strain along line 2. The cumulative eruption volume is shown for comparison. The strain direction is approximately southeast and the loading cycle is assumed to have started in 1868 after the last large earthquake on the south flank.

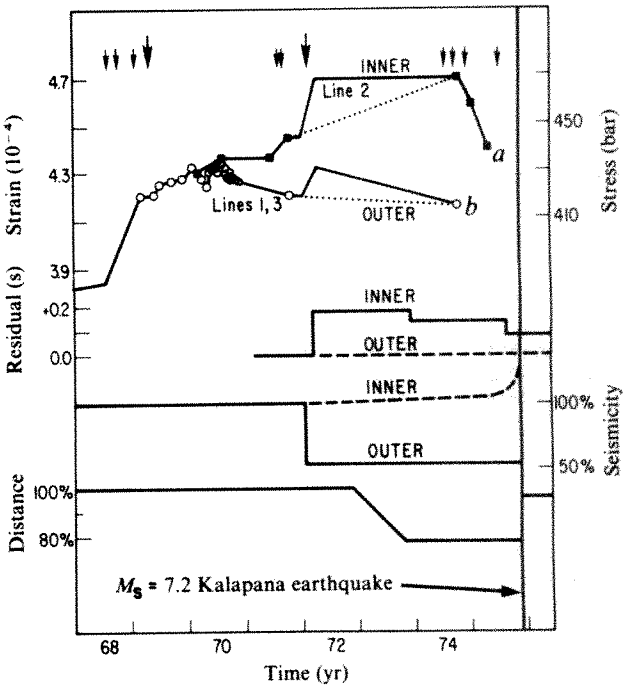

Fig. 6 Schematic summary of crustal parameters during the 8 yr before the Kalapana earthquake. Arrows at the top indicate times and relative size of volcanic intrusive episodes. The top curve shows geodetically measured horizontal strain increase in the western major asperity volume (■) and strain relaxation in the outer precursor volume (○). The dotted lines represent a possible alternate strain history between 1972 and 1975 when no measurements were made. The second curve shows the seismic-wave travel-time anomaly observed in the eastern asperity and the absence of such an anomaly in the outer precursor volume. The third curve shows the seismicity rates in the inner and outer precursor volumes (from Fig. 3). The final graph illustrates that the (normalized) average distance of earthquakes from the location of the large foreshock decreased beginning in 1972, which is an alternate way of quantitatively measuring the contrast between seismic activity in the inner and outer anomalous areas. Note that the anomaly onsets of the independent parameters occur at approximately the same time 1971 ± 1 yr. This strongly supports the idea that all of these events are related to the main-shock preparatory process, which may have been initiated by the 1972 large eruption/intrusion event.

The geodetic line 1 within the eastern asperity showed extension (relaxation) starting in 1970, and the line within the western asperity extended in early 1975 (Figs 5 and 6). This may mean that these two lines were contained entirely within their asperities until 1970 and 1975 respectively. After these times the creeping portions of the fault plane extended under the respective southern geodetic stations and the associated line began to lengthen. The central and northern parts of the asperities may have been locked until the time of the main shock. Unfortunately there is no geodetic data during the crucial period 1971–74, and the exact time of strain reversal is unknown.

This model of highly stressed asperities embedded in a strain-softening region of lower stress was derived from precursory geophysical data accumulated from the rupture zone of the Kalapana earthquake. It could, however, be considered a corollary of the known multiple-event nature of the main rupture (Fig. 2). Because the main rupture indicates that high-stress volumes were mixed with low-stress ones, the state of stress before the main shock must also have been one of contrasting high- and low-stressed volumes.

Based on laboratory observations, models similar to ours including strain-softening[18] and hard inclusions within strain-softening surroundings[19,20] have been proposed.

Conclusions

If our model is an accurate representation of the preparatory process to major earthquakes, it may prove difficult to detect high-stress-related earthquake precursors because they may be developed only in small portions of the precursor volume. If our observations can be scaled linearly to smaller and larger earthquakes in other tectonic environments, we expect that for a 5-mag earthquake the major asperities would have radii of ~1.5 km which may explain why no clear velocity anomalies have been detected for such events. For great earthquakes of several hundred kilometre source length, the asperities might have radii of ~40 km, which means that high-stress precursors might be detected with dense observation networks. The relationships between the number of asperities and earthquake size is not known. Our data do not exclude the possibility that large earthquakes contain numerous asperities with radii smaller than 5 km.

The precursor time for the Kalapana earthquake agrees approximately with the precursor time versus magnitude relations proposed elsewhere[3,4,21]. We have no evidence for diffusion of pore fluids, so the precursor time will more likely be a function of the ratio of locked-fault area to creeping-fault surface.

We conclude that three independent precursors (Fig. 6) have been observed for the Hawaii earthquake, which constrain the anomaly onset to approximately 1971 ± 1yr. They are of two types: high-stress precursors (decrease in P-wave velocity and foreshocks) and by contrast low-stress precursors, here observed as a 50% decrease in seismicity and strain relaxation. The high-stress phenomena are restricted to small volumes embedded in a larger volume characterized by lower stresses. The main-shock nucleation point was located in one of the major asperities and the area of largest surface deformations in the other. Our precursor model of hard asperities surrounded by creeping-fault area is analogous to the multiple rupture model for earthquakes. We suggest that future earthquakes may be predicted if patterns similar to those described here are observed.

We thank Robert Koyanagi and the staff of the Hawaiian Volcano Observatory for collecting and organizing data. This work was supported by NSF grant EAR 780-3633.

Upper mantle seismic anisotropy and lithospheric decoupling

J. H. Leven, I. Jackson & A. E. Ringwood

Research School of Earth Sciences, Australian National University, PO Box 4, Canberra 2600, Australia

The lithosphere underlying stable continental shield regions is thought to extend to a depth of ~200 km. Compressional wave velocity models derived from a recent approximately NS refraction profile in northern Australia include a pronounced high-velocity zone at a depth of around 200–250 km. Conventional petrological interpretations in terms of mineralogical or compositional changes cannot readily explain this feature. Calculated velocities for the garnet pyrolite model (using a derived geotherm), fit the velocities above and below this high-velocity zone, but cannot account for the high-velocity (~8.6 km s^{-1}) zone itself. This feature is explained in terms of velocity anisotropy, which might reflect mechanical decoupling of the continental lithosphere from the underlying mantle.

IT has been suggested that the lithosphere underlying continental shield regions extends to depths of the order of 200 km, and that the lithosphere (tectosphere)[1–3] beneath stable continental shields is depleted in low melting point components, is cooler than the normal mantle material at this depth, and hence would translate with the continental plates by virtue of its higher viscosity. Body and surface wave studies of the upper mantle structure beneath shield regions have not indicated any significant low-velocity zone above a depth of 200 km. A detailed study of the shear wave velocity structure beneath the Australian shield[4] has not found evidence for any region of low shear wave clocity above a depth of 150 km.

Lehmann[5,6] first postulated the existence of a seismic discontinuity in the upper mantle at a depth of around 200 km. This feature has subsequently been observed in many upper mantle refraction surveys, commonly at depths shallower than 200 km.

0028-0836/81/040234—06$01.00

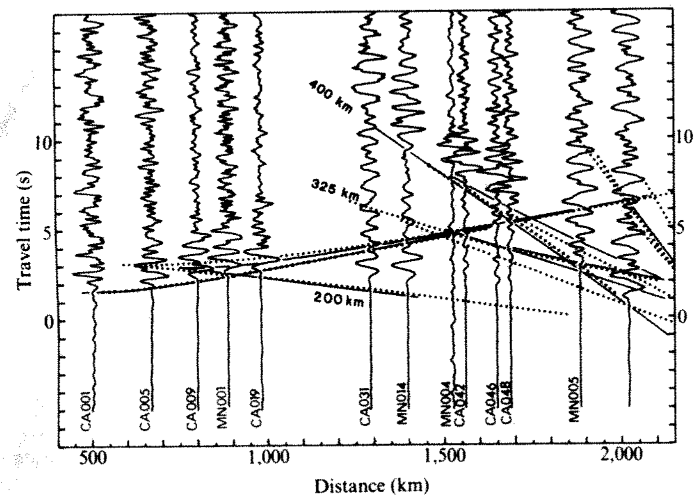

Fig. 1 Vertical component record section of event 256 from the Banda Sea Arc, with the travel time–distance curves of the model 8 (ref. 9) (dotted line) and CAPRI[11] (solid line) velocity models superimposed. The branch labelled 200 km corresponds to rays refracted below the 200 km discontinuity. This branch displays a rapid decrease in amplitude beyond an epicentral distance of 1,400 km, corresponding to the onset of a negative velocity gradient beneath the 200 km discontinuity (see Fig. 2).

Anderson[7] named this upper mantle feature the Lehman discontinuity. Hales[8] suggested that the relative motion of the Australian continental lithosphere over the underlying mantle material occurs "below a discontinuity in the P-wave velocity at a depth of about 200 km". Continents can move with comparable velocities to oceanic plates, so where is this zone of relative motion of the continental lithosphere over the underlying mantle and what is the relation, if any, of the '200 km' discontinuity to this zone?

Seismic observations

Hales *et al.*[9] analysed data from a long range upper mantle refraction profile conducted in Central Australia. Their upper mantle velocity model (model 8) has a velocity discontinuity at a depth of 200 km, with an increase in the compressional-wave velocity of 0.38 km s^{-1}. The depth of this feature has been constrained by the recorded arrivals of an event on the 14 October 1977 (event no. 256). The record (Fig. 1, see also Fig. 14 of ref. 9) of this event, which has been located in the depth range of 176 ± 5 km (on the basis of 164 readings), indicates that the 200 km discontinuity is significantly below the 176 km depth. The method of Gutenberg[9,10] constrains the velocity at the source depth of this event to be $\leq$8.28 km s^{-1}. Beneath the 200 km discontinuity, the velocity is well constrained to be 8.62 km s^{-1}, indicating that the velocity increase across the 200 km discontinuity is $>$0.3 km s^{-1}.

The 200 km prograde refraction branch, corresponding to rays which bottom below the 200 km discontinuity, shows an abrupt decrease in amplitude at an epicentral distance of around 1,700 km (depending on the source depth). Figure 12 of ref. 9 shows a fit of the travel time–distance curve derived from their model 5, to the record section for event no. 256. Model 5 did not incorporate any discontinuous increase in velocity around a depth of 200 km, so that this figure indicates the ease with which the 200 km discontinuity can remain undetected, especially when only shallow events are studied. Hales *et al.*[9] modelled the 200 km structure as a velocity knee with a layer having a negative velocity gradient below. Leven[11], using synthetic seismograms to model amplitudes, showed that the amplitude decay of the 200 km prograde branch can be explained by a low velocity zone which starts more sharply, around 30 km beneath the 200 km discontinuity. The exact nature of the velocity profile within the low velocity zone cannot be determined from present refraction data. However, synthetic seismogram modelling indicates that the negative velocity gradient commencing at a depth of 230 km must be sharper than that of model 8 (ref. 9), to explain this rapid decrease in amplitude near 1,700 km distance.

A sharp velocity increase at a depth of around 200 km, followed beneath by a velocity decrease, is a peculiar seismological feature. Similar high-velocity zones in the velocity models of other upper mantle studies can be found—but usually at shallower depths. For example, Lewis and Meyer[12] have a comparable structure at a depth of around 130 km, while in the model of Wiggins and Helmberger[13], this structure is at a depth of around 150 km. The abrupt decrease in amplitude of the 200 km branch has also been observed in other upper mantle refraction profiles, although the low velocity zone which is implied by this decrease has not been incorporated in the models resulting from these studies. Examples of this abrupt decay in the amplitude of the prograde 200 km branch can be clearly seen in Fig. 8 of ref. 14 and in Figs 11 and 12 of ref. 15. However, no convincing evidence of this type of velocity structure has been observed in the data of any of the Early Rise experiment profiles, which traverse North America with an excellent coverage of azimuth[16].

The existence of a negative velocity gradient at around 200 km depth is supported by the S to P conversion evident in records from teleseismic events. Sacks *et al.*[17] studied these converted phases recorded at the NORSAR array, and have interpreted precursors to the S onset as being S to P conversions from a negative velocity gradient at a depth of 250 ± 15 km.

Long range refraction surveys for oceanic paths have also indicated a similar velocity structure, but at a considerably shallower depth. Both Asada and Shimamura[18] and Hales *et al.*[19] have an analogous feature in the velocity models derived from oceanic refraction surveys. These velocity models both have a discontinuous increase to a compressional velocity of around 8.6 km s^{-1}, immediately above a low-velocity zone, the depth of this high-velocity zone in both cases being around 75 km. Leeds and others[20,21] have derived a model for the variation of the lithospheric thickness over the Pacific basin from surface wave studies. Their model indicates a thickening of the oceanic lithosphere from around 76 km in the younger regions, to 104 km in the older regions of the oceanic basin.

Conventional interpretations

Traditionally, seismic discontinuities in the Earth's mantle have been explained in terms of isochemical changes in mineralogy, changes in chemical composition, or a combination of both. The possible relevance of such phenomena to the 200 km discontinuity is now reviewed.

(1) Exsolution of $M_3^{2+}Al_2Si_3O_{12}$ (M = Mg, Fe, Ca) garnet from aluminous pyroxenes. The pressure-sensitivity of the Al_2O_3 content of pyroxenes coexisting with garnet provides the basis of pyroxene geobarometry[22,23]. Along the 1,200 °C isotherm, for example, the Al_2O_3 content of orthopyroxene coexisting with garnet in both synthetic and natural systems decreases, rather rapidly from 5–7% near 2.5 GPa to 1.5–2.5% near 4 GPa, and then more gradually to ~0.7% at 7 GPa and 0.4% in Ca-poor clinopyroxene at 14 GPa [ref. 23]. Green and Ringwood[24] (see also ref. 25) have shown that the orthopyroxene Al_2O_3 isopleths in the garnet pyrolite stability field are subparallel to the Clark and Ringwood[26] Precambrian shield geotherm—suggesting approximate constancy (at the 1.0–1.5% level) of orthopyroxene alumina content over the 2–5 GPa pressure range. The low alumina content of such orthopyroxene and the evidence for its gradual reduction with increasing pressure beyond 5 GPa exclude any possibility that exsolution of pyrope-rich $M_3^{2+}Al_2Si_3O_{12}$ (M = Mg, Fe, Ca) garnet from aluminous orthopyroxene is responsible for the discontinuous increase in compressional wave velocity near 200 km depth.

(2) Formation of complex $M_3^{2+}\,{}^{VI}(Al_2, M^{2+}Si)Si_3O_{12}$ garnet solid solutions. Ringwood's[27] study of the crystallization of a glass of 90% $MgSiO_3$–10% Al_2O_3 composition revealed a rapid

increase in both the garnet lattice parameter and the proportion of garnet near 10 GPa. More recently Akaogi and Akimoto[28] have confirmed the high pressure solubility of $MSiO_3$ pyroxene in the garnet structure, but suggest that such solution occurs gradually over the pressure range 4–14 GPa, with a pronounced increase in the proportion of garnet (and hence the density and P-wave velocity) in the 14–19 GPa pressure interval. The fact that the garnet lherzolite nodules of deepest origin (~200 km depth, 7 GPa pressure) brought to the Earth's surface by the Lesotho[23], Kao[22] and other kimberlite pipes contain 3.02–3.07 silicon atoms per 12 oxygen atoms is marginal evidence for the initiation of $M_3^{2+}(Al_2)Si_3O_{12} - M_3^{2+}(M^{2+}Si)\,Si_3O_{12}$ solid solution near this depth. However, neither laboratory experiments nor the garnet-bearing nodules indicate any abrupt increase in the $M_3^{2+}(M^{2+}Si)Si_3O_{12}$ content of garnet near 200 km depth in the Earth's mantle. This, coupled with the absence of other mineralogical changes in garnet lherzolite in the relevant pressure range, suggests that phase transformations are not responsible for the rapid increase in P-wave velocity near 200 km depth in the sub-continental mantle.

(3) Compositional change: harzburgite to garnet lherzolite. The long and complex geochemical history of subcontinental uppermost mantle, the geochemistry of ultramafic nodules from kimberlite pipes, and the absence of significant seismic low-velocity zones beneath Precambrian shields suggest that the sub-continental uppermost mantle is likely to be strongly (but variably) stripped of its low melting-point fraction. Under these circumstances, a transition would be expected, perhaps near 200 km depth, from barren harzburgite above, to fertile garnet lherzolite below[1,25]. The densities and P-wave velocities for these assemblages have been estimated to be 3.31 g cm^{-3} and 8.32 km s^{-1} for harzburgite and 3.38 g cm^{-3} and 8.38 km s^{-1} for pyrolite[25]. Jordan[29] has shown that removal (by 20% partial melting) of the basaltic fraction of pyrolite, decreases the density of the residium by ~0.05 g cm^{-3}, but leaves the P-wave velocity almost unchanged. The small change in P-wave velocity accompanying such differentiation is due to the near-cancellation between the velocity decrease associated with garnet removal and the velocity increase associated with the more magnesian composition of the residual olivine and orthopyroxene[29].

Clearly, although the subcontinental upper mantle must be chemically zoned as a result of differentiation, it is virtually impossible that a P-wave velocity discontinuity of the order of 0.3 km s^{-1} near 200 km depth, can be explained in these terms.

(4) Compositional change: garnet lherzolite (or harzburgite) to eclogite. Anderson[7,30] has suggested that the Lehmann discontinuity might represent a change in chemical composition from garnet lherzolite (or harzburgite) above the discontinuity to eclogite below. Such eclogite, whether produced by subduction of oceanic basaltic crust (as in Anderson's model), or by the necessarily relatively slow crystallization of basaltic magmas within the mantle, would be expected to possess an average mid-ocean ridge basaltic Mg number ($100\,Mg/(Mg+Fe^{2+})$) of about 60 (see refs 31, 32). In the former case, the basaltic major element chemistry might be perturbed during subduction by partial melting in the quartz eclogite stability field, resulting principally in significantly increased $(MgO+FeO)/CaO$ in the residium (see ref. 33). Typical mantle-derived eclogites are quartz-free, essentially bimineralic aggregates of pyroxene and garnet (in approximately equal proportions) with Mg numbers around 60.

Mean compressional-wave velocities for such mantle-derived eclogites[34–36] (samples 11, 14, and 15 of ref. 36 but not 8 which is very magnesian (Mg number 71) and contains 74.0% clinopyroxene, 16.6% garnet, and 7.9% zoisite) span the range 8.27–8.50 km s^{-1} at 1.0 GPa with measured velocity anisotropies of 0.8–3.4%. Shear-wave velocities are more variable (4.49–4.86 km s^{-1} at 1.0 GPa) with anisotropies of 1.5–4.9%. The Nové Dvory (Czechoslovakia) eclogite studied by Christensen to 3.0 GPa is representative of the highest P-wave velocity eclogites with $\rho = 3.56$ g cm^{-3}, and extrapolated compressional and shear wave velocities of 8.33 and 4.59 at atmospheric pressure. Our preferred parameters for garnet pyrolite are $\rho = 3.40$ g cm^{-3}, $V_p = 8.31$ km s^{-1}, and $V_s =$ 4.82 km s^{-1} (these differ slightly from those of Jordan[29] because of our use of the pyrope elastic moduli measured by Leitner *et al.*[37]).

Our analysis thus strongly reinforces other observations[7,25,34] concerning the indistinguishability of garnet lherzolite and eclogite P-wave velocities. We conclude that a change in chemical composition from garnet lherzolite to eclogite might produce a significant decrease in shear wave velocity but that no discernable change in compressional wave velocity would be expected. Under these circumstances, it seems unlikely that the Lehmann discontinuity reflects a chemical change of this type.

(5) Base of pronounced low-velocity zone. Many seismic models for upper mantle velocities beneath tectonically active continental regions (such as the western US) include a substantial and rapid increase in seismic wave velocities in the depth range 150–200 km (refs 38, 39). In most such models, the discontinuity represents the base of a pronounced low-velocity zone, so that a large part of the velocity contrast across the discontinuity is accounted for by a return to 'normal' upper mantle velocities (for example, at substantially subsolidus temperatures) below the discontinuity. The absence of significant low-velocity zones, shallower than 200 km depth, beneath Precambrian shield regions precludes such an interpretation for the Lehmann discontinuity.

Seismic-wave velocities for garnet pyrolite

The above arguments demonstrate the difficulty of accounting for the observed 0.3 km s^{-1} increase in V_p at ~200 km in terms of conventional explanations. To understand the nature of the seismic feature near 200 km depth, we now compare the CAPRI velocity-depth model[11] with calculated P-wave velocities for an assumed garnet pyrolite upper mantle.

For this calculation, we assume that the compressional-wave velocity (V_p of 8.31 ± 0.05 km s^{-1} at STP) varies linearly with pressure (to ~10 GPa) and temperature (to ~1,400 °C). Because volumetric strains will be no greater than 8% at 10 GPa, finite strain equations of state should not be necessary. The general tendency for both pressure and temperature derivatives of the elastic-wave velocity to decrease with increasing pressure and temperature suggests that linear extrapolation, using derivatives measured near STP, may result in slight overestimation of velocities at the upper end of the extrapolation. Any relaxation of ultrasonically determined shear moduli for upper mantle seismic-wave propagation would similarly result in an overestimation of the seismic velocities.

The pressure and temperature derivatives, used in the calculation:

$$\partial V_p/\partial P = 0.106 \text{ km s}^{-1}\text{ GPa}^{-1}$$

$$\partial V_p/\partial T = -0.55 \times 10^{-3} \text{ km s}^{-1}\text{ K}^{-1}$$

represent a weighted average (57% olivine, 17% orthopyroxene, 12% clinopyroxene, 14% garnet) of the mineral pressure and temperature derivatives. Data for Stillwater bronzitite ($\partial V_p/\partial P = 0.137$ km s^{-1} GPa^{-1} (refs 35, 40), are used in preference to the much higher value $\partial V_p/\partial P =$ 0.207 km s^{-1} GPa^{-1} derived from a study of single-crystal bronzite[41]. The latter value is grossly inconsistent with the expectation[42] that $(1/V_p)(\partial V_p/\partial P)$ is approximately equal to

$$\frac{39K + 16\,\mu}{6K(3K + 4\,\mu)}$$

This relation yields an expected $\partial V_p/\partial P$ of 0.138 km s^{-1} GPa^{-1}, in agreement with the measured value for Stillwater bronzitite. Furthermore, even if the unusually large single-crystal pressure derivatives ($dK/dP = 9.6$) were, in fact, appropriate at STP, it seems improbable that such a high derivative would be maintained over a substantial pressure range. Use of Frisillo and

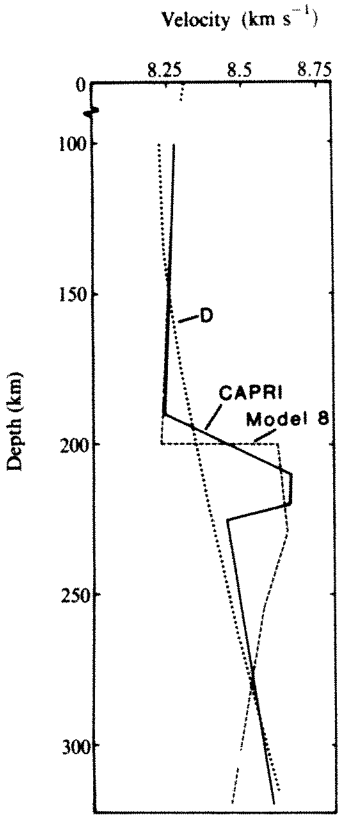

Fig. 2 A comparison of the model 8 and CAPRI compressional-wave velocity–depth models with calculated velocities (*D*) for a garnet pyrolite upper mantle based on the geotherm presented in the text.

Barsch data for orthopyroxene[9] would increase the garnet pyrolite $\partial V_p/\partial P$ to 0.128 km s^{-1} GPa^{-1} and hence raise the velocity at 200 km depth by ~0.14 km s^{-1}. Further experimental work on single-crystal and polycrystalline orthopyroxene is needed to resolve this uncertainty. Olivine and garnet pressure and temperature derivatives were taken from refs 43–45. A clinopyroxene ($\partial V_p/\partial P$) of 0.119 km s^{-1} GPa^{-1} was obtained by comparing Christensen's[35] data for Nové Dvory eclogite with the Bonczar *et al.*[45] data for garnet. Otherwise, it was assumed that the orthopyroxene derivatives also apply to clinopyroxene. In the initial calculations we used the geotherm of Harte[46]. The resulting compressional-wave velocity profile was broadly consistent with the model 8 of Hales *et al.*[9] and the CAPRI model in the 75–190 km and 225–320 km depth ranges but failed to explain the high velocities in the 190–225 km interval. Variation of the geotherm within reasonable limits[29] allowed a more satisfactory fit (Fig. 2) to the CAPRI velocities in the 75–190 km and 225–320 km depth ranges. The required geotherm

depth (km): 100; 150; 200; 250; 300
temperature (°C): 770; 1,050; 1,180; 1,320; 1,420

is between, and qualitatively similar to, Jordan's[29] S1 and S2 conductive geotherms, and would intersect adiabats for the oceanic upper mantle at depths between 300 and 400 km.

The comparison presented in Fig. 2 implies that the garnet pyrolite composition and mineralogy, combined with a reasonable geotherm, explains compressional-wave velocities for all but a narrow interval (190–225 km) of the 75–300 km depth range. Similar difficulties in explaining high velocities just below 200 km are evident in the studies of Graham[47], and of Ahrens[48] who noted that none of his calculated models "predict the 8.65 km s^{-1} P-velocity maximum . . . at 200 km depth in profile HWNE" (of Wiggins and Helmberger[13]). There have been similar comments[49] on the difficulty of explaining compressional-wave velocities $\geqslant$8.5 km s^{-1} in some seismic models of the oceanic lithosphere, in terms of the calculated elastic properties of petrologically appropriate isotropic aggregates.

The match between the calculated velocities and the CAPRI model, other than in the 190–225 km depth range, precludes neither a more barren harzburgitic chemistry above 200 km, nor a gradual increase in the $M_3^{2+}(M^{2+}Si)Si_3O_{12}$ component of the garnet with increasing depth below 200–250 km.

Seismic velocity anisotropy?

We are clearly concerned, not with a seismic discontinuity in the usual sense, but rather with a zone of the order of 50 km thick, characterized by higher velocities than both overlying and underlying mantle.

We have demonstrated the difficulty involved in explaining the 0.3 km s^{-1} velocity increase near 200 km, in terms of mineralogical or chemical changes. The negative velocity gradient below 230 km is also not readily explained in conventional terms. Leven[11] inferred that this velocity gradient must be more negative than −0.002 km^{-1} s^{-1} km^{-1} to produce synthetic seismograms consistent with the observed rapid decrease in first arrival amplitudes near $\Delta = 1{,}700$ km. Using P-wave velocity pressure and temperature derivatives appropriate for garnet pyrolite, we find that an unusually large (but not impossible) temperature gradient, of at least 9 °C km^{-1}, would be required if the negative velocity gradient below 230 km depth[9], were to be explained in terms of the combined effects of pressure and temperature.

On the other hand, this sub-continental 'high-velocity zone' bears a strong qualitative resemblance to shallower high-velocity lids capping low-velocity zones in many velocity models for the sub-oceanic upper mantle. These considerations, and the variability of its observation suggest that this unusual seismic feature might be explained in terms of seismic velocity anisotropy associated with deformation-induced preferred orientation of olivine (and possibly orthopyroxene) crystals in a shear zone, at 200–250 km depth, which is responsible for decoupling of the continental lithosphere from the underlying mantle. This hypothesis is supported by the following observations.

(1) Extensive field and laboratory studies of deformed peridotites from the Lanzo massif in Northern Italy (believed to represent subcontinental mantle), have established a firm relationship between the observed 7% velocity anisotropy, the fabric and the flow coordinates[50,51]. The velocity anisotropy is associated with preferred orientation of the [100] axes of olivine crystals at a low angle of inclination ($\theta = 10°$, Fig. 3) to the flow direction during high temperature (~1,200 °C) deformation at an inferred strain rate of 10^{-14} s^{-1}.

(2) Experiments conducted over a wide range of temperature and strain rate[51–54], have demonstrated the development of strong preferred orientation of olivine ([010]//σ_1 and [100]//σ_3) as a consequence of laboratory deformation of dunite. At high temperatures and moderate strain rates (moderate flow stress), the preferred orientation seems to be derived primarily from syntectonic recrystallization driven by strain accumulation, due principally to dislocation glide on the system (010)[100]. The coincidence of principal axes of stress and strain in most laboratory deformation experiments[52,54] results in an ambiguity concerning predicted fabric orientation in natural triaxial deformations which may resolve the apparent conflict between the orientations of the natural and laboratory fabrics mentioned above.

(3) Studies of the azimuthal variation of compressional-wave velocities in the oceanic upper mantle[55,56] have established the velocity anisotropy of the sub-oceanic mantle. The fast direction in each case is sub-parallel to the spreading direction, that is normal to the mid-ocean ridge. The azimuthal range in P-wave velocities (~0.3 km s^{-1}) and the association of fast velocities with the direction of plate movement over underlying mantle are both appropriate for explanation of the high P-wave velocities at 200–250 km depth along a NS profile beneath the Australian plate (Fig. 3).

(4) The seismic implications of the development of such an olivine preferred orientation are more fully explored in Fig. 3. For small inclinations of the fast [100] axis to the flow direction (N), propagation directions within 45° of the flow direction display compressional (or quasi-compressional) mode velocities significantly higher than 8.42 km s^{-1} which is the Voigt–Reuss–Hill (VRH) average. Note that the considerable shear wave birefringence—the difference in quasi-shear mode velocities is as much as 0.7 km s^{-1} for some propagation directions. Thorough characterization[57] of an essentially monominerallic sample of Twin Sisters dunite with a strong preferred orientation revealed a high degree of seismic anisotropy ($7.98 \leq V_p \leq 9.24$ km s^{-1}, $4.57 \leq V_s \leq 5.01$ km s^{-1}) and shear wave birefringence (maximum $\delta V_s = 0.38$ km s^{-1}). In upper mantle garnet peridotite, the magnitude of these effects will be reduced because of the reduced proportion of olivine. Nevertheless, the results of Fig. 3 provide a firm semiquantitative basis for testing the preferred orientation hypothesis.

The model provides a qualitative explanation of the high compressional-wave velocities for approximately NS propagation at depths of 200–250 km in the Australian upper mantle. The results presented in Fig. 3 (see especially $\theta = \phi = 22.5°$) suggest that significant shear wave birefringence might also be observed (on both horizontal and vertical components) at appropriate azimuths.

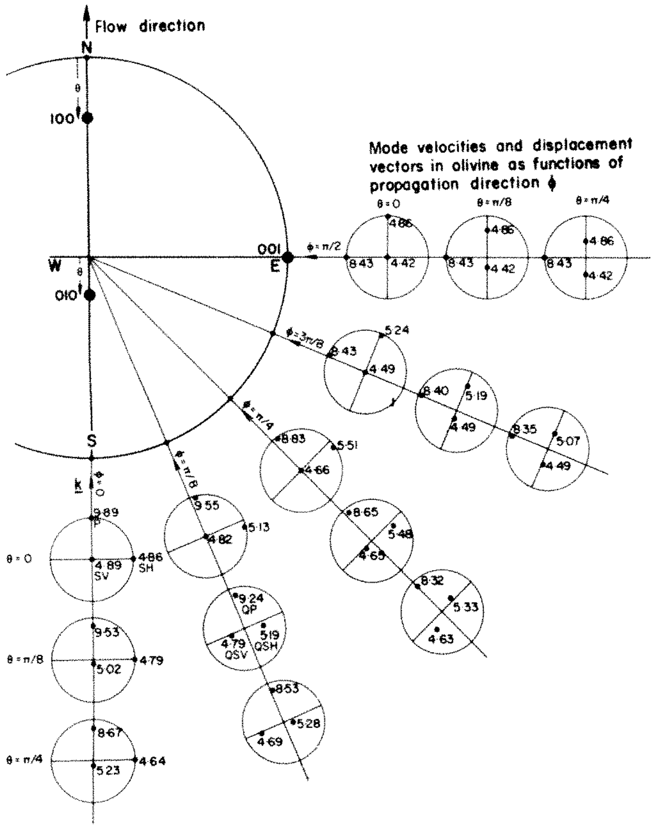

Fig. 3 Seismic anisotropy and shear-wave birefringence of olivine. The crystal orientation is the expected preferred orientation of olivine (see text) in the Australian upper mantle: flow plane horizontal, plate movement over underlying mantle due North. The olivine *c*-axis (001) lies EW while the inclination θ of the *a*-axis (001) to the flow direction is varied between 0 and $\pi/4$ (see text). Mode velocities and displacement vectors for horizontal propagation vectors **k** are calculated as functions of azimuth ϕ and inclination θ from the single crystal moduli[43]. The particle displacement vectors for the three independent propagation modes for each (ϕ, θ) pair are plotted (●) on a stereographic projection and labelled with the appropriate velocities (in km s^{-1}). Note that off-axis propagation directions involve modes for which particle displacement is neither parallel nor orthogonal to the propagation vector. Such coupled modes are labelled QP, OSH, QSV[67]. The results may be applied in the SW quadrant by virtue of the mirror symmetry of olivine about the plane normal to 001.

(5) Both the chemistries and textures of deep-seated ultramafic modules contained in kimberlite pipes are consistent with the view that decoupling of the continental lithosphere and the underlying mantle is concentrated at depths near 200 km (ref. 58). The observation that ultramafic nodules of deepest origin (~200 km), brought to the surface by South African kimberlites varying in age by more than 1,000 Myr (refs 22, 59) display more primitive chemistry than their shallower counterparts, suggests that the former are derived from a zone of the mantle which is continuously replenished from a large mantle reservoir. Furthermore, while the highly sheared mosaic textures of the deepest-seated xenoliths are probably not representative of steady-state mantle deformation processes[60], the contrasting fabrics of these and the relatively undeformed coarse-grained xenoliths[49] of shallower origin, are suggestive, at least, of very different modes of xenolith incorporation and magma transport.

(6) The combination of more primitive chemistry below 200 km depth and the general characteristics of upper mantle geotherms suggests that the zone between 200 and 300 km depth may be characterized by higher homologous temperatures (T/T_m) for olivine than for the shallower and the deeper mantle. Under these circumstances, this region is a plausible zone for strain concentration, although the relative roles of dislocation creep—syntectonic recrystallization (which may be subject to strain hardening) and grain boundary sliding[61], remain to be determined. Anderson[30] similarly concludes that the viscosity of subcontinental mantle should attain a minimum value near 200–250 km depth.

Conclusions

We have demonstrated the difficulty involved in explaining high compressional-wave velocities for approximately NS propagation at 200–250 km depth in the Australian upper mantle in terms of various suggested variations of mantle mineralogy and chemistry. Having rejected conventional interpretations, we suggest that the observed high P-wave velocities may derive from preferred orientation of olivine crystals in a deformation zone responsible for the mechanical decoupling of the lithosphere from the underlying mantle.

Refraction profiles of the Australian upper mantle[9,62–64], while in general agreement on the need for a substantial increase in compressional-wave velocity near 200 km depth for profiles within 45° of NS, provide limited information for other azimuths. The only indication of a possible 200 km discontinuity on an approximately EW profile is provided by a single first arrival[65] at $\Delta \sim 2{,}100$ km (Meekatharra, Western Australia) from an explosion at Mt Fitton (South Australia). This datum, while possibly compatible with NS profiles, does not provide a strong independent constraint on the velocity below 200 km depth for EW propagation azimuths. Clearly, the anisotropy hypothesis needs further testing. Carefully controlled experiments over a wide range of azimuths (such as those conducted on the suboceanic mantle[56]) will be required to test for anisotropy and possible shear wave birefringence (see ref. 66) of the continental upper mantle.

However, observation of subcontinental upper mantle seismic anisotropy may be subject to considerable variability. Spatial variation in the abundances of key volatile species (such as H_2O), and of mantle geotherms and strain rates may result in variability of the dominant upper mantle deformation mechanism, with some plausible flow mechanisms (such as grain boundary sliding) having little tendency to produce a strong preferred orientation. Even where an appropriate mechanism (such as dislocation creep–syntectonic recrystallization) dominates, the development of an observable seismic anisotropy may depend on a long, consistent and current history of relative motion of the lithospheric plate with respect to underlying mantle.

Such anisotropy beneath both continental and oceanic lithosphere, would facilitate seismic mapping of the vertical extent of the lithosphere, and provide considerable insight into the rheological behaviour of the upper mantle.

We thank P. N. Chopra, D. A. Gust, A. L. Hales, and K. J. Muirhead for useful discussion.

Regulation of transcription in expressed and unexpressed mating type cassettes of yeast

Amar J. S. Klar, Jeffrey N. Strathern, James R. Broach* & James B. Hicks

Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724

The genes that control the a, α *and* a/α *cell types in* Saccharomyces *are carried on transposable elements known as* a *and* α *cassettes which reside at three different chromosomal loci. Examination of the transcripts by R-looping and filter hybridization indicates that each cassette is capable of producing two divergent transcripts. Cassettes at the* MAT *locus are transcribed constitutively. Transcription of cassettes at* HML *and* HMR *is prevented by* trans-*acting negative regulators.*

THE genes controlling mating type in *Saccharomyces* yeasts reside on movable elements, referred to as cassettes, which become activated on transposition from silent storage sites to the mating type locus (*MAT*)[1-5]. The particular mating type gene activated in a cell determines the mating type of that cell. Cells expressing only an *α* mating type gene are phenotypically *α* cells: that is, they can mate with *a* cells but not with other *α* cells. Conversely, cells expressing only an *a* mating type gene are phenotypically *a* cells: they can mate with *α* but not with *a* cells. Cells that express both *a* and *α* mating type genes display a third phenotype (designated *a*/*α*): they can mate with neither *a* nor *α* cells and, if diploid, can undergo meiosis and sporulation. All cells contain three distinct genetic loci on yeast chromosome III at which mating type genes may reside. At two of these loci, *HML* and *HMR*, the genes are normally unexpressed. Only the gene present at the *MAT* locus (either *a* or *α*) is expressed in wild-type cells.

We describe here observations on the transcription of mating type cassettes located at both the *MAT* locus and the *HML* and *HMR* storage sites in a variety of strains. The results of this study have allowed us to refine current hypotheses which deal with two specific questions of mating type regulation. First, what is the mechanism by which *MATa* and *MATα* products determine cell type? Second, what is the mechanism which allows expression of *a* and *α* DNA at *MAT* but keeps them unexpressed at *HML* and *HMR*?

Genetic analyses suggest that *MATa* and *MATα* do not code for all the cell-type specific functions, but determine cell type by regulating the expression of cell-type specific genes elsewhere in the genome[6]. Several of these structural genes involved in the sexual cycle have been identified as mutations that result in *a*- or *α*-specific defects in mating or as mutations defective in meiosis and sporulation of *a*/*α* cells. Two complementation groups in *MATα* and one complementation group in *MATa* have been identified and their roles in the regulation of *a*-specific, *α*-specific and *a*/*α*-specific genes defined[7-9]. *MATα*1 is a positive regulator of *α*-specific genes (*matα*1 mutants are sterile). *MATα*2 is a negative regulator of *a*-specific genes (*matα*2 mutants express both *a*-specific and *α*-specific genes and hence are sterile). *MATα*2 is also a positive regulator of *a*/*α*-specific

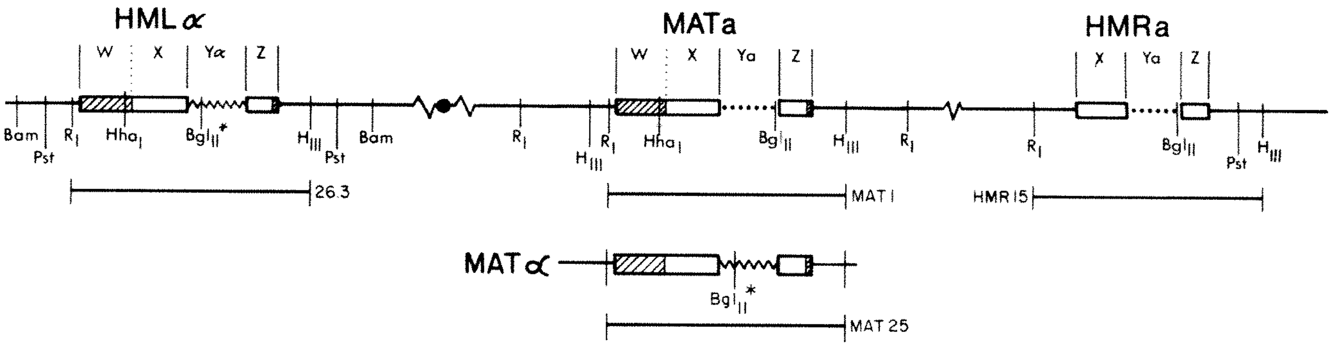

Fig. 1 Organization of the mating type cassettes on yeast chromosome III. Open boxes represent sequences common to all three loci, *MAT, HML* and *HMR*. Hatched regions are present at *HML* and *MAT* only. Sequences specific to *a* or *α* cassettes are denoted by dotted and zig-zag lines, respectively. The solid circle denotes the centromere. Detailed restriction maps are presented elsewhere[4]. Only restriction fragments used as probes in subsequent figures are labelled. The *BglII* site in the *α* cassettes labelled with an asterisk is presented only in strains derived from *Saccharomyces carlsbergensis*.

genes (*mataα2/MATa* diploids are sporulation defective). *MATa* has no role in the mating ability of *a* cells (*mata*$^-$ mutants mate efficiently with *α* cells), but *MATa* is required, along with *MATα*2, for the *a/α* phenotype (*mata*$^-$*/MATα* diploids behave like *α* cells)[10]. The observations reported here contribute further to our understanding of how *MATa* and *MATα* regulate cell type.

There is substantial genetic and structural information available regarding the mechanism by which the mating type cassettes at the storage sites are prevented from being expressed. The two storage sites for the *a* and *α* cassettes, *HML* and *HMR*, are located at opposite ends of the same chromosome in which the *MAT* locus resides[11]. Each storage site contains one copy of a mating type cassette, which can be either *a* or *α*[3-5]. Recent structural analysis of cloned DNA molecules from *MAT* and the storage loci, *HML* and *HMR*, has shown that all three loci share two regions of sequence homology flanking a 600- or 750-base pair sequence unique to *a* or *α*, respectively[3,4]. The physical structure of *HML, HMR* and *MAT* and their orientation on the chromosome are shown in Fig. 1. Finally, genetic analysis indicates that *HML* and *HMR* are under apparent negative control by the combined action of several distinct genes variously known as *MAR, SIR* and *CMT*[12-14]. These genes are genetically unlinked to each other or to *HML, HMR* or *MAT*: The *MAR*1 locus has been mapped to chromosome IV (ref. 12). *MAR*2 has been mapped to chromosome XII and is allelic to *CMT* (unpublished results). A mutation in either of these genes is sufficient to cause phenotypic expression of *HML* and *HMR*. These genes, therefore, operationally act as co-repressors of *HML* and *HMR*. In strains with the most common arrangement of storage genes, that is, *HMLα* and *HMRa*, the *mar*1-1 mutation yields a non-mating, *a/α*-like phenotype, presumably because both *α* and *a* functions are being expressed[12].

Thus, the mating type cassettes encode products which regulate expression of unlinked genes involved in the mating and sporulation pathways and are themselves regulated when located in the storage sites. To examine the nature of these controls further, we have examined the transcription patterns of the *MATa* and *MATα* genes in *a*, *α* and *a/α* cells. We have mapped these transcripts and assayed their expression in mutant straints defective in normal control functions. We have also examined transcription from the *a* and *α* elements residing at *HML* and *HMR* in normal strains and in strains carrying *mar*$^-$ mutations which result in the expression of these loci.

Identification of transcripts

The *MATa* and *MATα* alleles each produce two mature RNA transcripts. These transcripts were detected by electrophoretic separation of poly(A)$^+$-selected RNA on agarose gels followed by transfer to diazotized filter paper[15] and hybridization with ^{32}P-labelled *a* and *α* DNA cloned in bacterial plasmids. Figure 2 displays a series of RNA gel blots from normal haploid strains in which only the *MAT* locus is expressed and *mar*1$^-$ non-mating strains in which all three loci containing mating type cassettes are expressed (discussed below). Tracks *a* and *c* of Fig. 2 contain RNA from normal *MATa* and *MATα* haploid strains probed with an *Eco*RI–*Hin*dIII fragment of *HMLα* DNA, and tracks *e* and *g* contain the same RNAs probed with a *Eco*RI–*Hin*dIII fragment of *MATa* DNA. The sizes of the labelled transcripts were determined relative to pBR322 restriction fragment markers run on the same gel. A comparison of these four tracks yields the following conclusions: (1) there are two transcripts from *MATa*, one of 650 bases (*a*x) and one of approximately 450 bases (*a*y); (2) only the 650 base *MATa* transcript is homologous with *α* DNA from *HMLα* (Fig. 2, track *a*); (3) *MATα* produces a broad band (tracks *c*, *g*) which consists of two transcripts of similar size, ~800 bases (*α*1) and 750 bases (*α*2). An additional band high in gel tracks *e–h* represents a transcript not associated with mating type but which overlaps the cloned *MAT* fragment used as a hybridization probe. The *MATα* transcripts, which are not separated on the gel shown in Fig. 2, can be distinguished both by R-loop analysis in the electron microscope and by hybridization mapping, as described below. More detailed mapping of these transcripts is also presented below.

In addition to the normal haploid strains we have also analysed the patterns of transcripts in *mar*1$^-$ haploids. As described above, genetic characterization of strains harbouring the *mar*1$^-$ allele indicates that such strains express the storage loci, *HML* and *HMR*, in addition to the *MAT* locus[12]. Hybridizations to RNA from *mar*1$^-$ strains of genotype *HMLα MATα MATa* (Fig. 2, tracks *d, h*) and *HMLα MATa HMRa* (tracks *b, f*) are shown. In the tracks probed with *MATa* DNA both characteristic *a* transcripts appear as well as at least one *α* transcript. This pattern of bands is identical with that obtained using RNA from normal *a/α* diploid (see Fig. 4, track *j*). Therefore, we assume here that the state of mating type expression in non-mating *mar*$^-$ cells is equivalent to that in a *a/α* diploid. The relative intensities of the bands with tracks of RNA from *mar*1$^-$ strains correspond roughly to the gene dosage of *a* and *α* cassettes in each strain, suggesting that all three loci are being expressed at comparable levels. Comparison of *mar*1$^-$ and *MAR*1$^+$ strains indicates that the *HML* and *HMR* loci are apparently under transcriptional control through the *MAR* functions. Similar results have been obtained for mutants carrying the *mar*2$^-$ allele which defines a *MAR* function mapping on chromosome XII (data not shown). The tracks probed with *HMLα* yield a similar result with the exception that the small *a* transcript is missing, indicating that this 450-base transcript comes from the sequences unique to the *a* cassette.

Mapping the transcripts

The positions of both *α* transcripts (*α*1 and *α*2) and the longer of the two *a* transcripts (*a*x) were determined by electron microscopy of R-loops formed by hybridization of poly(A)$^+$ RNA to a *Eco*RI–*Hin*dIII fragment containing *MATa* or *MATα* DNA cloned in the bacterial plasmid pBR322. A histogram of

R-looped molecules is shown in Fig. 3. One α transcript was mapped to the X region of the *MAT* locus and the other extends from approximately the middle of the Yα region rightwards through Z. Both α transcripts would therefore be expected to show homology with the *MATa* gene as well as *MATα* because the X and Z regions are common to both (see Fig. 1). One of the *MATa* transcripts (ax) was also found to map in the X region of the *MAT* locus. It seems to share the same left-hand end point as the homologous α transcript ($\alpha 1$) but is somewhat shorter than $\alpha 1$, as expected from the gel blotting experiments. Only two molecules containing the a transcript (ay) were found in our R-loop preparations. However, blotting results in Fig. 2 and additional studies described below clearly indicate that ay is not homologous to the *MATα* gene and must therefore lie in the Ya region of the *MATa* gene.

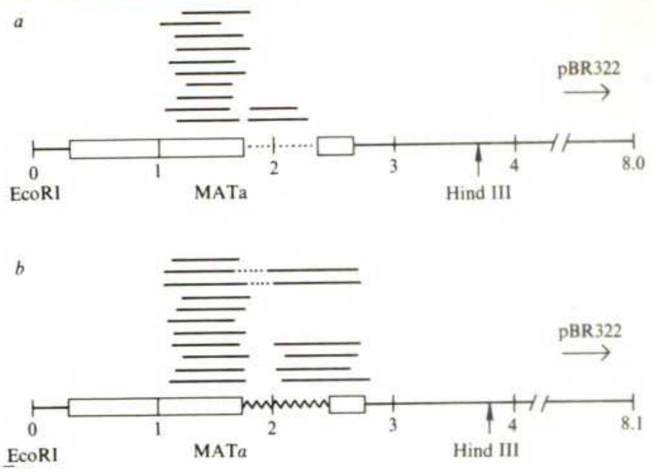

Fig. 3 Histogram of R-looped plasmid molecules containing the *MATa* gene (pBR-*MAT*1) hybridized with RNA from a *MATa* strain (a) and the *MATα* gene (pBR-*MAT*25) hybridized with RNA from a *MATα* strain (b). Both cloned *MAT* genes were inserted in pBR322 as *Eco*RI–*Hin*dIII fragments and the hybrid plasmids were digested with *Eco*RI. Dotted lines indicate individual molecules containing both R-loops, measured molecules represent approximately 50% of those observed to contain R-loops. Bacteriophage ΦX–double stranded DNA was included as a size standard. R-looping was performed according to the method of Kaback *et al.*[21] and measurements were made on a Numonics electronic planimeter.

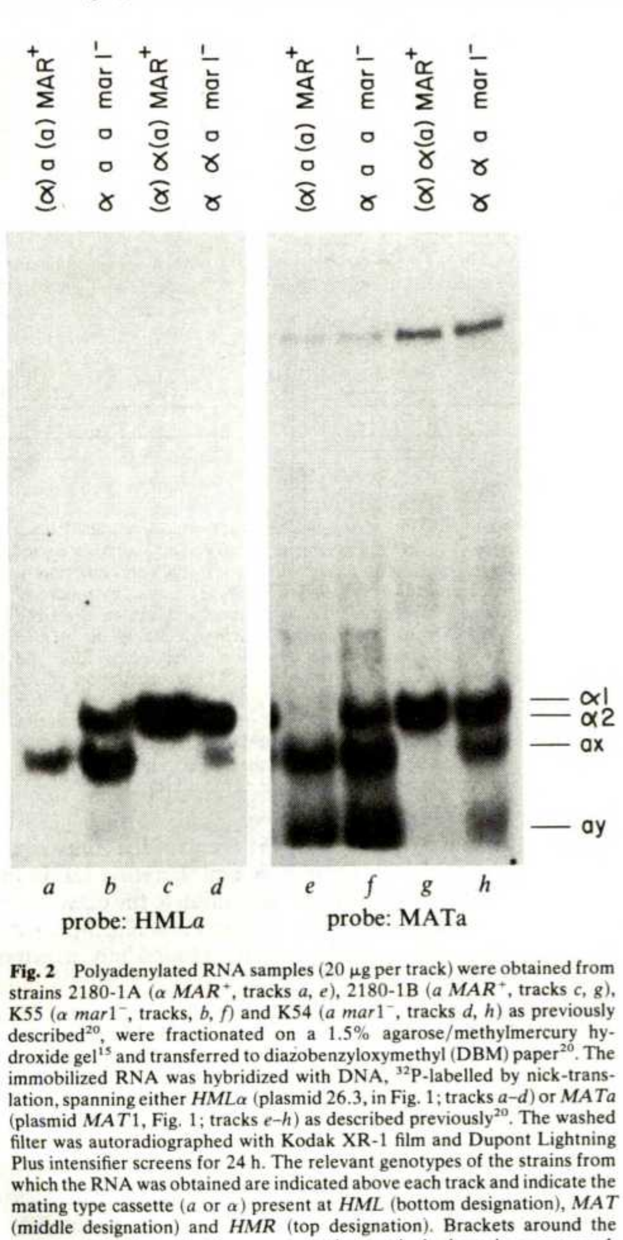

Fig. 2 Polyadenylated RNA samples (20 μg per track) were obtained from strains 2180-1A (α *MAR*$^+$, tracks a, e), 2180-1B (a *MAR*$^+$, tracks c, g), K55 (α *mar*1$^-$, tracks, b, f) and K54 (a *mar*1$^-$, tracks d, h) as previously described[20], were fractionated on a 1.5% agarose/methylmercury hydroxide gel[15] and transferred to diazobenzyloxymethyl (DBM) paper[20]. The immobilized RNA was hybridized with DNA, ^{32}P-labelled by nick-translation, spanning either *HMLα* (plasmid 26.3, in Fig. 1; tracks a–d) or *MATa* (plasmid *MAT*1, Fig. 1; tracks e–h) as described previously[20]. The washed filter was autoradiographed with Kodak XR-1 film and Dupont Lightning Plus intensifier screens for 24 h. The relevant genotypes of the strains from which the RNA was obtained are indicated above each track and indicate the mating type cassette (a or α) present at *HML* (bottom designation), *MAT* (middle designation) and *HMR* (top designation). Brackets around the designation indicate that the cassette at that particular locus is unexpressed, as established by genetic criteria. The absence of brackets indicates that the cassette is expressed at that particular locus. Bands corresponding to $\alpha 1$, $\alpha 2$, ax and ay transcripts, identified as described in the text, are indicated to the right of the autoradiogram. Molecular weights were estimated using restriction fragments of bacterial plasmid pBR322 as standards (not shown).

Additional mapping data were obtained by probing RNA blots with purified restriction fragments from cloned mating type genes as shown in Fig. 4. Tracks a–f in Fig. 4 represent a single pair of blotted tracks hybridized sequentially to three different probes. Tracks a, c and e contain RNA from *mar*1$^-$ non-mating a/α-like strain, tracks b, d and f contain RNA from a normal α haploid. Tracks a and b are probed with a fragment which covers Ya, Z and overlaps the X region of *MATa*. The probe reveals a single band in the a/α tracks, at ~750 bases, but shows a doublet at 800/750 bases in the α track. We interpret this result to mean that two transcripts are made from the *MATα* locus in strains exhibiting the α phenotype but only one in a/α strains. This interpretation was confirmed by additional hybridization studies described below. Knowing the positions of the α transcripts, we could confirm that only one of two α transcripts is present in a/α cells. This was done by testing the original filter in Fig. 4a,b with probes containing only X-region homology (103.4) and Z-region homology (103.5). Using the high molecular weight band associated with the right-hand end of the *MAT* probe as an internal standard it is clear (Fig. 4, tracks c–f) that the Z-region transcript ($\alpha 1$) is not present in the a/α strain but the X-region transcript ($\alpha 2$) is present in both α and a/α cells. The presence of two transcripts from *MATα* is consistent with the observation of two complementation groups *MATα*1 and *MATα*2 as described above. Further, the absence of the $\alpha 1$ transcript in a/α cells correlates with the fact that a functional *MATα*1 allele is not required for the a/α phenotype. On the other hand, *MATα*2 is a required function in a/α diploids. We therefore identify the message which is present only in α haploid strains ($\alpha 1$) as the transcript for the *MATα*1 gene and the message present in both α and a/α strains ($\alpha 2$) as the transcript of *MATα*2. This interpretation is consistent with genetic recombination results suggesting that *MATα*2 is proximal to *MATα*1 (refs 7, 9) and has been confirmed by *in vitro* mutagenesis by Nasmyth *et al.* (see accompanying article[16]).

Figure 4 also yields information concerning the location of the a transcripts. Both ax and ay transcripts are clearly present in a *HMLα MATα HMRa mar*1$^-$ strain when probed with whole *MATa* DNA (Fig. 2, track h; see also the a/α strain in Fig. 5). However, when probed with fragment 103.8, only the smaller of the a transcripts, ay, is revealed in the a/α track, indicating that the 650-base transcript (ax) lies mainly to the left of the *Hha*I restriction site in the region X. Furthermore, as the small a transcript does not hybridize significantly with *HMLα* DNA (Fig. 2), it must lie mainly within the Ya region. This interpretation is confirmed by additional hybridization of a/α and a strains with the X-region probe 103.7 (Fig. 4g,h) and an a strain with the Y-region probe 103.8 (Fig. 4i). In additional experiments (data not shown) the W region probe 103.6 was used against a and α RNA. No hybridization was detected with this probe to any of the RNA species. Because either mating type cassette can be expressed at *HMR*[17], even though the W region is not represented there[4,5], it was not required that those sequences be transcribed.

Direction of transcription

The direction of transcription of the mating type genes was determined by hybridization of RNA gel blots to separated strands of λ bacteriophage carrying cloned *HML*α or *HMRa* sequences followed by subsequent hybridization to wild-type λ DNA labelled with ^{32}P by nick translation. The orientation of the cloned genes in the λ vector was determined by heteroduplex analysis in the electron microscope. The result of these experiments is shown in Fig. 5. The tracks on the left represent parallel electrophoresis of poly(A)$^+$ RNA from an α haploid strain *S245c* hybridized with the R and L strand, respectively, of the hybrid λ clone *MAT*25 (*MAT*α). The $\alpha 1$ band hybridizes to the R strand of the λ clone, that is, it is transcribed from Yα towards Z, whereas $\alpha 2$ hybridizes to the L strand and is thus transcribed leftward as the locus is drawn in Figs 1 and 5. The pair of tracks on the right contain poly(A)$^+$ RNA from a a/α diploid strain probed with separated strands from λ clone *HMR*15c (*HMRa*). As described previously, this RNA preparation would be expected to contain the transcripts designated ax, ay and $\alpha 2$, all of which should be detected by the *HMR*15c probe. These tracks show that ax as well as $\alpha 2$ hybridizes to the L strand and is transcribed leftward in the X region of the cassette. The ay transcript hybridizes to the opposite strand and is thus transcribed to the right in region Ya. Thus, both a and α cassettes are transcribed divergently from within the middle of the cassette. At least for $\alpha 1$ and ay the 5′ end of the transcript is inside the unique Yα or Ya sequence and therefore inside the transposed portion of the cassette. In addition to the direction of transcription, a comparison of tracks a and c in Fig. 5 provides additional evidence that the $\alpha 1$ transcript is found only in cells of the α mating type and not in a/α diploids.

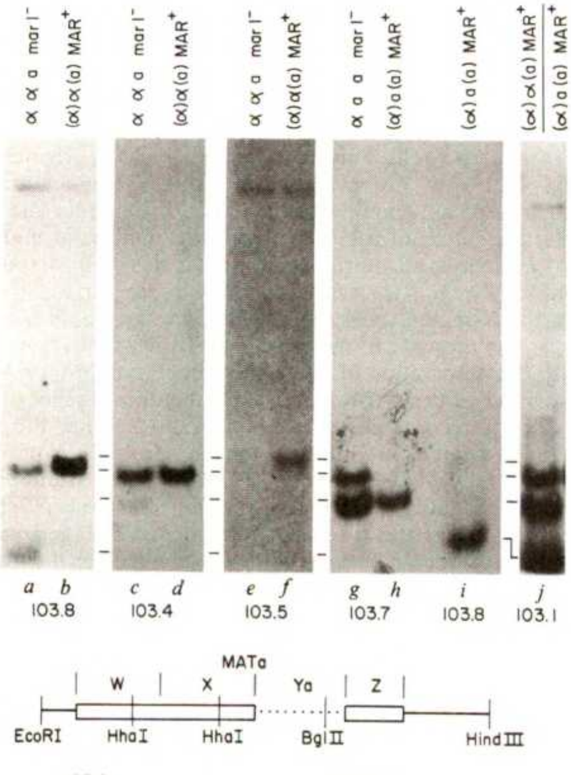

Fig. 4 Mapping the a and α transcripts by hybridization of RNA gel blots with specific probes. tracks a–f represent the same filter probed sequentially with the probes indicated. Between hybridizations the previous probe was removed by treatment with 99% formamide and 10 mM HEPES buffer, pH 7.5, at 65 °C for 1 h. Relevant genotypes of the strains used are indicated above each track as described in Fig. 2 legend. Parentheses denote silent *HML*α and *HMRa* cassettes.

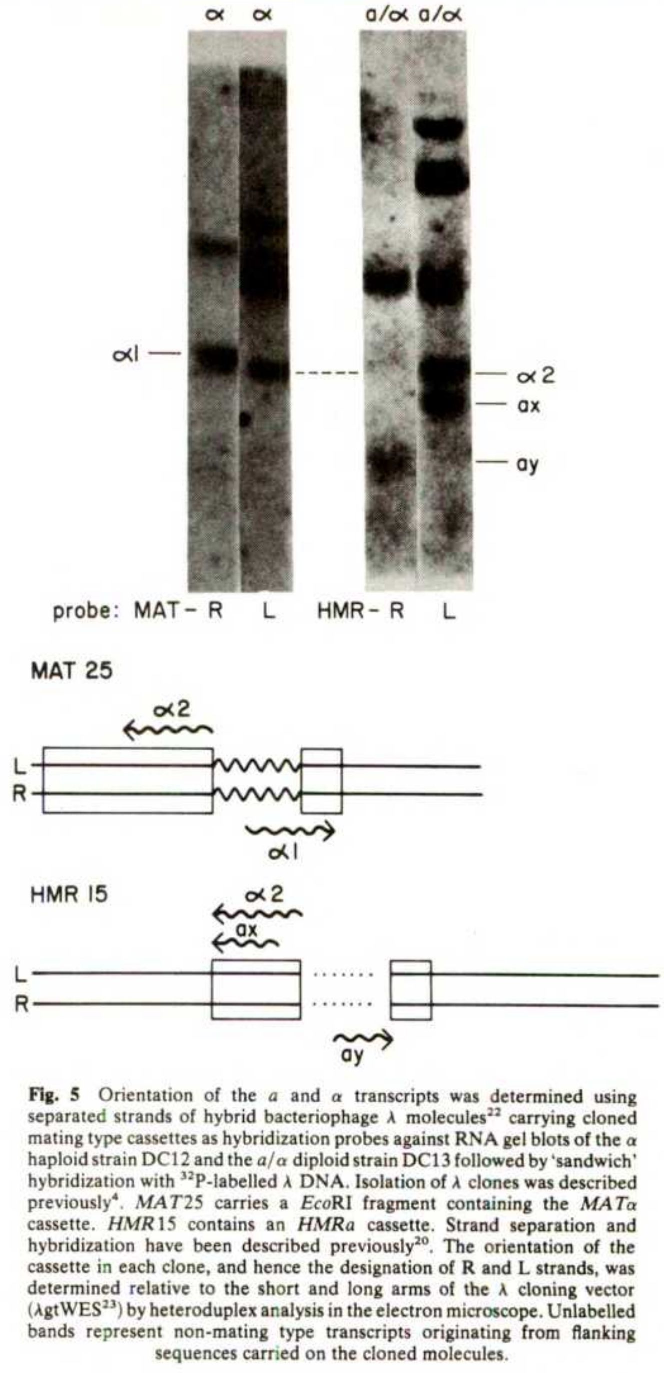

Fig. 5 Orientation of the a and α transcripts was determined using separated strands of hybrid bacteriophage λ molecules[22] carrying cloned mating type cassettes as hybridization probes against RNA gel blots of the α haploid strain DC12 and the a/α diploid strain DC13 followed by 'sandwich' hybridization with ^{32}P-labelled λ DNA. Isolation of λ clones was described previously[4]. *MAT*25 carries a *Eco*RI fragment containing the *MAT*α cassette. *HMR*15 contains an *HMRa* cassette. Strand separation and hybridization have been described previously[20]. The orientation of the cassette in each clone, and hence the designation of R and L strands, was determined relative to the short and long arms of the λ cloning vector (λgtWES[23]) by heteroduplex analysis in the electron microscope. Unlabelled bands represent non-mating type transcripts originating from flanking sequences carried on the cloned molecules.

Control of $\alpha 1$ transcription in a/α cells

The transcript mapping results described above showed that one of the two α transcripts ($\alpha 1$) is not present in a/α (non-mating) cells. This is consistent with genetic results indicating that *MAT*$\alpha 1$ is not required for expression of the a/α cell type but is required in α cells to turn on α-specific mating functions. We have therefore investigated whether *MAT*$\alpha 1$ is turned off by the products of the *MATa* allele (ax and/or ay) or by the combined action of *MATa* and *MAT*$\alpha 2$. Poly(A)$^+$ RNA was isolated from *mat*$\alpha 2$/*MATa* diploids and tested for expression of the $\alpha 1$ transcript by hybridization with the whole *MATa* probe (homologous to $\alpha 1$, $\alpha 2$, ax and ay) and a purified probe containing only the *MAT*α yz region specific to $\alpha 1$. The autoradiographs in Fig. 6 show sequential hybridizations of these two probes to the same filter containing two $mat\alpha 2^-/MATa$ diploids, a normal $MATa/MAT\alpha$ diploid and a $MAT\alpha$ haploid strain. The $\alpha 1$ and $\alpha 2$ bands are not resolved, but the positive signal at the $\alpha 1/\alpha 2$ position in the mutant diploids when probed with $MAT\alpha YZ$ indicates that the $\alpha 1$ transcript is present. As expected, no signal is seen at that position in the $MATa/MAT\alpha$ diploid. Thus, it is clear that both $MAT\alpha 2$ and the product(s) of the $MATa$ gene are required for turn-off of $MAT\alpha 1$. The possible mechanisms of $MAT\alpha 2$ and $MATa$ action are described further below.

Control of cell type

The results presented here, combined with genetic results described elsewhere, can be used to generate a circuit diagram for the control of cell type in *Saccharomyces*. Figure 7 shows the inferred regulatory pathways in α strains, *a* strains and a/α strains. In the α strain shown in Fig. 7*a* both $MAT\alpha 1$ and $MAT\alpha 2$ have active regulatory roles. Because $MAT\alpha 1$ is necessary for efficient mating but not for sporulation it is proposed to be a positive regulator of α-specific functions. $MAT\alpha 2$, on the other hand, is proposed to act as a negative regulator of *a*-specific functions. A $mat\alpha 2^-$ mutant is presumed to be defective in mating as both α and *a* mating functions are turned on.

In the mating type *a* strain shown in Fig. 7*b*, no control functions are assigned to the products of the $MATa$ allele. This is because no recessive mutations at the $MATa$ locus have been shown to cause defects in *a* mating ability. We presume, therefore, that the *a*-specific genes are constitutive in the absence of $MAT\alpha 2$, and that even though $MATa$ is transcribed in both *a* and a/α strains, its products only exert an effect in a/α strains.

Regulation in a $MATa/MAT\alpha$ diploid strain is shown in Fig. 7*c*. In addition to the turn on of a/α-specific functions by $MAT\alpha 2$ and $MATa$, some control mechanism shutting off *a*- and α-specific functions is required. Several genetic arguments suggest that $MAT\alpha 2$ is responsible for shutting off *a*-specific functions in a/α cells just as it does in α cells[9]. We show here that α-specific functions are turned off in a/α diploids by the combined action of $MAT\alpha 2$ and $MATa$ repressing the transcription of the positive regulator of α genes, $MAT\alpha 1$. This analysis does not determine whether it is *a*x or *a*y (or both) that are required for the a/α cell type. *In vitro* mutagenesis of cloned $MATa$-containing plasmids by Nasmyth *et al.* (see accompanying article[16]) indicates that only *a*y is necessary for this interaction. No function has been established for *a*x. We therefore propose that an interaction occurs between the $MAT\alpha 2$ and the $MATa$ product(s) which changes their regulatory specificities. This interaction creates a new regulatory molecule which serves to turn off $MAT\alpha 1$ and also to turn on the a/α-specific genes whose functions are required for meiosis and sporulation. Of course, it is also possible that $MAT\alpha 2$ and the products of $MATa$ do not interact with each other but must act at independent sites on the DNA so as to regulate $\alpha 1$ and the a/α specific genes.

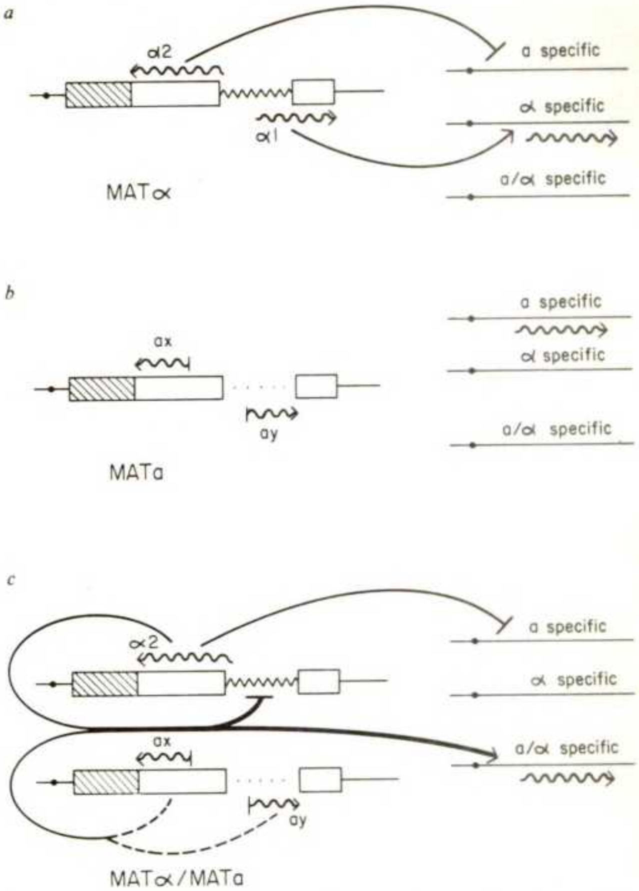

Fig. 7 Control of cell type in *Saccharomyces*. (*a*) *a* cells; (*b*) α cells; (*c*) a/α cells. Straight arrows indicate positive control. T-bars indicate negative control. Wavy arrows are the transcripts described in the text. Other symbols as in Fig. 1. The requirement of both *a*x and *a*y in control of cell type has not been determined. Genetic analyses of control of cell type are described elsewhere[6–10].

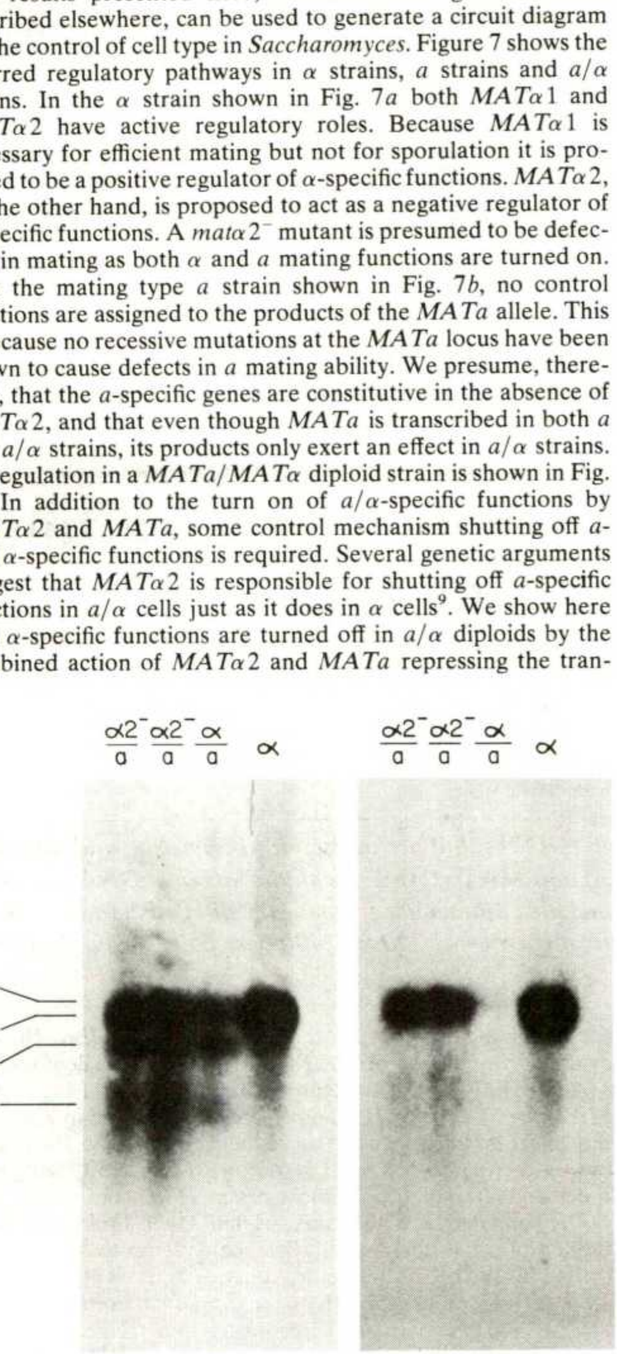

Fig. 6 Sequential hybridization of RNA from a series of strains blotted on diazotized paper[20] to probes containing a complete $MATa$ cassette ($MAT1$, Fig. 1) and the right half of a $MATa$ cassette ($MAT\alpha YZ$). Two independently isolated $mat\alpha 2^-/a$ diploids (DC100, DC101), a normal a/α diploid (DC13) and an α haploid (DC12) were used. The $MAT\alpha$ YZ probe was made by cutting a cloned α cassette from strain CB11 at the *Bgl*II site in the Y region[4] yielding a probe specific for the $mat\alpha 1$ transcript.

Control of the silent genes

In addition to the control of cell type itself the transcription mapping presented here provides insight into the mechanism by which the storage cassettes, *HML* and *HMR*, are kept silent. There is much genetic evidence indicating that *HML* and *HMR* are under negative control and the results presented here show that control is apparently at the level of transcription. At least four distinct genetic loci, known as *MAR* or *SIR*, have been identified which are required to prevent expression of *HML* and *HMR*. In both $mar1^-$ and $mar2^-$ mutants mature transcripts are produced at *HML* and *HMR* and these transcripts seem to be identical to their mature counterparts from *MAT*. These results are particularly surprising considering the 5′ end of at least one α transcript ($\alpha 1$) and one *a* transcript (*a*y) map within the region of the cassette which must be transposed during mating type switching.

How, then, can that region of the cassette be silent at one chromosomal locus and active at another? On one hand, it is possible that the 5′ end of the observed transcripts do not reflect the actual transcription initiation site. The transcripts could start near the ends of the cassettes and proceed in opposite directions, crossing each other to reach the regions maintained in the mature transcript. In this model the transcription initiation sites could be in or near regions not shared by *MAT* and the storage loci and hence subject to different control. On the other hand, transcriptional initiation may occur near the 5′ ends of the mature transcripts. In this case, differential regulation of the cassettes could be effected by differential accessibility of the promoter site depending on whether the cassette is located at *MAT* or at *HML* or *HMR*. The accessibility of the promoter would be established by the interaction of sites outside the regions of homology with the *MAR* and *SIR* products and could reflect differential chromatin structure[18], phasing of nucleosomes[19] or differential methylation. The structure of certain intrachromosomal rearrangements[4] suggests that the sites of action of the negative regulators lie to the left of the W–X regions at *HML* and *HMR*. Deletion of these sequences results in the expression of the normally silent *HML* and *HMR* cassettes.

Regardless of the particular mechanistic model, it is clear that mating type expression in yeast is an example of a genetic positional effect; that is, the expression of a DNA sequence depends on its location in the genome. The availability of mutants which allow expression of the silent cassettes and the existence of cloned DNA from *MAT*, *HML* and *HMR* should permit a detailed analysis of the molecular basis of this positional effect.

We thank David Kaback for assistance with the R-looping analysis, Ira Herskowitz for comments on the manuscript, Jean McIndoo, Carolyn McGill, Victoria Guarascio and Sajida Ismail for technical assistance, Louisa Dalessandro for preparation of the manuscript and Mike Ockler for the figures. This research was supported by NIH research grant GM25678-03 to A.K., GM25634-03 to J.H. and J.S and GM24226 to J.B.

A position effect in the control of transcription at yeast mating type loci

Kim A. Nasmyth[*], **Kelly Tatchell**[*], **Benjamin D. Hall**[*], **Caroline Astell**[†] **& Michael Smith**[†]

[*] Department of Genetics, SK-50, University of Washington, Seattle, Washington 98195
[†] Department of Biochemistry, Faculty of Medicine, University of British Columbia, 2075 Westbrook Place, Vancouver, British Columbia, Canada V6T 1W5

The two mating type loci MATa *and* MATα *each produce two mRNAs that are transcribed in opposite and diverging directions from central promoters. Silent copies of* MATa (HMRa) *and* MATα (HMLα) *contain identical DNA sequences throughout the transcribed region, yet are not transcribed. It is concluded that sequences to the left of* HMRa (*and probably* HMLα) *must somehow affect transcription initiated at the centre of each locus 700 to 1,400 base pairs away. A possible mechanism for this position effect is discussed.*

THE mating type of a yeast cell, *a* or *α*, is determined by a single locus on chromosome III called *MAT* (ref. 1) which may contain one of two types of DNA sequence[2,3]. In heterothallic cells, *MATa* and *MATα*, are stable mendelian 'alleles' which when hemizygous or homozygous (as in *a* or *α* haploid cells or *a*/*a* or *α*/*α* diploid cells) confer an ability to mate with cells of the opposite mating type and when heterozygous (as in *a*/*α* diploid cells) turn off mating functions and allow the cell to sporulate[1]. wver, in cells containing the homothallism gene (*HO*), *MATa* and *MATα* are interconvertible, switching mating type at almost every cell division until conjugation leads to the formation of a stable *a*/*α* diploid whereupon the *MAT* alleles are stable[4,5].

In addition to the *HO* gene, an *a* to *α* switch requires another locus, *HMLα*, located on the left arm of chromosome III. Similarly, an *α* to *a* interconversion requires *HMRa*, located at the far end of the right arm of chromosome III[6,7]. Genetic[8] and physical[2,3] analyses of the *MAT* loci have revealed that interconversion occurs by a replacement of information present at *MAT* with a copy of information of the opposite mating type present at one of the *HM* loci. In other words, *HMLα* is a silent or unexpressed copy of *MATα*, and *HMRa* is a silent copy of *MATa*. The physical structures and chromosomal location of *MATa* or *MATα*, *HMLα* and *HMRa* are depicted in Fig. 1. At the centre of each locus lies a sequence specific to the mating type, either a 650-base pair *a* specific (Y*a*) or 750-base pair *α* specific (Y*α*) sequence. In most strains *HML* contains Y*α* and *HMR* contains Y*a*. The sequences flanking Y are found at both silent and active loci—a 700-base pair region to the left of Y (called X) and a 230-base pair sequence to its right (called Z1). Two further blocks of DNA are found at both *MAT* and *HML*—700 base pairs adjoining the left end of X (called W) and 90 base pairs adjoining the right end of Z1 (called Z2). W and Z2 are found at *MAT* and *HML* but not at *HMR*, irrespective of whether *a* or *α* information is present.

MAT seems to determine cell type by the control of unlinked *a* or *α* specific genes rather than by direct expression of all structural information required for mating[9]. *MATα* performs this function through the action of at least two genes, *α*1 and *α*2 (ref. 9). The *MATα*1 gene product is necessary for the expres-

0028-0836/81/040244—07$01.00

Table 1 Relative level of *MAT* transcripts in different strains

Genotype		RNA *a*1	*a*2	*α*1	*α*2
HMLα MATa	*HMRa*	++	++	−	−
HMLα MATα	*HMRa*	−	−	++	++
HMLα MATa/MATα	*HMRa*	++	++	−	+
HMLα MATa/matα2	*HMRa*	++	++	++	++
HMLα mata1/MATα	*HMRa*	++	++	++	++
*HMLα MATa SIR*1	*HMRa*	ND	++	±	±
*HMLα MATa SIR*3 or 4 23°C	*HMRa*	ND	++	−	−
*HMLα MATa SIR*3 or 4 34°C	*HMRa*	ND	++	−	+
*HMLα MATα/MATα SAD*1/*SAD*1	*HMRa*	−or±	−or±	++	++
HMLα MATα/a-lethal (HΔ)	*HMRa*	++	++	−	+

The relative levels of each *MAT* transcript in different strains are shown. + + Signifies the highest level seen for a given transcript, + signifies a significant or 3- to 10-fold reduction, ± signifies a 10- to 100-fold reduction and − signifies our inability to detect it. No correspondence is intended for comparisons between transcripts; for these, see the text. Most of the data summarized here can be found by examining Fig. 3. Sometimes ± is written when no such transcript is visible in Fig. 3. This is due to inadequate reproduction of the latter. The Hawthorne deletion removes all DNA on chromosome III between *MAT* and *HMR*, due to an intrachromosomal recombination between these two loci[3]. The *SAD*1 mutation is also due to a recombination between *MAT* and *HMR*, but is an interchromosomal recombination that results in the duplication of all DNA on chromosome III between *MAT* and *HMR* (J. Hicks, personal communication). ND, not determined.

sion of genes unlinked to *MAT* that specify an *α* mating type. *MATα*2, on the other hand, is necessary for repressing *a* specific genes which are otherwise expressed constitutively and would therefore antagonize the expression of an *α* mating type. This model[9] for the determination of mating type implies that *MATa* plays no part in the specification of an *a* mating type as the genes necessary are constitutively expressed in the absence of the *α*2 gene. A gene at *MATa* (*a*1) is, however, necessary for specifying, in conjunction with the *α*2 gene, the non-mating *a*/*α* diploid cell type and therefore the ability to sporulate[10].

The mating type genes, although also present at the silent loci *HMR* and *HML*, are normally exclusively expressed at *MAT*. Recessive mutations at a number of unlinked loci(*SIR*1, 2, 3 and 4)[11,12] allow the silent copies to be expressed, suggesting that *HML* and *HMR* are under negative control of the *SIR* gene products.

Our aim here is to define the process whereby ty genes at *HMRa* and *HMLα* are activated on transposition to *MAT*. We have therefore focused on the location and control of transcripts made from mating type loci. Our results reveal that *MATa* and *MATα* each produce two transcripts (*a*1 and *a*2, *α*1 and *α*2) neither of which is made at their corresponding silent copies *HMRa* and *HMLα*, even though all transcript sequences and their immediate surroundings are present there. More precisely, the sequences flanking the left-hand end of each silent locus is apparently responsible, in conjunction with *SIR* gene products, for preventing the initiation of transcription within the Y regions at the centre of each locus. This situation is reminiscent of position effects in *Drosophila*[13] and similar phenomena recently discovered at the haemoglobin locus in humans[14].

In addition to defining the control of transcription at the silent (*HM*) loci, our results have revealed that *MAT* controls its own transcription; *MATa*1 and *MATα*2 together repress the transcription of *MATα*1 in *a*/*α* diploids, thereby ensuring their non-mating phenotype.

MAT transcripts

We have mapped RNA transcripts in the region of *MAT* by two different methods, R-looping[15] and S_1 nuclease protection[16]. We have used the former to estimate the number and approximate position of transcripts and the latter to discover their direction of transcription and the position of their termini at a nucleotide level.

R-looping

The details of our R-looping are described in Fig. 2 and its legend. Figure 2*A* shows typical examples of R-loops formed between linearized *MATa* or *MATα* plasmid DNA and poly(A)$^+$RNA from *a* or *α* cells. Figure 2*B* shows our conclusions, which can be summarized as follows. First, *a* cells contain two distinct RNA species homologous to *MATa* in roughly equal abundance. One, which corresponds to the *a*1 gene[17], is about 450 base pairs and is transcribed from the Y*a* region with its (centromere proximal) left-hand terminus about 100 base pairs to the right of the X–Y*a* boundary. The other transcript, which we call *a*2, is about 600 base pairs long and is found within the X region with its right-hand (centromere distal) end near the X–Y*a* boundary. Neither *a* transcript seems to have an intervening sequence sufficiently large to be detected by electron microscopy. Second, *α* cells also contain two distinct RNA species homologous to *MATα*. One, which corresponds to the *α*1 gene[17], is about 700 base pairs long and is transcribed from a region extending from the middle of the Y*α* to the end of Z2. The other, which corresponds to the *α*2 gene (ref. 17), is about 720 base pairs long and is transcribed from the X region with its right-hand end just within the Y*α* region. Neither of the *α* transcripts seem to have intervening sequences.

S_1 mapping

Figure 3 shows the strategy used to map the exact 5′ and 3′ termini of all four *MAT* transcripts. We have used the extent of protection from S_1 nuclease, by RNA of single-stranded end-labelled restriction fragments, as a measure of the distance from a labelled restriction site to an RNA terminus. The details of this analysis are described in Fig. 3 and its legend (Table 2 shows the genotype of the strains used in Fig. 3). In the text, therefore, we will confine ourselves to its conclusions.

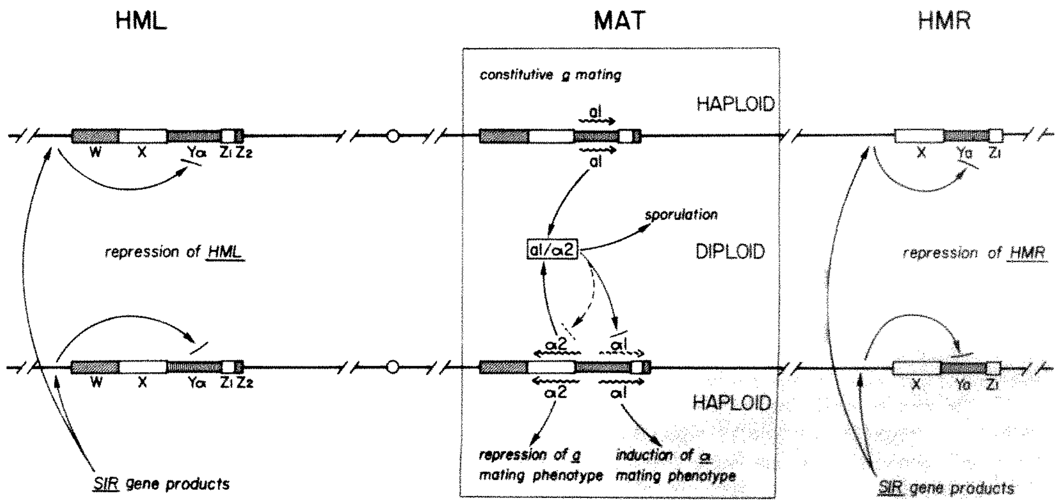

Fig. 1 An overview of yeast mating type loci on chromosome III and the control of cell type by *MATa* and *MATα*. The boxed area refers to the activity of *MATa* and *MATα* in their determination of *a*, *α* or *a*/*α* cell types. The rest of the figure sets these activities in the perspective of other 'silent' copies of *MAT* on the left (*HMLα*) and right (*HMRa*) arms of chromosome III. A description of the comparative structures of *MAT*, *HML* and *HMR* is given in the text. Positive controls are represented by connecting arrows and negative controls by arrows interrupted by a bar.

Table 2 Genotype of strains used

No.	Strain	Genotype		Source
S1	XP8-4A	*MATa ho his6 leu1 met1 trp5-1 gal2 can1*	isogeneic derivatives of XT 1172-S245C	P. Kushner
S2	XP8-10B	*MATα ho his6 leu1 met1 trp5-1 gal2 can1*		P. Kushner
S3	XP11	XP8-4A × XP8-10B		P. Kushner
S4	XR29-10C	*MATa ho sir1-1 ade6 arg4 leu2 trp1 RME*		G. Sprague

S15	G200-15a	*matα2-1 ho sir1-1 ade6 met1 his6 RME*		G. Sprague

(1) The *a*1 and *a*2 genes are transcribed in opposite and diverging directions. The *a*1 transcript is initiated about 90 base pairs to the right of the X–Y*a* (see Figs 3, 4) boundary and extends rightward 510–530 base pairs through the Y*a* region (see Fig. 3, fragment 6). The *a*2 transcript, on the other hand, is initiated about 50 base pairs to the left of the X–Y*a* boundary (Figs 3, 4) and extends leftwards through the X region for 600 base pairs (Fig. 3, fragment 1).

(2) The α1 and α2 genes are also transcribed in opposite and diverging directions. Both are initiated within the Yα region—the α2 gene at a point about 90 base pairs (Figs 3, 4) and the α1 gene at a point about 300 base pairs from the X–Yα boundary (Figs 3, 4). The *a*2 and α2 transcripts have exactly the same termination point (Fig. 3, fragment 1).

(3) All genes, to a greater or lesser extent, have heterogeneous 5′ and 3′ termini. The 5′ end of the *a*2 transcript is a good example of this heterogeneity. Essentially the same spectrum of termini is found, barring a consistent 5-base pair difference, whether S_1 or the single-strand specific exonuclease ExoVII (ref. 16) is used to degrade unprotected fragment 2 DNA (Fig. 3). This suggests that the pattern seen is a true reflection of RNA termini and not an S_1 degradation artefact. We do not know, however, whether this heterogeneity of RNA termini is due to genuine heterogeneous initiation (or termination) or to processing or degradation.

(4) We have mapped all transcript sequences between their termini by the S_1 protection method. This has been achieved either by mapping both 5′ and 3′ termini from a common site within the gene (for example, *MATa*2, Fig. 3) or by also analysing the protection by RNA of end-labelled DNA fragments internal to the gene (such as *MATa*1, Fig. 3). As a result, we have shown that none of the *MAT* transcripts has an intervening sequence between the termini defined by our analysis. This, however, does not exclude splicing of terminal sequences. To exclude the latter in the case of the 5′ end of the *a*2 gene, we have directly compared the results of S_1 and ExoVII digestion and have found no discrepancy except for a consistent 5–7-base pair difference in the length of the protected fragment. ExoVII apparently cannot degrade the last 5 base pairs of a single-strand tail adjacent to duplex DNA (Fig. 3, fragment 2).

Control of *MAT* transcripts

We have studied two aspects of the control of *MAT* transcripts: (1) the regulation of transcription at the 'silent' copies of *MAT*, *HML* and *HMR* and (2) the autoregulation of *MAT* transcription by *MAT* itself.

MATa cells contain neither α1 nor α2 transcripts. Likewise, *MATα* cells contain neither *a*1 nor *a*2 RNAs. This implies that the 'silence' of *HMLα* and *HMRa* is due to a failure in transcription. Recessive mutations at any one of four loci (*SIR* 1, 2, 3 or 4) result in the expression of *HMLα* and *HMRa*[11,12]. Figure 3 (fragment 9) and Table 1 show that, at least in the case of the α2 gene, this is due to a failure to repress *HMLα* transcription. The α2 transcript found in *MATa SIR*1, *SIR*3 or *SIR*4 strains has identical 5′ termini to those found in *a*/α diploids (the most comparable genotype). In the case of *SIR*3 and *SIR*4, we have analysed temperature-sensitive alleles of these loci and have shown that α2 transcription is also temperature sensitive.

SIR gene products, therefore, repress transcription at *HMLα*. It is not clear, however, how this repression is mediated. *MATα* and *HMLα* have identical DNA sequences[18,19] from the left end of W to the right end of Z (a total of 2,500 base pairs), with the apparent promoter region in the middle of this homology. The specific repression of *HMLα* by *SIR* gene products must presumably be effected by flanking sequences outside this homology, beyond the 3′ ends of both α1 and α2 transcripts. The same is presumably true for *HMRa*.

To characterize further the mode of *SIR* gene product action, we have analysed the levels of *a*1 and *a*2 transcription from two variants of *HMRa* which have different flanking sequences; the first is that caused by the Hawthorne deletion[3,20] which replaces the left-hand flanking sequences with those from *MAT* but leaves the right-hand flanking sequences intact, and the second is the converse rearrangement, called *SAD*1 (refs 21, 22), which replaces the right-hand flanking sequences with those from *MAT* but leaves the left-hand flanking sequences intact (J. Hicks, personal communication). Table 1 shows that the former produces the same amount of *a*1 and *a*2 mRNA as *MATa* whereas the latter produces much less of each transcript (<1%). This implies that sequences flanking the left end of *HMRa* are necessary for the *SIR*-mediated repression, whereas those flanking the right end are not. Further explanation of these variant *HMRa* loci is provided in Table 1 legend.

Regulation of *MAT* transcripts by *MATa*1 and *MATα*2

Figure 3 and Table 1 show that the spectrum of *MAT* transcripts in *MATa*/*MATα* diploids is not the sum of its *MATa* and *MATα* parents. Whereas the *a*1 transcript is present in comparable amounts in *a* and *a*/α cells, the α2 transcript is reduced at least fivefold and that of α1 is entirely absent in *a*/α diploids. The α2 transcript starts at three discrete positions in haploids (Fig. 3 and ref. 18), one (<5%) 8 base pairs upstream from the AUG, a second (>90%) 12 base pairs upstream and a third (<5%) 28 base pairs upstream from the AUG. Only the first and second of these transcripts are subject to repression (about 10-fold reduction) in *a*/α diploids. The repression of α1 and α2 transcription in *a*/α diploids requires the action of both *MATa*1 and *MATα*2 genes (Fig. 3, Table 1).

DNA sequence of putative control regions in *MATa* and *MATα*

We have determined the sequence of *MATa* DNA between the starts of *a*1 and *a*2, of *MATα* DNA between the starts of α1 and α2, and the corresponding region of *HML* (see Fig. 4). The following points are noteworthy. First, the region between *a*1 and *a*2 in Y*a* and the corresponding region in Yα have neither extensive sequence homology nor analogous sequence patterns; second, the sequence of the region between α1 and α2 in *MAT*α is identical to that in *HML*α; third, the regions between the structural genes of both *MATa* and *MAT*α contain symmetrical structures (boxed sequences of Fig. 4).

Control of silent copy transcription: a position effect

*MAT*α produces two transcripts that are initiated within 250 base pairs of each other within the unique α region (Yα) and are transcribed in diverging directions. We have shown by DNA sequence analysis[18,19] that for α1 and α2 the entire coding region of the mature transcripts and the sequences between them is virtually identical in *MAT*α and *HML*α. However, *MAT*α and *HML*α differ drastically in their expression of identical *MAT* genes. *HML*α will produce neither α1 nor α2 mature transcript except when mutations at unlinked *SIR* loci are present. The sequence of *MAT*α and *HML*α does diverge beyond the 3′ ends of the transcripts, 800 base pairs to the left of the α2 transcript termination point and at the termination point of the α1 transcript. Somehow, then, sequences downstream of the 3′ ends of the α1 and α2 genes are responsible for the differential repression of transcription at *MAT*α and *HML*α by *SIR* gene products.

A similar situation exists for *MATa* and *HMRa*, although here we have not demonstrated identity at the DNA sequence level. Comparison of the levels of *MATa* transcripts in the Hawthorne deletion[20] and the *SAD*1 mutation[21,22] (Table 1) suggests that sequences flanking the left (centromere proximal) but not the right of *HMRa* are primarily responsible for mediating the repression by *SIR* gene products (Fig. 1).

It is possible that the observed transcripts made from *MATa* and *MAT*α are initiated not, as they seem, within Y*a* and Yα, but from the sequences flanking *MAT*. By this hypothesis, *MAT*α1 would be processed from a long precursor initiated in flanking regions to the left of *MAT*, and *MAT*α2 would be processed from a precursor initiated in flanking regions to its right. One might then interpret the regions of pronounced dyad symmetry in Y*a* and Yα as being for RNA secondary structures involved in processing. The most serious empirical objection to this hypothesis is our observation that *HMRa* with its left-hand flanking sequences replaced by those from *MAT* (the Hawthorne deletion) produces *MAT* levels of both *a*1 and *a*2 transcript, whereas with its right-hand flanking sequences replaced by those from *MAT* (*SAD*1), it barely produces either transcript. In addition to this, the RNA processing hypothesis does not have a convincing explanation for the phenotype of *SIR* mutants. For instance, one would have to postulate that the promoters flanking *MAT* also existed in the nonhomologous sequences flanking *HML*α and *HMRa* but that they were specifically repressed by *SIR* gene products.

If we reject the processing hypothesis, we are forced to conclude that sequences flanking the left end of *HMR* can

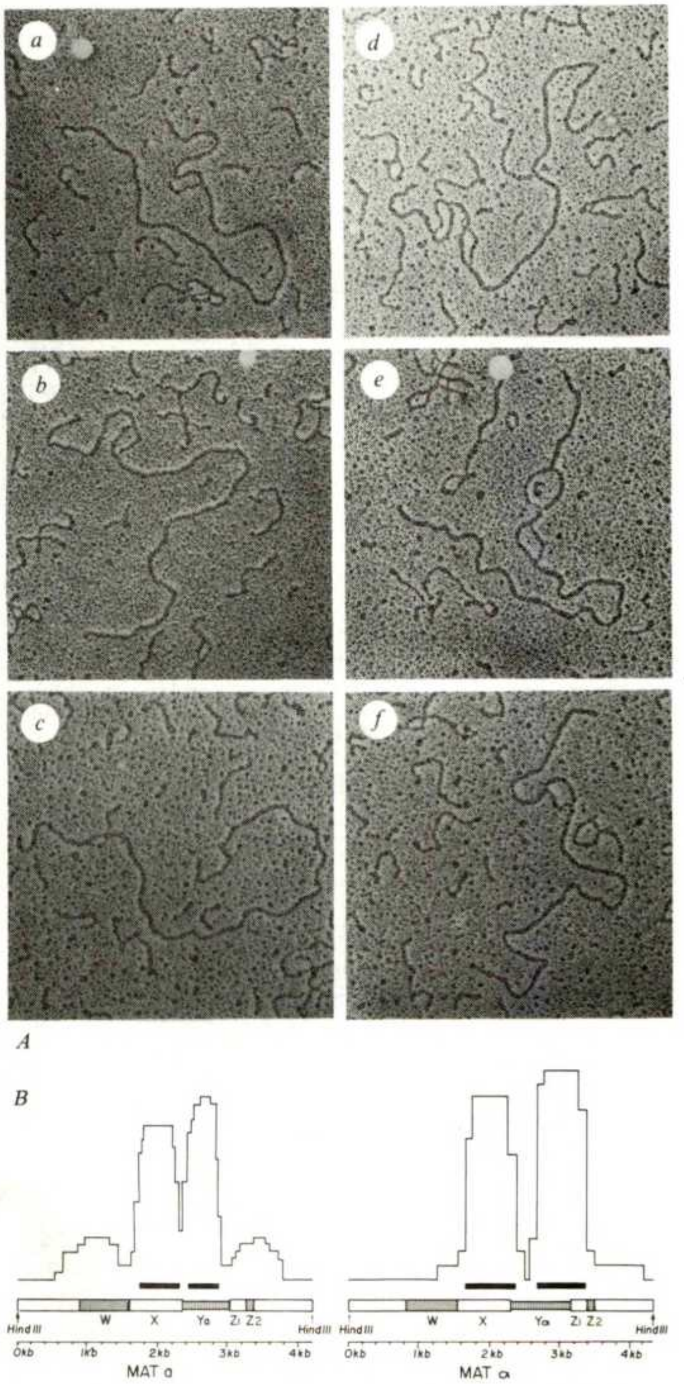

Fig. 2 R-loops formed between linearized *MATa* or α plasmids and poly(A)$^+$ RNA from *a* and α cells. (*a*) *MATa* DNA–*a* RNA: shows *a*1; (*b*) *MATa* DNA–*a* RNA: shows *a*2; (*c*) *MATa* DNA–α RNA: shows α1 (note the tail); (*d*) *MAT*αDNA–α RNA: shows α1 and α2; (*e*) as (*d*); (*f*) *MATa* DNA–α RNA; shows α2 (note the tail). All R-loops were formed between pBR322 containing a 4.3-kilobase *MATa* or *MAT*α *Hin*dIII fragment (inserted into its *Hin*dIII site with the centromere distal side towards the *Bam*Hi site of pBR322) and poly(A)$^+$ RNA made from *a* (S1) or α (S2) cells. The procedure used was essentially that described by Kaback *et al.*[27]. This method involves the use of cross-linked DNA which occasionally results in R-loops being interrupted by a cross-link; see, for instance, (*d*). Plasmid DNA was linearized by restriction with endonuclease *Bam*HI, extracted once with phenol/chloroform, ethanol precipitated, cross-linked with trioxsalen (2–3 cross-links per molecule) and hybridized at 52°C for 15–18 h at $5\ \mu g\ ml^{-1}$ with $1\ mg\ ml^{-1}$ poly(A)$^+$ RNA in a total volume of $25\ \mu l$ sealed in a glass capillary. After hybridization, $4\ \mu l$ of deionized glyoxal (Baker) was added to the pre-cooled (to 0°C) hybridization mixture, which was then incubated at 12–14°C for 2 h. Spreading was perfomed directly without prior purification of RNA loops from the unhybridized RNA, by diluting an aliquot of the glyoxalated mixture with 9 vols of 0°C TE buffer (10 mM Tris-HCl, 1 mM EDTA, *p*H 8.0) and adding $1-2\ \mu l$ of the diluted R-loops to $100\ \mu l$ of spreading solution (50% formamide to be spread on a 20% formamide hypophase). Spreads, their preparation for electron microscopy, their viewing and photography were performed as previously described[2]. A quantitative analysis of the R-loops seen is shown in the lower half of the figure. We have seen R-loops within most regions of the *MAT Hin*dIII fragment, but have only been able to characterize properly transcripts from its central *MAT* region, the others being too rare and having insufficiently precise end points to be characterised by this technique (see later S_1 mapping). *MATa* and *MAT*α both produce two discrete transcripts that are apparent in the histograms beneath the R-loop pictures. The apparent difference between *MATa* and *MAT*α in the occurrence of flanking transcripts is probably due to the *MAT* specific transcripts from the former being at a lower level (of detection, possibly) than those from the latter. Underneath the histogram is a map of *MAT* with the position of *MAT* transcripts placed on it. These positions were estimated by averaging the end points of the molecules observed. The *MAT*α transcripts both overlap homologous (X or Z) and unique (Yα) regions. Thus, one might predict the occurrence of different types of R-loop if α RNA was hybridized instead to *MATa* DNA. One should find in the case of α2 a slightly shorter R-loop with a short RNA tail and in the case of α1 a very much shorter R-loop with a long RNA tail. *We have consistently found the latter structure* in the predicted position but have only found individual examples of the former, (see (*c*) and (*f*), respectively).

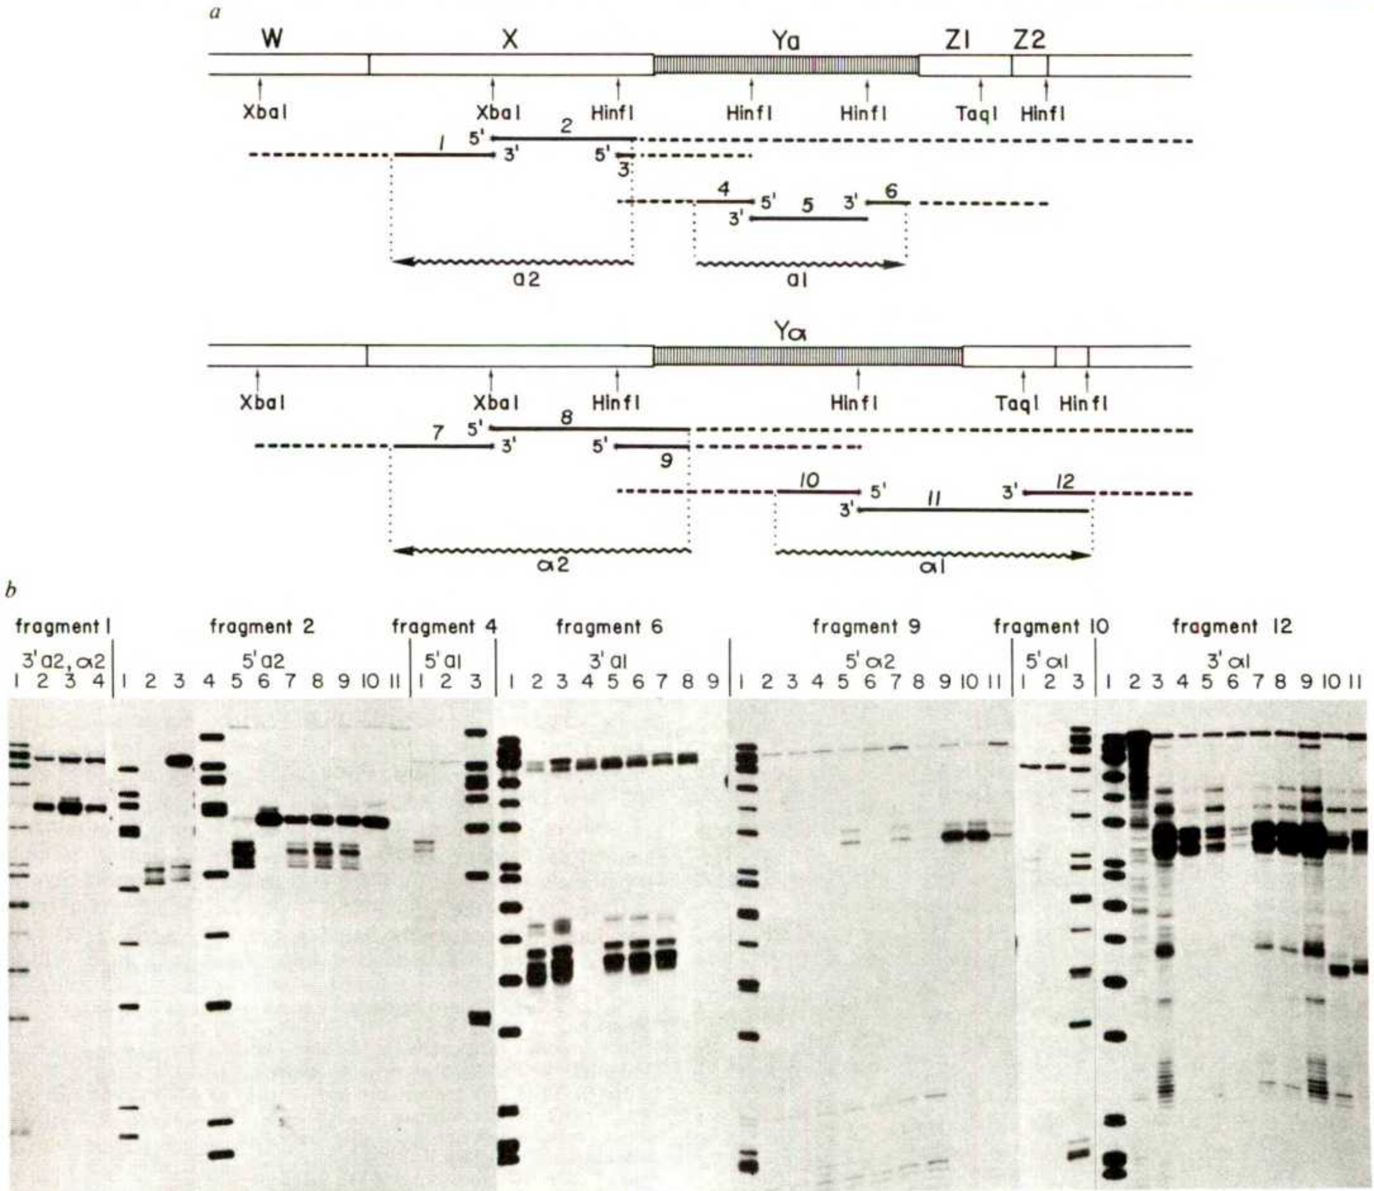

Fig. 3 S_1 transcription mapping. The upper part of the figure shows the strategy by which we have mapped the exact 5′ and 3′ termini of all four *MAT* transcripts. By hybridizing total poly(A) RNA to end-labelled separated strands of restriction fragments, then measuring the lengths of the ^{32}P-DNA strands remaining after nuclease digestion, we have measured the distance from each RNA terminus to a physically mapped restriction site. The single-stranded, end-labelled fragments used as probes are given numbers (1–12). The *Xba*I, *Hin*fI and *Taq*I fragments were derived from wild-type *MATa* or *MATα* DNA (*Hin*dIII fragments) cloned in pBR322. Fragment 2 was derived from an *in vitro* manufactured mutant with a *Xho*I site within Y*a* (*mata*23, ref. 17). 5′* at the end of each fragment indicates an end labelled by polynucleotide kinase and 3′* indicates an end labelled with Klenow DNA polymerase. Solid lines indicate stretches of DNA protected from S_1 nuclease by RNA whereas dashed lines indicate sensitivity. Apart from the four major transcripts presented here, we have evidence for at least three more transcripts within the *MAT* region (W–Z of fig. 2). One of these, made at least in *a* cells (see R-looping), covers part of the W region. Another (called *MAT*3), made from both *MATa* and *MATα* in *a*/*α* cells, starts some point before the *Taq*I site of Z1 and ends at the same points as the *MATα*1 transcript. S_1 protection experiments comparing *a*/*α* cells with *a* lethal (Hawthorne deletion)/*α* cells[20] show that half of these *MAT*3 transcripts cease to have any homology to *MATa* from a point 88 base pairs from the *Taq*I site. This implies that the Z1–Z2 boundary occurs at this point. A third minor transcript, made at least in *α* cells, starts somewhere to the right of the *Taq*I site to the right of the Z1 *Taq*1 site, and ends somewhere near or close to the left of the latter. We do not know the biological significance of these minor transcripts. Only those restriction sites used for S_1 mapping are shown. The lower half of the figure presents the autoradiograms of end-labelled fragments. The markers are either ΦX174 or pBR322 cut with *Hin*fI and end-labelled with Klenow DNA polymerase. The numbers in parentheses after the *MAT* genotypes refer to the strain number of Table 2. Unless otherwise stated, all digestions were performed with S_1 nuclease and cells were grown at 30°C in YEPD (1). **Fragment 1 (or 7):** The 3′ end of *MATa*2 and *MATα*2. Protection of fragment 1 or 7 by RNA at 1 mg ml^{-1}. (1) ΦX174, (2) *MATa* (S1), (3) *MATα* (S2), (4) *MATa*/*MATα* (S3). **Fragment 2:** The 5′ end of *MATa*2. Protection of fragment 2 by RNA at 1 mg ml^{-1} (lanes 2, 3) or 2.5 mg ml^{-1} (lanes 5–10). (1) ΦX174; (2) *MATa* (S1)—S_1 nuclease; (3) *MATa* (S1)—ExoVII; (4) ΦX174; (5) *MATa* (S1); (6) *MATα* (S2); (7) *MATa*/*MATα* (S3); (8) *mata*1/*MATα* (S10); (9) *MATa*/*matα*2 (S9); (10) *MATα*/*MATα SAD*1/*SAD*1 (S12); (11) no RNA. The intense band(s) at 400 nucleotides in lanes 6–10 corresponds to *α*2 RNA, which is also homologous to the probe up to the X–Y boundary. **Fragment 4:** The 5′ end of *MATa*1. Protection by RNA at 1 mg ml^{-1}. (1) *MATa* (S1); (2) *MATα* (S2); (3) ΦX174. **Fragment 6:** The 3′ end of *MATa*1. Protection by RNA at 2.5 mg ml^{-1}. (1) ΦX174; (2) *MATa* (S1); (3) *MATa* (S7); (4) *MATα* (S2); (5) *MATa*/*MATα* (S3); (6) *mata*1/*MATα* (S10); (7) *MATa*/*matα*2 (S9); (8) *MATα*/*MATα SAD*1/*SAD*1 (S12); (9) no RNA. **Fragment 9:** The 5′ end of *MATα*2. Protection by RNA at 1 mg ml^{-1}. (1) ΦX174; (2) *MATa* (S1) grown at 23°C; (3) *MATa* (S1) 34°C; (4) *MATa SIR*3 (S5) 23°C; (5) *MATa SIR*3 (S5) 34°C; (6) *MATa SIR*4 (S6) 23°C; (7) *MATa SIR*4 (S6) 34°C; (8) *MATa SIR*1-1 (S4) 23°C; (9) *MATα* (S2) 23°C; (10) *MATα* (S2) 34°C; (11) *MATa*/*MATα* (S3) 30°C. **Fragment 10:** The 5′ end at *MATα*1. Protection by RNA at 1 mg ml^{-1}. (1) *MATα* (S2); (2) *MATa*/*MATα* (S3); (3) pBR322. **Fragment 12:** The 3′ end of *MATα*1. All lanes except lane 2 show protection of fragment 12 by RNA at 2.5 mg ml^{-1}. Lane 2 shows protection of the opposite strand to fragment 12. (1) ΦX174; (2) *MATα* (S2); (3) *MATα* (S2); (4) *MATα* (S2) 0.5 mg ml^{-1} RNA; (5) *MATa* (S1); (6) *MATa*/*MATα* (S3); (7) *mata*1/*MATα* (S10); (8) *MATa*/*matα*2 (S9); (9) *MATα*/*MATα SAD*1/*SAD*1 (S12); (10) *MATa sir*1-1 (S4); (11) *MATa sir*3 (S5) grown at 34°C. Lanes 5 and 6 show bands characteristic of *α*1 termini even though no transcripts with the 5′ sequences of *α*1 have been detected in these strains (see fragment 10). These termini probably belong to a transcript (*MAT*3?) that starts in Z and terminates at the same points as *α*1 (see below). Klenow DNA polymerase and T4 polynucleotide kinase were used to label the 3′ and 5′ ends, respectively, of restriction fragments which were then strand separated by electrophoresis. Kinase reactions and strand separations were done as described by Maxam and Gilbert[28] and the Klenow polymerase I reaction and all further procedures as described by K.A.N. *et al.*[18]. Poly(A)$^+$ RNA and single-strand end-labelled DNA fragments were annealed at 65°C followed by S_1 (or ExoVII) digestion. After digestion the samples were ethanol precipitated, redissolved in NaOH–urea loading buffer and run on 6.0% or 8.0% acrylamide sequencing gels[28]. Gels were exposed to X-ray film plus intensifying screen at −70°C for 1–14 days.

somehow affect the initiation of transcription within Y*a*, a situation reminiscent of position effects in *Drosophila*[13] and similar phenomena at the haemoglobin locus in humans[14].

Possible mechanisms for the position effect

Hypothetical mechanisms for the position effect can be divided into two distinct types: one in which the DNA sequence is solely responsible for the effect and another in which chromosome structure is also involved.

The first type of mechanism could, for example, involve the action of an enzyme like the bacterial type I restriction endonucleases[23], which can recognize a particular sequence on a DNA molecule and then modify or cut the same molecule at a point distant from the recognition site. It is possible that the recognition site for such an enzyme (a *SIR* gene product?) exists within the left-hand flanking region of *HMLα* and *HMRa* and that DNA modification (or some other interaction) subsequently occurs within Y*a* or Y*α*.

There are, of course, many variants of the second type of mechanism in which chromosome structure has an important role. These range from the very general, that *HML* and *HMR* sit within a heterochromatic region, to the very specific, that the precise composition or phasing of nucleosomes is responsible. One can, in fact, distinguish two general pathways whereby the left-hand flanking sequences of *HML* and *HMR* could influence the structure of Y*a* and Y*α*. Information from the flanking sequences could be transmitted to Y*a* or Y*α* either directly by some form of physical bridge or indirectly along the axis of the DNA molecule separating them. Higher order chromosome folding might be involved in the case of the former, whereas the precise phasing of nucleosomes might be involved in the latter.

We propose that of all the possible explanations for the position effect, the most readily tested is the notion that the sequences flanking the left end of *HML* and *HMR* are responsible, possibly in conjunction with *SIR* gene products, for initiating, from left to right, a precise phasing of nucleosomes such that promoters of transcription at Y*a* or Y*α* are either hidden or sites for repressors of transcription (*SIR* gene products) are exposed at these two loci but not at *MAT*. *MAT*, having different flanking sequences, might either be phased differently or not at all (as might be the case for a repressor model). The phasing of nucleosomes could affect the availability or activity of control sequences at Y*a* or Y*α* at two levels. At a gross level, it could be responsible for bringing sequences into juxtaposition or not; for instance, by their being wrapped around the same rather than a neighbouring core particle. At a finer level, it could also, or instead, be responsible for the exact orientation of sequences with respect to their coiling around a core particle; for instance, whether they face in or out.

Possibly relevant to the phasing hypothesis is the recent observation by Hicks (personal communication) that restriction fragments containing *HMLα* and *HMRa* both contain replication origins whereas that containing *MAT* does not. If the inheritance of nucleosomes is conservative, one must postulate some means by which the naked daughter chromatid is rapidly covered with in-phase nucleosomes. This could be more readily achieved if the replication origins are also orgins of phasing, as found in the case of SV40[25]. The proximity of replication origins at the silent copies may be sufficient to effect the correct phasing. On the other hand, one or more *SIR* gene products may be involved in initiating as well as maintaining phasing.

Whatever the mechanism of the position effect on the expression of *MAT* genes, it is worth pointing out possible parallels with various phenomena associated with mating type interconversion. For instance, how does a homothallic yeast cell distinguish *MAT* from *HML* as the target of an interconversion when they are so extensively homologous? It is tempting to speculate that the same property that distinguishes their transcription may also be used to distinguish their roles as donor and recipient in an interconversion of mating type. This notion raises the question of the role of recombinant mating type loci (such as the *MAT*/*HMR* recombinant caused by the Hawthorne deletion) in an interconversion; that is, whether they serve as donors or recipients. Pursuing the analogy still further, a conservative inheritance of nucleosomes at *MAT* or its silent copies may be responsible for the ability of mother cells, but not daughter cells, to undergo mating type interconversion[4,5].

Regulation of *MAT* transcription and the determination of cell type in yeast

Genetic analyses have identified three genes involved in the specification of cell type in yeast: *α*1, *α*2 and *a*1 (refs 9, 10). The present investigation has shown that *MATa* and *MATα* each produce two major transcripts starting in or near their Y regions, one going leftwards and another rightwards. A series of experiments in which plasmids containing *MATa* or *MATα* were mutated *in vitro* and subsequently tested for *in vivo* function have shown that the left *α* transcript corresponds to the *α*2 gene, the right *α* transcript to the *α*1 gene, and the right *a* transcript to the *a*1 gene[17]. This leaves the left (*a*2) transcript unassigned to a known complementation group. The same series of experiments implied that this transcript was, however, not essential for any of the known functions performed by plasmids carrying a wild-type *MATa* fragment; that is, deletions within the *a*2 region had no effect on the plasmid's ability to suppress *α* mating functions or to induce sporulation (in *a*/*α* cells). We therefore believe the *α*1, *α*2 and *a*1 genes to be both necessary and sufficient for specifying all three yeast cell types: the *a* mater, the *α* mater and the non-mating but sporulating *a*/*α* cell[1].

How, then, do these three genes determine cell type? Strathern *et al.*[9] have suggested that the *α*1 gene is necessary for promoting the expression of unlinked *α* specific mating genes and the *α*2 gene for repressing the expression of unlinked and constitutive *a* specific mating genes. With both of these active, as in *α* haploids, *α* specific mating genes will be expressed but *a* specific mating genes not. In the absence of either, as in *a* haploids, only the constitutive *a* specific mating genes will be expressed. The presence, albeit lower, of *α*2 and complete absence of *α*1 transcripts in *a*/*α* diploids therefore accounts for the non-mating phenotype of these cells (Fig. 1).

The repression of *MATα* transcription that results in the complete absence of *α*1 and lowering of *α*2 transcripts in *a*/*α* cells requires both the *a*1 and *α*2 genes. The sequence between the promoters of the *α*1 and *α*2 genes contains a symmetrical region that may be the target of the hypothetical repressor of *α*1 and *α*2. No similar structure is seen near the start of the *MATa*1 transcript, which we have shown to be refractory to the repression by *a*1 and *α*2,

The *a*1 and *α*2 genes are necessary not only for suppressing mating functions in *a*/*α* diploids but also for inducing their ability to sporulate. This function cannot be just a consequence of turning off *α*1 and turning down *α*2 because it can be expressed in circumstances in which the repression of *α*1 and *α*2 is absent[21]. It is, therefore, an independent property of the *a*1/*α*2 state (Fig. 1). Our analysis of transcription in *a*/*α* *SAD*1/*SAD*1 strains suggests that the induction of sporulation by *a*1/*α*2 requires less *a*1 gene product than does the repression of *α*1 and *α*2 transcription. The existence of recessive mutations (for example, *CSP*, ref. 26) that allow sporulation of *a*/*a* or *α*/*α* cells suggests that sporulation is normally under negative control. It is tempting to speculate that the *a*1/*α*2 repression of *α*1 transcription and induction of sporulation are mediated by a common mechanism; that is, the transcription of *CSP* is repressed by *a*1/*α*2 in a manner similar, though not identical, to that of *α*1.

As the amino acid sequence of all *MAT* gene products has recently been deduced from their DNA sequence[18,19], we may speculate on the physical mechanisms by which they control cell type. We know that some of the consequences of their action are regulation of transcription. However, we do not yet know whether they act so themselves or through intermediates. With this in mind, it is interesting that the *MAT* gene products are all basic proteins that may be capable of binding to DNA.

Fig. 4 DNA sequences around the starts of *MAT* transcripts. The DNA sequences around and between the starts of *MATa* and *MATα* transcripts are shown. The sequences were determined by the method of Maxam and Gilbert[28]. The sequencing strategy will be described elsewhere along with a more complete sequence of the region[19]. In *MATa*, the X–Y*a* boundary is marked by a vertical bracket. The equivalent boundary for *MATα* and *HMLα* (X–Y*α*) is 48 base pairs beyond the left end of the sequence shown. Putative coding sequences are signified using the one-letter amino acid code. Those of the *a*2 transcript are not marked because there is no evidence that this transcript encodes a functional protein. Arrows mark the start points of RNAs as determined by S_1 mapping. Each transcript has two or more start points. The boxed sequences are regions that have a dyad symmetry around an axis marked with an asterisk. At each end of the *α* symmetrical region is a 7-base pair inverted repeat sequence that would extend the region of perfect symmetry except for 7 extra base pairs inserted between it and the left-hand end of the symmetrical region. The dashed boxes in the *MATa* sequence are regions of symmetry with respect to purine and pyrimidine content.

We thank Hal Weintrub for helpful discussions on nucleosome phasing, Don Hawthorne and George Sprague for supplying crucial strains, and Jane Garnett for help in compiling the paper. This investigation was supported by a grant to B.D.H. from the National Institute of Medical Sciences, a Jane Coffin Childs postdoctoral fellowship awarded to K.A.N. and a Damon Runyon-Walter Winchell Cancer fund postdoctoral fellowship to K.T.

Homology and non-homology at the yeast mating type locus

George F. Sprague Jr, Jasper Rine* & Ira Herskowitz

Institute of Molecular Biology and Department of Biology, University of Oregon, Eugene, Oregon 97403

Four mutations of the α mating type locus of Saccharomyces cerevisiae *have been analysed to determine their relationship to the* a *mating type locus.* Matα$^+$ *recombinants are produced by* matα2$^-$/MATa *but not by* matα1$^-$/MATa *diploids.* MATα *and* MATa *thus contain regions of homology (coding for at least part of* MATα2*) and regions of non-homology (coding for at least part of* MATα1*)—the genetic determinant for cell type is larger than the non-homologous sequence seen by DNA–DNA heteroduplexes and genetic analysis. The segment transposed in mating type interconversion includes both types of sequence.*

THE mating type locus determines which of three distinct and complex cell types (*a*, *α* and *a*/*α*) is expressed by the yeast, *Saccharomyces cerevisiae*. It has been proposed that alleles of this locus, *MATa* and *MATα*, code for different regulators controlling the expression of unlinked genes necessary for mating and sporulation[1–3]. Several lines of evidence suggest that *MATa* and *MATα* are 'complex' alleles, that is, are genetic alternatives coding for several different functions. First, there are at least two complementation groups in *MAT*α, α1 and α2; only one complementation group is known for *MATa*. *MAT*α1 and *MAT*α2 are required for mating in haploids; *MAT*α2 and *MATa* are required for sporulation in diploids[2-5]. Second, heteroduplex analysis of cloned *MATa* and *MAT*α DNA (as well as cloned cryptic mating type information from the *HML*α and *HMRa* loci) reveals a region of non-homology (region Y) between *a* and α information of ~750 base pairs (Y*a* for *a* and Yα for α). Heteroduplexes between *HML*α and *MATa* and between *HMRa* and *MAT*α show that the non-homology region is flanked by regions of apparent homology of at least 700 base pairs on one side (the X region) and at least 200 base pairs on the other side (the Z region)[6,7]. The physical picture of the mating type locus derived from heteroduplex analysis does not provide information on the coding regions within the mating type locus. Thus, they could be entirely within the non-homology (Y), entirely within the regions of apparent homology (X and Z) or distributed throughout X, Y and Z regions. We have made detailed studies of four mutations of the α mating type locus, two in each of the known complementation groups, to determine their genetic relationship to the *a* mating type locus. To investigate whether *mat*α mutations are in regions of homology or non-homology with respect to *MATa*, we have constructed a series of *mat*α$^-$/*MATa* diploids and have analysed the meiotic products for *MAT*α$^+$ recombinants. If a mutation is in a region of *MAT*α that is non-homologous with *MATa*, genetic rescue of the wild-type allele from *MATa* should not be possible, but genetic rescue should be possible if the mutation is in a region that is homologous with *MATa*. The mutations analysed here (isolated by MacKay and Manney[8]) all differ: *mat*α1-5 causes a temperature-sensitive mating phenotype (G. F. S. and J. R., unpublished), *mat*α1-2 is an *amber* mutation[9], and *mat*α2-1 and *mat*α2-4 have different effects on sporulation (G. Sprague and J. Strathern, unpublished). We report here results obtained with three types of diploid: *mat*α1$^-$/*MATa*, *mat*α2$^-$/*MATa*, and *mat*α1$^-$/*mat*α2$^-$, which show that the wild-type alleles of *mat*α2 mutations but not of *mat*α1 mutations are rescued from *MATa*.

---

* Present address: Department of Biochemistry, Stanford University School of Medicine, Stanford, California 94305.

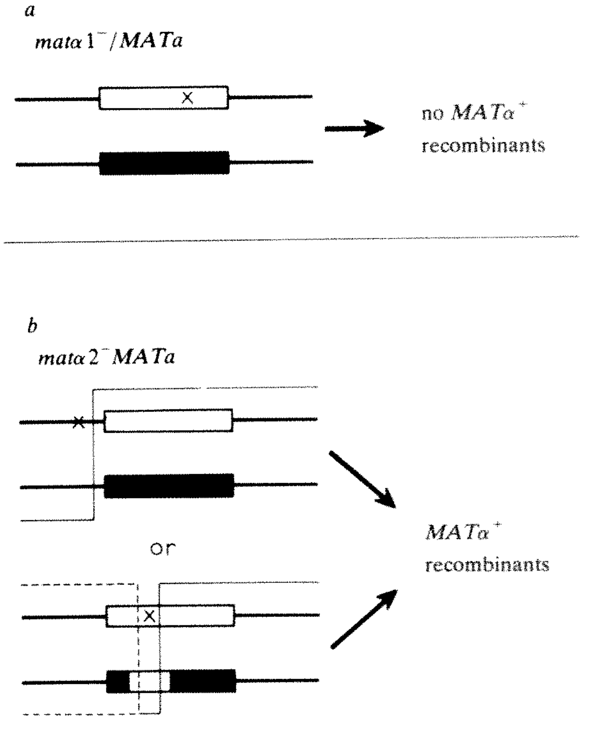

Fig. 1 Interpretation of genetic rescue experiments between *mat*α mutations and *MATa*. X, sites of *mat*α1 or MATα mutations. *a*, Failure to obtain *MAT*α$^+$ recombinants in crosses between *mat*α1-5 and *MATa*. Filled and open rectangles indicate non-homologous segments of *MATa* and *MAT*α, respectively. *b*, Production of *MAT*α$^+$ recombinants in crosses between MATα$^-$ and *MATa*. Upper diagram: symbols as in *a*. Lower diagram: a region of homology is located between sequences that are non-homologous in *MATa* and *MAT*α.

Production of *MAT*α$^+$ segregants from *mat*α$^-$/*MATa* diploids

Segregants that mate as α cells are found at the same low frequency (~5×10^{-5}) among the meiotic products of two *mat*α1$^-$/*MATa* diploids carrying different *mat*α1 mutations—*mat*α1-5 and *mat*α1-2 (strains DG1 and DG2, respectively, Table 1). Subsequent crosses show that the α mating phenotype is due to the presence of a wild-type α mating type locus in these recombinants (see Table 1 legend). Because these *MAT*α$^+$ segregants may have arisen by recombination between the *mat*α1 allele and cryptic α information at the *HML*α locus rather than by recombination between *mat*α1 and *MATa*, we have constructed a *mat*α1-5/*MATa* diploid lacking cryptic α information. Such a strain (DG3, *mat*α1/*MATa* *HMLa*/*HMLa* *HMRa*/*HMRa*) does not yield *MAT*α$^+$ segregants. This result indicates that the wild-type allele of the *mat*α1-5 mutation cannot be rescued from *MATa*.

In contrast to these results, *MAT*α$^+$ segregants arise at high frequency (~2×10^{-3}) from *mat*α2$^-$/*MATa* diploids carrying either of two different *mat*α2 mutations, *mat*α2-4 and *mat*α 2-1. This result has been documented most thoroughly for the *mat*α2-4 mutation. In particular, the production of *MAT*α$^+$ segregants from *mat*α2-4/*MATa* diploids is not dependent on the presence of the *HML*α allele (Table 1: compare strain DG5, which is homozygous for *HMLa* and *HMRa*, with strain DG4, which is *HML*α *HMRa*). Two observations indicate further that the *MAT*α$^+$ segregants are the products of recombination between *mat*α2-4 and *MATa*. First, the frequency of *MAT*α$^+$ segregants is at least 100-fold higher than the reversion frequency of the *mat*α2-4 mutation (HG2, Table 1). Moreover, half of the *MAT*α$^+$ segregants are recombinant at the closely linked *CRY*1 locus, which indicates that *MAT*α$^+$ has been generated by a recombination event rather than by reversion.

It is possible that the observed frequency of *MAT*α$^+$ segregants from *mat*α2-4/*MATa* diploids is an overestimation of the true frequency, because DG4 and DG5 are defective in the *MAT*α2 function and therefore sporulate poorly. Wild-type *MAT*α recombinants or revertants that arise in DG4 or DG5 may be enriched among the spore progeny due to efficient *MAT*α$^+$-promoted sporulation. To test this possibility, we determined the frequency of *MAT*α$^+$ segregants from a *mat*α2-4/*MATa* diploid (DG6) homozygous for a mutation, *sir*1-1, which permits *in situ* expression of the cryptic mating type information[10]. This diploid sporulates well because wild-type *MAT*α2 function is provided by α information at *HML*α. *MAT*α$^+$ segregants arise from DG6 at the same frequency as from DG4 and DG5 (Table 1). A *mat*α2-1/*MATa* *sir*1-1/*sir*1-1 diploid likewise yields *MAT*α$^+$ recombinants at high frequency (DG7, Table 1). Consequently, the frequency of *MAT*α$^+$ segregants from diploids DG4, 5, 6 and 7 seems to be a true reflection of recombination between *MATa* and the MATα$^-$ mutations and is not biased by a selection for revertants or recombinants.

To evaluate the significance of the recombination frequencies reported above, we have determined the frequency of recombination between two *mat*α mutations. The frequency of recombination in *mat*α1$^-$/*mat*α2$^-$ diploids (~10^{-2}, DG8 and DG9, Table 1) is similar to that obtained from MATα$^-$/MATa diploids. This value for recombination across homologous mating type loci places an upper limit on the frequency of

*MATα*2$^+$ recombinants expected from *matα*2-1/*MATa* or *matα*2-4/*MATa* diploids (for example, DG4, 5, 6, 7 above), in which *MATα*2$^+$ recombinants are formed by a recombination event occurring between the *matα* mutation and the end of the *MATa* non-homology region.

Table 1 Frequency of α mating type clones obtained

Strain	Genotype	Frequency of α-maters Clone	 Frequency
DG1	*matα*1-5 / *MATa*	A B	$\sim 4\times10^{-5}$ (2) $\sim 6\times10^{-5}$ (3)
DG2	*matα*1-2 / *MATa*	A B	$\sim 1\times10^{-4}$ (2) $\sim 4\times10^{-5}$ (1)
DG3	*HMLa matα*1-5 *HMRa* / *HMLa MATa HMRa*	A B	$<1.5\times10^{-5}$ (0) $<1.2\times10^{-5}$ (0)
DG4	*matα*2-4 / *MATa*	A B	1.6×10^{-3} (54) 2×10^{-3} (60)
DG5	*HMLa matα*2-4 *HMRa* / *HMLa MATa HMRa*	A B	1.3×10^{-3} (21) 1.3×10^{-3} (48)
DG6	*matα*2-4 *sir*1-1 / *MATa sir*1-1	A B	3×10^{-3} (54) 4×10^{-3} (54)
DG7	*matα*2-1 *sir*1-1 / *MATa sir*1-1	A B	3×10^{-3} (21) 2×10^{-3} (27)
DG8	*matα*1-5 / *matα*2-4		$\sim 4\times10^{-3}$ (2)
DG9	*matα*1-5 / *matα*2-1		9×10^{-3} (9)
HG1	*matα*1-5	A B	$<5\times10^{-5}$ (0) $<3\times10^{-5}$ (0)
HG2	*HMLa matα*2-4 *HMRa*	A B	$<4\times10^{-5}$ (0) $<4\times10^{-5}$ (0)

Strains and markers: Diploid strains were constructed by prototroph selection. Genotypes were confirmed by analysis of the segregants. HG1 and HG2 were the *matα* parents of DG1 and DG5. All diploids except DG1 were heterozygous at the *CAN*1 locus, which segregates independently from *MAT* (ref. 8). DG1, 2, 3 and 5 were *cry*1/*CRY*1, with *cry*1 coupled to *MATa* in DG2 and *CRY*1 coupled to *MATa* in the others. DG3 and DG5 were shown to be homozygous for *HMLa* and *HMRa*; other strains are assumed to have the standard *HMLα HMRa* genotype. Isolation of meiotic products: Haploid segregants were isolated from two clones from each diploid (DG1, 2, 3, 4, 5, 6, 7) by random spore analysis: asci from sporulated cultures were treated with Glusulase (Endo), sonicated and plated onto medium containing cryptopleurine (for DG1) or canavanine (for the other diploids), which selects for haploids because resistance alleles *cry*1 and *can*1 are recessive[8,15]. Haploid segregants were isolated from sporulated cultures of DG8 and DG9 by ascus dissection. Assay of *MATα* segregants: Spore clones with α mating type were identified by replica plating colonies onto a lawn of *a* cells and assaying mating by prototroph formation. Frequency was the number of α colonies per total number of spore clones tested. Numbers in parentheses indicate the number of α colonies observed. Subsequent crosses showed that all α colonies tested were *MATα*. Tests were performed on all α segregants from DG1, DG2, DG8 and DG9; on 3 each from DG4A, DG4B, DG5B, DG6A and DG6B, and on 19 from DG5A. Sporulation: *MATα*2/*MATa* strains DG1, DG2 and DG3 sporulated efficiently (60% for DG3). *matα*2/*MATa* strains DG4 and DG5 sporulated poorly (4% for DG5). *matα*2/*MATa* strains DG6 and DG7 sporulated efficiently due to homozygosity for *sir*1-1 (47% sporulation for DG6). *matα*1/*matα*2 strains DG8 and DG9 sporulated (albeit inefficiently) due to homozygosity for *rme*1, which bypasses the requirement of *MATα*2 and *MATa*1 for sporulation[4].

Regions of homology and non-homology

Our genetic results indicate that *MATα* and *MATa* contain regions of homology as well as regions of non-homology: two sites in *MATα*1 are non-homologous with *MATa*, and two sites in *MATα*2 are homologous with *MATa* (Fig. 1). Studies are in progress to determine whether *MATa*$^+$ recombinants can be obtained from *mata*$^-$/*MATα* diploids and *mata*$^-$ recombinants from MATα$^-$/MATa diploids. Although the extent and position of the homology between *MATα*2 and *MATa* cannot be rigorously determined from our data, the similar frequencies of *MATα*$^+$ recombinants from *matα*2/*MATa* and *matα*2/*matα*1 diploids lead us to favour the view that the homologous sequence is outside the non-homologous sequence (Fig. 1*b*, top) rather than being within it (Fig. 1*b*, bottom). These results therefore suggest that the genetic information determining cell type is larger than the non-homologous sequence observed in heteroduplexes between *MATa* and *MATα* (refs 6, 7). This view is reinforced by the observation that the α mating type locus codes for two transcripts, one primarily within the non-homologous region, and the other primarily outside this region[11,12]. Our observations on homology and non-homology between *MATα* and *MATa* lead us to propose that the latter RNA codes for *MATα*2 and the former for *MATα*1.

Yeast cells can change the information present at *MAT* (an *a* or α 'cassette') by replacing it with a cassette from *HML* or *HMR* (reviewed in ref. 3). This change reflects a transposition of at least the Y region information from *HML* or *HMR* to *MAT* (refs 7, 13). Is the Y region the only information that is transposed? Our findings indicate that homologous sequences are also transposed. This conclusion follows from the observations that MATα mutations can be switched to *MATα*2$^+$ by mating type interconversion[14] and, as shown here, that MATα mutations are outside the non-homology region. Hence, the cassette that is transposed during mating type interconversion must include not only Y information but also flanking sequence information (from X or Z).

We thank Kim Nasmyth and Jim Hicks for communicating their results before publication, Karen Sprague for comments on the manuscript, Julie Dunn for preparation of the manuscript, and David Hagen for preparation of the figure. Nucleotide sequences at host–proviral junctions for mouse mammary tumour virus

John E. Majors & Harold E. Varmus

Department of Microbiology and Immunology, University of California, San Francisco, California 94143

Proviruses cloned from rat cells infected with mouse mammary tumour virus, a B-type retrovirus regulated by glucocorticoid hormones, show the structural features of transposable elements: short inverted repeats conclude long direct repeats at the ends of viral DNA, and short sequences of cellular DNA are duplicated during integration and flank each provirus. The integrative mechanism joins a precise site in viral DNA to non-homologous sites in host DNA.

INTEGRATION of a DNA copy of viral RNA into the genome of the host cell is a central event in the life cycle of retroviruses (see Fig. 1; for a review see ref. 1). The viral genome is composed of two identical subunits of single-stranded RNA, each 5–10 kilobases long. On infection, a linear duplex form of viral DNA, slightly longer than a subunit of viral RNA and bearing long terminally repeated units (LTRs)[2–4], is synthesized in the cytoplasm. The LTRs are composed of sequences unique to the 3′ and 5′ ends of viral RNA (U_3 and U_5) and a single copy of a short sequence (R) repeated at the ends of viral RNA, in a manner represented by U_3RU_5 (Fig. 1). Some of the linear unintegrated DNA is carried to the nucleus where a portion at least is converted to closed circular species[5], mostly monomers which contain either one or two copies of the LTR sequence[2,3,6–8]. Integration of viral DNA into the host genome can occur at a wide variety of sites in cellular DNA, possibly at random; the structure of integrated (proviral) DNA is invariably very similar, if not identical, to that of unintegrated linear DNA[9,10], although the immediate precursor of the provirus has not been determined. The primary product of transcription is likely to be equivalent to a subunit of genomic RNA, which can be processed to subgenomic, spliced mRNAs for expression of internal cistrons[1].

Mouse mammary tumour virus (MMTV) is a type B retrovirus with at least three genes (*gag*, *pol* and *env*) on genomic RNA subunits of eight to nine kilobases (see Fig. 1). Although its generally poor infectivity in tissue culture has impeded biochemical study, MMTV seems to replicate like other retroviruses and has the experimental advantages of causing mammary carcinomas in mice and showing dramatic regulation of viral RNA synthesis by glucocorticoid hormones in many types of infected cells (for reviews see refs 11, 12). The mechanisms of carcinogenesis and steroidal regulation by this agent are poorly understood, and an analysis of integration sites of MMTV DNA seemed likely to clarify these aspects and also the general mechanism of integration of retroviral DNA.

We used molecular cloning and DNA sequencing to analyse the structure and integration sites of three proviruses of MMTV DNA introduced into the genome of rat cells (XC cells) by infection in culture. Our analysis demonstrates the remarkable precision of the integrative mechanism and reveals additional striking similarities between the structure of proviruses and that of several transposable elements: short inverted repeats (six base pairs) within the LTRs (1.4 kilobases) terminate each provirus, and duplications of five or six base pairs of host cell DNA are generated during the integration process.

To optimize the possibility of correlating structural and functional properties of proviruses, we isolated a set of clonal rat (XC) cell lines which contain single MMTV proviruses. The lines were chosen from a larger set of clonal lines of XC cells which had been infected by about one infectious unit per cell with the C3H strain of MMTV[13]. To analyse these clones for MMTV sequences, DNA from each clone was digested with *Eco*RI, electrophoresed through agarose, blotted on to nitrocellulose paper by the technique of Southern[14] and hybridized with ^{32}P-MMTV cDNA. Because there is a single recognition site for *Eco*RI within the MMTV(C3H) genome, each normal provirus should yield two hybridizing fragments, the sizes of which are determined by the location of recognition sites in neighbouring cell DNA (Fig. 1*b* shows a restriction map of MMTV DNA).

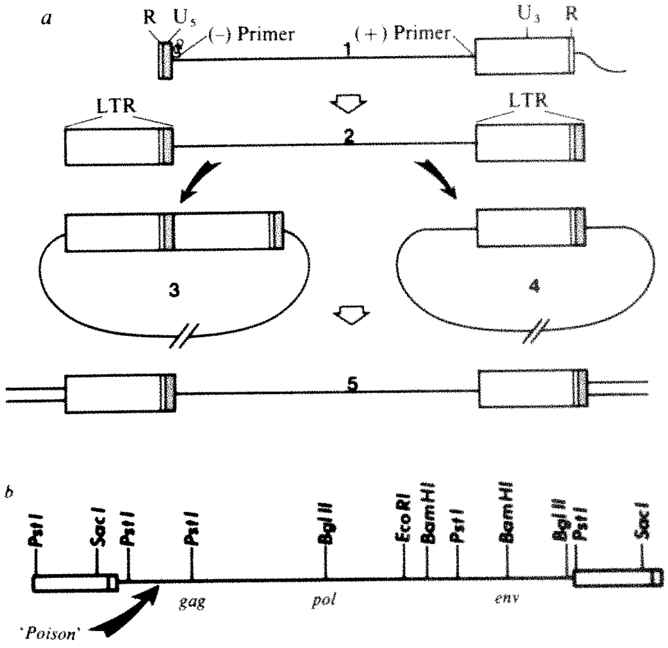

Fig. 1 *a*, Steps in the replication of retroviruses. The RNA subunit of the MMTV genome (1) is shown with features relevant to the present study: the site for priming of the negative (−) DNA strand by tRNA^{Lys} bound near the 5′ terminus[21,22] (shown on the left); the site probably used for priming (+)strand synthesis[2,4]; the short direct repeat (R, probably ~13 bases for MMTV) at both ends of viral RNA; and the regions unique to the 3′ and 5′ ends of viral RNA located between the priming sites and R (U_3, ~1,300 bases; U_5, ~130 bases). At an early step in DNA synthesis these two regions are fused via the R sequence to form the LTR U_3RU_5 which is in turn duplicated during the completion of linear duplex DNA[2–4,6]. The linear DNA (2) is a precursor to the two circular forms which contain either two copies (3) or one copy (4) of the LTR unit[2,3,6,7]. One of these unintegrated forms (2, 3 or 4) is presumably the precursor to the integrated (proviral) form[9,10,23] (5), which serves as the template for synthesis of viral RNA. *b*, A map of restriction sites in MMTV-C3H DNA which are relevant to the present study[6,23]. As described in the text we have been unable to clone the region marked 'poison'.

0028-0836/81/040253—06$01.00

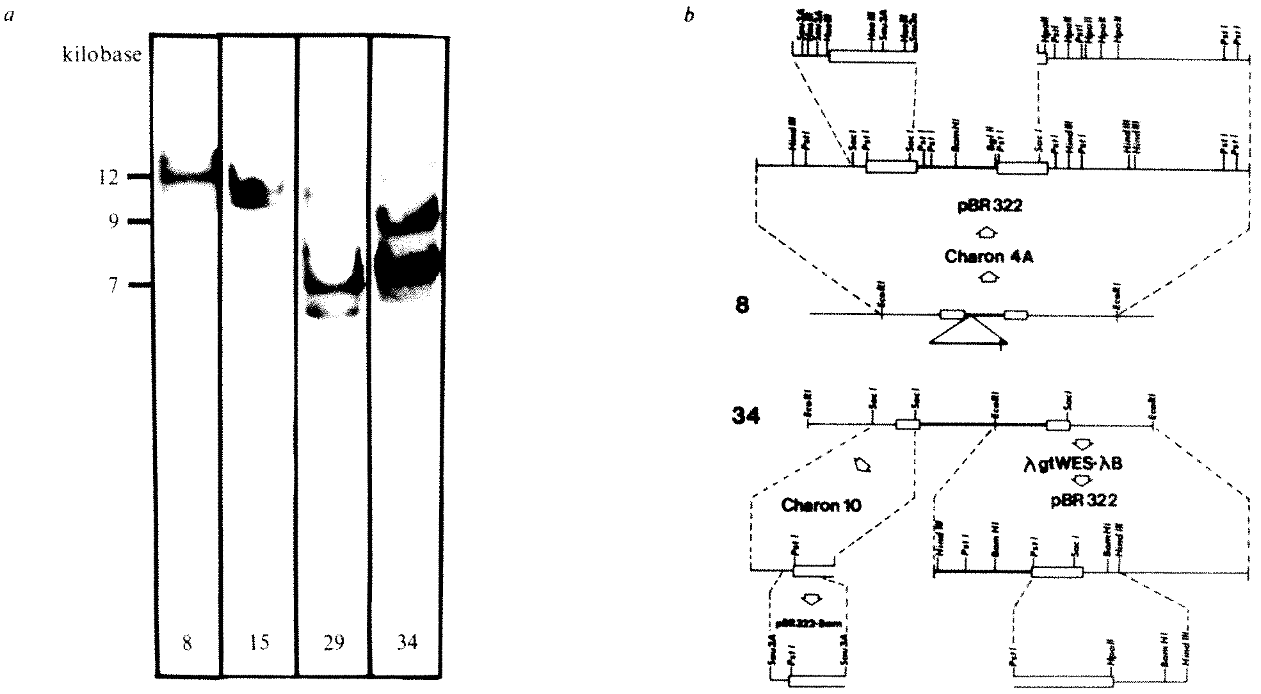

Fig. 2 *a*, Identification of MMTV proviruses in clones of infected rat cells. Rat (XC) cells[46] were infected with MMTV-C3H, seeded in multiple-well plates at a concentration <1 cell per well, and propagated in Dulbecco's minimal essential medium plus 10% calf serum (without added hormones). Purified DNA prepared from each clonal line ($\sim 10\ \mu g$) was digested with *Eco*RI, electrophoresed in 0.8% agarose, transferred to nitrocellulose sheets[14] and hybridized with ^{32}P-labelled cDNA randomly transcribed from MMTV-C3H RNA[6,23]. The figure shows an autoradiogram of an analysis of DNAs from four clones, including 8, 15 and 34, described in the text. *b*, Strategies for cloning the virus–cell junctions of the proviruses from lines 8 and 34. DNA (mg aliquots) from each line were cleaved with *Eco*RI and passed through 0.8% agarose in a fractionating gel electrophoresis apparatus[47]. The eluted fractions were analysed for fragments of interest as described for *a*. To isolate the junctions from line 8, DNA from the fractions containing the 12-kilobase *Eco*RI fragment was ligated with purified Charon 4A arms and then packaged *in vitro* as described by Blattner *et al.*[48]. The assembled phages were plated onto the strain DP50SupF (ref. 18) and screened for proviral inserts by the procedure of Benton and Davis[49] using MMTV ^{32}P-labelled cDNA$_{\mathrm{rep}}$. A positively hybridizing plaque was isolated for further analysis. The insert from this phage was transferred into pBR322 using vector DNA that had been cleaved with *Eco*RI and treated with calf intestinal alkaline phosphatase. DNA from one such clone was isolated and used as a substrate for restriction cleavage analysis. For sequencing, the indicated *Sac*I fragments were purified by preparative electrophoresis through 0.8% Sea-Plaque (Marine Colloids) agarose gels, then further restricted for the construction of fine structure maps. The two junctions from the provirus in line 34 were isolated separately. DNA from fractions containing the right end 4.4-kilobase *Eco*RI fragment was ligated with purified arms from the vector λgtWES · λB, then packaged, plated and assayed as described above. After isolation, the purified insert was then transferred into pB322 and used in restriction enzyme analysis. DNA from fractions containing the six-kilobase *Eco*RI fragment from the left end of the provirus was further digested with *Sac*I, then ligated to purified arms from the vector Charon 10 (ref. 20). Packaging, plating and screening were as described above. After preliminary characterization and preparative electrophoresis through 0.8% Sea-Plaque agarose, the inserted *Sac*I fragment was cleaved with the restriction enzyme *Sau*3A, and the cleavage products ligated to *Bam*HI-cleaved pBR322 that had been treated with calf intestinal alkaline phosphatase. After transformation of the bacterial strain HB101 (ref. 50), ampicillin-resistant recombinants were screened with a probe specific for the MMTV LTR, using the procedure of Hanahan and Meselson[51], for those containing the junction.

Using this criterion, of the 45 clones analysed, 12 had two or more proviruses, 14 had a single provirus and 19 had escaped infection. Figure 2*a* shows the results of such an analysis of four of the clones carrying single proviruses. We chose three of these, designated 8, 15 and 34, for further analysis. One (clone 8) carried a truncated provirus (see Fig. 2*b*) expressed under the control of glucocorticoid hormones (our unpublished data and those of D. Robertson); the second (clone 34) contained a full-sized provirus from which little, if any, stable RNA was transcribed in the presence or absence of hormone (Fig. 2*b*, unpublished data); the third, not fully analysed here, contained a full-sized provirus under steroid control (unpublished data).

Cloning unintegrated and proviral MMTV DNA

Our choice of strategies for cloning MMTV proviral DNA was influenced by a difficulty we encountered in attempting to isolate unintegrated forms of MMTV DNAs by molecular cloning in *Escherichia coli* (similar difficulties have been encountered in attempts to clone integrated MMTV DNA (ref. 15 and D. Ucker, personal communication)). Circular MMTV molecules were isolated from dexamethasone-stimulated rat XC cells that were chronically infected with the C3H strain of MMTV. (Heterologous cells chronically infected by MMTV generally contain 1–10 copies of unintegrated DNA, apparently synthesized by reverse transcriptase, when grown in the presence of glucocorticoids[6,16,17].) After partial purification by Hirt fractionation and CsCl–propidium diiodide equilibrium centrifugation[6,16], the viral DNA was cleaved with *Eco*RI and cloned into the vector λgtWES·λB (ref. 18). Although the virus-specific material that we ligated to the vector arms seemed to be primarily intact *Eco*RI-cleaved circular molecules, each of the positively hybridizing λgtWES · MMTV recombinants had suffered deletions or rearrangements of MMTV sequences. The deletion end points were variable, but each lesion covered a common set of MMTV sequences that lie within a region of the genome (which is designated 'poison' in Fig. 1) which probably codes for gag proteins.

To investigate this phenomenon further, we cleaved the same DNA preparation with *Pst*I, an enzyme with several recognition sites within the MMTV genome, and cloned the fragments in the *Pst*I site of the plasmid vector pBR322. We isolated recombinants containing all the expected MMTV *Pst*I fragments except the 1-kilobase fragment containing the 'poison' sequence. We concluded from these experiments that there is a sequence within the 1-kilobase *Pst* I fragment which propagates poorly, if at all, in the strains of *E. coli* used. We cannot explain this result and have not yet isolated those sequences. In analysing integration sites, we were forced to use strategies which allowed us to circumvent this cloning difficulty.

Figure 2*b* shows partial restriction maps of the two proviruses and describes the cloning strategies. The provirus from clone 34 seems normal, that is, the restriction fragments generated from internal regions of the provirus were identical to those of unintegrated linear DNA. The provirus in clone 8 is abnormal in that cleavage with *Eco*RI released only a single 12-kilobase fragment which hybridized with MMTV cDNA$_{rep}$. Further analysis with *Pst*I, *Bam*HI, *Hin*dIII and *Sac*I showed that the clone 8 provirus had incurred a large deletion of viral sequences, probably covering the *gag–pol* region of the MMTV genome; this deletion was fortuitous in that it eliminated both the poison sequence and the internal *Eco*RI site, and we were able to clone the entire steroid-responsive provirus with its flanking cell sequences in the *Eco*RI site of the λ phage vector Charon 4A (ref. 19).

Fig. 3 *a*, Junctions at the right ends. The end of U$_5$ was determined from the sequence of 'strong stop' (–) strand DNA (RU$_5$) synthesized *in vitro* (1) and from the sequence of the junction between the left-hand LTR and the region encoding the binding site for tRNA^{Lys} (2). The latter was derived from a *Pst*I subclone of the relevant region from line 8 provirus. These sequences were then compared with the sequences of the junctions between viral and host DNA at the right ends of proviruses from lines 8, 15 and 34 (3). The sequence of strong stop DNA was determined by two methods: a modification of the di-deoxy chain termination method[52] was used to analyse products synthesized by purified avian myeloblastosis virus (AMV) DNA polymerase on a template of MMTV-C3H 70S RNA; the chemical sequencing technique of Maxam and Gilbert[53] was used to analyse strong stop DNA synthesized by detergent-disrupted virions of MMTV-GR (provided by Dr Nurul Sarkar). For each junction sequence, both viral: cell and U$_5$:primer binding site, DNA was labelled at a *Hpa*II site within the U$_5$ sequence, 30 base pairs from its right end. *b*, Junctions at the left ends. The end of the U$_3$ sequence was estimated from the position of the indicated *Pst*I site and from a comparison of sequences from the Schmidt-Ruppin A strain of ASV DNA[24,25] (4) and from MMTV line 8 proviral DNA at the leftward boundary of the right-hand LTR (5) (see text). The 11-base homology is boxed in and the arrow indicates the boundary of the ASV U$_3$ region. These sequences were then compared with those from the viral-host junctions at the left ends of the two proviruses (6). The (+) primer:U$_3$ junction was derived from DNA labelled at the *Bgl*II site within the line 8 proviral sequences. The cell-virus junctions were derived from DNA labelled at sites within the host flanking sequences, a *Hae*III site for line 8 and a *Sau*3A site for line 34 (see Fig. 2*b*). Presumed viral U$_5$ and U$_3$ sequences are enclosed within solid lines and the repeated cell sequences are indicated by large letters. Sequences were obtained by the chemical cleavage method of Maxam and Gilbert[53], using DNA fragments that had been labelled at 3' ends either with AMV reverse transcriptase or *E. coli* DNA polymerase I.

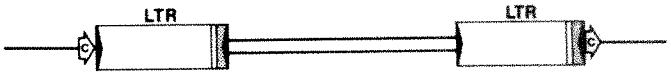

Fig. 4 Schematic diagram of an MMTV provirus. The inverted repeats at the ends of the LTRs are shown as inverted solid triangles. The direct repeat of the cell sequence at the junction site is indicated by C within the open arrow. Viral DNA is shown as a double line, flanking cellular DNA as a single line. Other symbols are as described for Fig. 1.

The strategy for cloning the ends of the proviruses in clones 34 and 15 was dictated by the need to circumvent the poison sequence. The *Eco*RI fragments containing the right ends were cloned in λgtWES · λB. The *Sac*I site in the U$_3$ region of the LTR at the left end separates the virus–cell junction from the poison sequence; therefore the left-hand virus–cell junction from line 34 was cloned as a *Sac*I fragment in the lambda phage vector Charon 10 (ref. 20) (Fig. 2*b*).

Determining the boundaries of the LTR

To determine the fate of viral sequences during integration we had to know accurately the structure of viral DNA before integration. It was particularly necessary to define the boundaries of the long terminal repeat, the right and left ends of which are also the right and left ends of the linear form of unintegrated DNA (Fig. 1).

The right end should be the site of initiation of viral reverse transcription[21], a sequence determined by direct DNA sequencing of the initial or 'strong stop' (–) strand DNA made *in vitro* (unpublished). Figure 3*a* shows the sequence of the region in the provirus from clone 8 covering the boundary between the left LTR and viral sequences outside the LTR, that is, the boundary between U$_5$ (the strong stop sequence) and the tRNA primer binding site. The strong stop transcript begins GCTGC, which is immediately preceded by 18 bases identical to the 3' end of tRNA$_3^{Lys}$, the primer for MMTV negative strand synthesis[22].

Present replication models argue that the left end of the LTR should correspond to the initiation point for (+) strand strong stop synthesis[4]. We have no direct evidence with which to define this point; therefore we have resorted to indirect arguments. There is a *Pst*I site within the LTR, near the left end of this previously described repeat unit of ~1.4 kilobases (see Fig. 1 and refs 6, 10, 23). Figure 3*b* shows the sequence extending leftwards from that *Pst*I site, towards the viral *Bgl*II site, which is on the 5' side of the rightward LTR. This sequence should contain the left boundary of the LTR, and within it are two features which seem useful for defining the boundary: (1) in the (+) strand there is a polypurine tract of 20 bases ending ~10 bases from the *Pst*I site; (2) a sequence of 11 base pairs, including the last nine of the polypurine tract, has precise homology with a sequence from the analogous region of avian sarcoma virus (ASV) DNA [24,25]. Swanstrom *et al.*[24] have shown, by sequencing the junction between the LTRs of a cloned ASV circular molecule containing two copies of the LTR, that the left end of the ASV LTR is probably at the position marked with an arrow in Fig. 3*b*. We suggest that the left end of the MMTV LTR is at the homologous site and that the polypurine tract is involved with plus strand strong stop priming. Comparison of the proposed sequences at the left and right ends of the LTR unit show them to be related by an inverted repeat of six bases (AATGCCGC.... GCGGCAGC), starting two base pairs from the ends. This supports our choice of boundaries because short inverted repeats of various lengths have been found at the ends of the LTRs of murine leukaemia and sarcoma viruses[26-28], spleen necrosis virus (SNV)[29] and ASV (ref. 24).

Sequences at the host–viral junctions

Sequencing of virus–cell junctions was facilitated by transferring the *Eco*RI fragments from Charon 4A·8, λgtWES·34R and λgtWES·15R into the plasmid pBR322. To analyse the cell–virus junction in Charon 10·34L, the *Sac*I insert was cleaved with *Sau*3A and the fragment containing the junction cloned into the *Bam*HI site of pBR322. Restriction maps derived from certain of these plasmid clones are shown in Fig. 2. Sequences from the right-end junctions were obtained by labelling at a *Hpa*II site in the U_5 region and sequencing across the junction into host DNA. Figure 3 compares those sequences with that from the boundary between the right end of the leftward LTR and the tRNA primer binding site. Two proviruses are missing at least one base of U_5 sequence and the right end of the third provirus (from line 15) is missing at least two bases from the U_5 sequence. (All three probably lack the first two bases of U_5 at this end.) Also shown are the viral–host junction sequence derived from the 34L *Sau*3A subclone and that of the left junction of the provirus from line 8 derived from the *Eco*RI fragment cloned into pBR322. A comparison with the expected left end of the LTR shows that each provirus is lacking two base pairs from the proposed terminus of the LTR.

Comparison of the cellular sequences at the right and left junctions of the provirus from both lines 8 and 34 shows that there are direct repeats in the cellular sequence at the site of integration—these comprise six base pairs for both proviruses. In each case, the assignment of a GC base pair to cellular or viral sequences is ambiguous. However we argue that symmetry and consistency make a six-base pair repeat of cell DNA, with two base pairs missing from both ends of viral DNA, the logical provisional assignment.

The two base pairs removed are those which are mismatched in the inverted repeats at the ends of the LTR, and their removal leaves a perfect inverted repeat of 6 base pairs in the viral sequences at the ends of the provirus. Thus an MMTV provirus has the structure shown in Fig. 4: unique coding sequences, flanked by large terminal direct repeats, which in turn are flanked by short inverted repeats, with a direct repeat in the cell sequence at the integration site. These features are strikingly analogous to those of several transposable elements, particularly Tn9 of *E. coli*[30,31], *copia* of *Drosophila*[32-34] and Ty1 of yeast[35-37].

The repeated cell sequence flanking the provirus is duplicated due to integration

It has been shown for several transposable elements that the direct repeat in the host sequence which flanks the element is the result of a duplication generated during integrative recombination[38]. To verify that a similar process is involved in retrovirus integration and to exclude the formal possibility of integration into a duplicated region of host DNA, we cloned the *Eco*RI fragment into which the provirus from line 8 was integrated. A restriction map of that fragment is indistinguishable from that of the flanking sequences in the fragment containing the line 8 provirus (Fig. 5). The sequence of the integration site shows that the six-base pair repeat which flanks the provirus in clone 8 was present only once in the integration site before insertion; thus we conclude that the duplication was generated during the integration process.

Specificity of integration sites

Analyses of proviruses of several retroviruses indicate that there must be many integration sites available for each virus in each host cell[9,10,23,39] (see Fig. 2). However, mapping procedures are inadequate to determine whether a repeated host sequence is common to the integration sites used by any of these viruses. Figure 6 shows a comparison of the sequences for the integration sites for MMTV proviruses in clones 8 and 34. There seem to be no common features between these sites or between either site and the ends of the proviruses. In addition, there is no obvious relationship between these sequences and those flanking the right end of the provirus in clone 15 (Fig. 3*a*) or those flanking the right ends of three proviruses present in a mouse mammary tumour cell[15]. This limited survey is thus consistent with the idea that integration occurs randomly within the host genome; however, our small sample size makes the detection of any subtle specificities unlikely. For instance, fine structure analysis of the target sites for a large number of insertions of the transposable elements Tn3 and Tn9 shows a correlation between the probability of integration and both base composition and homology with end sequences[38].

Models for integration of retroviral DNA

This analysis of MMTV DNA and similar analyses of other retroviral DNAs[27-29] argue that any model for retroviral integration should account for the following observations: (1) A precisely defined region of viral DNA, corresponding within a few base pairs to the ends of linear DNA, seems to be invariably linked to host DNA. This implies either that a mechanism exists to recognize a specific site in viral circular DNA or that linear DNA integrates directly. (2) A limited number of base pairs, probably two, are lost from both the right and left ends of viral DNA during integration. Note that these bases are 'lost' only with respect to the probable structure of the unintegrated linear DNA. The proximal precursor to the provirus could be a circular form with a different complement of sequences in the relevant region. Furthermore, the lost base pairs do not affect the genetic

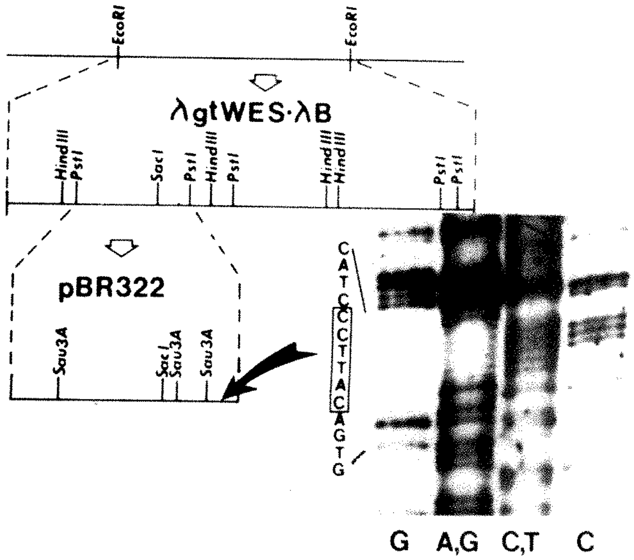

Fig. 5 The target site for the provirus in line 8. A hybridization probe made against the entire 12-kilobase *Eco*RI fragment from the line 8 provirus cloned in pBR322 was used to isolate fractions containing the target site fragment from a preparation of fractionated *Eco*RI-cleaved DNA from line 34. DNA from those fractions was ligated to purified λgtWes · λB arms and a recombinant phage carrying the fragment which contained the target site was isolated as described in Fig. 2 legend. The purified recombinant DNA was used for restriction enzyme cleavage analysis. For sequence analysis the *Eco*RI insert was first transferred into pBR322; the *Pst*I fragment containing the target site was then sub-cloned into the *Pst*I site of pBR322. The sequence was obtained by Maxam–Gilbert chemical cleavage analysis of the *Sau*3A-*Pst*I fragment which had been labelled at the 3' terminus of the *Sau*3A site. The relevant part of a 10% acrylamide sequencing gel and the inferred sequence are shown. The band present in all four lanes is the result of a partial *Sau*3A cleavage 5' to the sequence CATC.

Fig. 6 A comparison of two targets for MMTV integration into rat XC cell DNA. The sequence of the integration site used for the provirus in line 8 was determined directly as described in Fig. 5 legend. The sequence of the site used in line 34 was deduced from the sequences flanking the ends of the provirus (Fig. 3).

capacity of the provirus because they originate from regions which are repeated in linear DNA but present uniquely in viral RNA (see Fig. 1). (3) Host sequences are duplicated at the site of integration. (4) Viral DNA terminates with short inverted repeats. (5) A large number of regions in host DNA, including sites with sequences unrelated to each other or to viral DNA, can accommodate proviral DNA.

Although proviral elements from all retroviruses analysed have shown these general features, there are potentially significant differences in their fine structures: (1) The terminal base pairs which are lost from MMTV DNA after integration are not included within terminal inverted repeat sequences, whereas those from other retroviral DNAs are part of an inverted repeat[27–29]. (2) The size of the inverted repeats in proviral DNA varies from 20 base pairs (with four mismatches) in Moloney murine leukaemia virus (Mo-MuLV) DNA[28] to three base pairs in SNV DNA[29]. (3) The length of duplication in cellular sequences generated by integration seems to be specific for each retrovirus; thus, Moloney strains of MuLV and murine sarcoma virus (MSV) generate a four-base pair repeat[27,28], SNV generates a five-base pair repeat[29] and MMTV probably generates a six-base pair repeat.

The duplication of cellular sequences strongly suggests that an early step in the integrative process will prove to be the introduction of a staggered scission in host chromosomal DNA, as proposed for transposable elements[40,41]. The lack of homology between the two MMTV integration sites described here indicates that the enzyme responsible for this nucleolytic activity may have little sequence specificity. No such host or virus-coded activity has yet been described, although an endonucleolytic activity, encoded in the viral *pol* gene, has been found in virions of avian myeloblastosis virus[42].

Unfortunately, our structural studies shed little light on the identity of the viral integrative precursor. Both the linear and the two circular forms of unintegrated DNA can be accommodated as precursors within credible models for integration[28], each of which is closely related to that proposed by Shapiro[41] for the transposition of bacterial transposons. Recent work on the mechanism of restriction of MuLV replication by alleles at the *Fv-1* locus can be interpreted as supporting a circular precursor[43,44]. In some cases, *Fv-1* alleles inhibit both the accumulation of circular forms of MuLV DNA and the integration of MuLV DNA into mouse DNA. However, it is possible that these two observations both reflect the defective nature of linear DNA; thus the identity of the proximal precursor to the provirus remains an open issue.

Functional implications of proviral structure

The significance of the structural similarities between proviruses and transposable elements (Fig. 4) is uncertain in the absence of mechanistic details about retrovirus integration or about transposition of bacterial or eukaryotic transposons. Duplications at the sites of integration argue that the generation of staggered single-stranded scissions in host DNA is an early event in both processes. Terminal inverted repeats should allow an enzyme with a single recognition specificity to operate on both ends of an integrating molecule; however, this feature may not be essential for transposition because the Ty1 elements of yeast lack terminal inverted repeats[36,37].

There is no information concerning the possibility that proviruses can be relocated at new sites in host genomes by means other than transcription into RNA, subsequent reverse transcription and reintegration. Experiments to test for direct transposition are difficult to design and unlikely to yield unambiguous results. However, there is evidence to suggest that retroviruses can show other forms of behaviour observed for transposable elements, including deletion formation, insertional mutagenesis and promotion of transcription into flanking cellular DNA[45]. Each of these may have significant genetic consequences for the host, apart from the expression of viral genes.

The structural studies reported here do not directly further our understanding of hormonal regulation or carcinogenesis in MMTV-infected cells. However, the provirus from clone 8 is under glucocorticoid control and has been cloned intact with large regions of flanking cellular DNA; it should serve as a useful reagent for examining the role of viral and context (host) sequences in the mediation of the hormone response. The sequence of the MMTV LTR (studies to be presented elsewhere) includes an A+T-rich region characteristic of putative eukaryotic promoters. This region, which reads TATAAAAGA, is positioned 24–32 bases from the probable initiation site for RNA synthesis, the site corresponding to the 5′ terminus of genomic RNA. Thus we favour the notion that LTRs, like repeated units in transposons, may provide signals for gene expression[24–29].

The complete nucleotide sequence of the transforming gene of a mouse sarcoma virus has been determined. It codes for a protein of 374 amino acids. The nucleotide sequence of the junctions between a murine leukaemia virus and cellular sequences leading to the formation of the viral transforming gene have also been elucidated. The viral transforming sequence and its cellular homologue share an uninterrupted stretch of 1,159 nucleotides, with few base substitutions. The predicted amino acid sequence of the mouse sarcoma virus transforming gene was found to share considerable homology with the proposed amino acid sequence of the avian sarcoma virus oncogene (src) *product.*

MANY of the retroviruses capable of cellular transformation have acquired a normal cellular sequence as an integral part of their genome[1]. The acquired cellular sequences can be expressed either as an independent viral gene or as a product fused with viral structural proteins[2-10]. With the exception of Rous sarcoma viruses (RSV), acquisition of cellular sequences occurs at the expense of viral genomic sequences required for replication[1,11-18]. Not surprisingly, most retroviruses capable of inducing cellular transformation are unable to propagate without helper viruses.

We were interested in the biogenesis of a transforming gene at the level of nucleotide sequences. We chose to study Moloney mouse sarcoma virus (Mo-MSV) which is able to transform fibroblasts *in vitro* and induce neoplasia *in vivo*, but is unable to replicate[19-21]. It was obtained from sarcomas induced in BALB/c mice after passage of high doses of Moloney murine leukaemia virus (Mo-MLV)[22]. The genome of a cloned isolate of Mo-MSV (clone 124, ref. 23) has been characterized extensively. Briefly, the Mo-MSV genomic RNA is about 5.3 kilobases long and shares 60–70% sequence homology with Mo-MLV[24]. Figure 1 shows a schematic heteroduplex formed between a genome-length Mo-MLV cDNA transcript and Mo-MSV 124 genomic RNA. The Mo-MSV genome has a sequence substitution of about 1.2 kilobases and two deletions of approximately 1.2 and 1.6 kilobases. About 2.0 kilobases at the 5′ end and 0.6–0.7 kilobases at the 3′ end are shared between the two viruses[11-15].

We have molecularly cloned the unintegrated circular forms of Mo-MSV clone 124 and Mo-MLV DNA in bacteriophage λ (refs 25, 26). by using molecularly cloned Mo-MSV^{src}-specific DNA fragments as probe, a 14.0-kilobase *Eco*RI fragment from uninfected mouse cells was identified and subsequently molecularly cloned in bacteriophage λ (refs 27, 28). The cloned cellular DNA fragment contains an uninterrupted stretch of about 1.1 kilobases homologous to Mo-MSV-specific sequences. The Mo-MSV^{src}-specific sequences will be referred to here as v-*mos*$^{\mathrm{Mo}}$ [viral (v), mouse sarcoma virus (*mos*), Moloney (Mo)] and their cellular homologue is referred to as c-*mos*$^{\mathrm{Mo}}$ [cellular (c)]. We were interested in determining the nucleotide sequence in the region of the junctions of c-*mos*$^{\mathrm{Mo}}$ and Mo-MLV sequences to learn more about the process leading to the formation of the v-*mos*$^{\mathrm{Mo}}$ gene. We present here the following results: (1) the complete nucleotide sequence of the v-*mos*$^{\mathrm{Mo}}$ gene of Mo-MSV clone 124; (2) the predicted amino acid sequence of the v-*mos*$^{\mathrm{Mo}}$ gene product; (3) nucleotide sequences of the 5′ and 3′ extremities of c-*mos*$^{\mathrm{Mo}}$ and Mo-MLV leading to the formation of the v-*mos*$^{\mathrm{Mo}}$ gene; (4) nucleotide sequence comparison of the portions of v-*mos*$^{\mathrm{Mo}}$ and c-*mos*$^{\mathrm{Mo}}$; (5) comparison of the predicted amino acid sequence of the v-*mos*$^{\mathrm{Mo}}$ gene product with the proposed avian sarcoma virus oncogene (*src*) product.

Construction of plasmids

The following plasmids were constructed for the purpose of determining the nucleotide sequence of the appropriate regions (Fig. 2). The plasmid, p·MSV-1, contains the entire Mo-MSV DNA, whereas the plasmid, p·MSV-21, contains a majority of the v-*mos*$^{\mathrm{Mo}}$ gene sequences. The cellular DNA fragment containing the c-*mos*$^{\mathrm{Mo}}$ sequence was cloned in bacteriophage Charon 4A and portions of it were subsequently subcloned in the plasmid pBR322. The plasmid, p·CS-1, contains the 5′ half of the c-*mos*$^{\mathrm{Mo}}$ and cellular sequences, whereas p·CS-2 contains the entire coding region of c-*mos*$^{\mathrm{Mo}}$ and adjacent cellular sequences. The plasmid, p·MLV-1, contains the entire Mo-MLV genome. The approximate position of the junction of Mo-MLV and v-*mos*$^{\mathrm{Mo}}$ sequences was obtained from the heteroduplex map (Fig. 1) and physical maps generated by restriction endonucleases[29,30].

Nucleotide sequences of the v-*mos*$^{\mathrm{Mo}}$ gene

The Maxam–Gilbert method of DNA sequencing was used. In general, 5′→3′ sequences were determined by labelling with polynucleotide kinase and [γ-^{32}P]ATP, and the 3′→5′ sequences were determined by labelling the 3′ end with [α-^{32}P]CTP and terminal transferase. The complete nucleotide

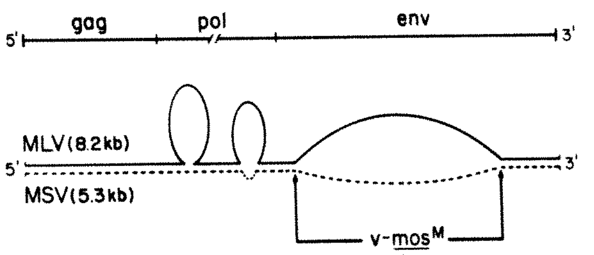

Fig. 1 Schematic heteroduplex formed between genome-length Mo-MLV DNA and Mo-MSV 124 genomic RNA[11]. kb, Kilobases.

sequence of a DNA fragment encompassing the v-*mos*$^{\mathrm{Mo}}$ gene of Mo-MSV 124 is shown in Fig. 3. The nucleotide sequence from just before the first *Bgl*I site through the *Hin*dIII site (1,356 base pairs) was obtained from p·MSV-21 (Fig. 2). The nucleotide sequence of v-*mos*$^{\mathrm{Mo}}$ past the *Hin*dIII site was determined from p·MSV-1.

There is only one major region in which a reading frame in either direction is open for translation. It starts with an ATG about 10 nucleotides downstream from the single *Xba*I site (Fig. 2), and can encode a protein containing 374 amino acids. The open reading frame terminates with an opal codon (TGA) within the acquired cellular sequences. Figure 3 also shows the predicted amino acid sequence of the v-*mos*$^{\mathrm{Mo}}$ gene product. Based on the predicted sequence, the largest possible v-*mos*$^{\mathrm{Mo}}$ gene product has a molecular weight of 40,992, which is in good agreement with the estimated size of a 37,000 molecular weight (37 K) protein and a related family of proteins synthesized in an *in vitro* translation of Mo-MSV clone 124 genomic RNA[31]. The synthesis of the 37K protein and a related family of polypeptides is specifically inhibited when the Mo-MSV 124 genomic RNA is preannealed to v-*mos*$^{\mathrm{Mo}}$-specific DNA fragments (J. Papkoff, T. Hunter and I. M. V., unpublished results). The synthesis of other viral proteins, like the p60 *gag* gene product, is not inhibited by the v-*mos*$^{\mathrm{Mo}}$-specific fragments. Note, however, that the 37K and related polypeptides synthesized *in vitro* have not been conclusively shown to be *in vivo* v-*mos*$^{\mathrm{Mo}}$ gene products, as no antisera against these polypeptides are yet available. Based on its amino acid sequence, the v-*mos*$^{\mathrm{Mo}}$ gene product has a net positive charge, in agreement with the mobility of the *in vitro* 37K protein on isoelectric focusing gels (J. Papkoff and T. Hunter, personal communication).

Nucleotide sequence of the c-*mos*$^{\mathrm{Mo}}$ and Mo-MLV junctions

To determine the nucleotide sequences at the 5' and 3' junctions of the c-*mos*$^{\mathrm{Mo}}$ and Mo-MLV leading to the formation of the v-*mos*$^{\mathrm{Mo}}$ gene, we used DNA fragments from the plasmids p·CS-1, p·CS-2 and p·MLV-1 (Fig. 2). Figure 4 shows the

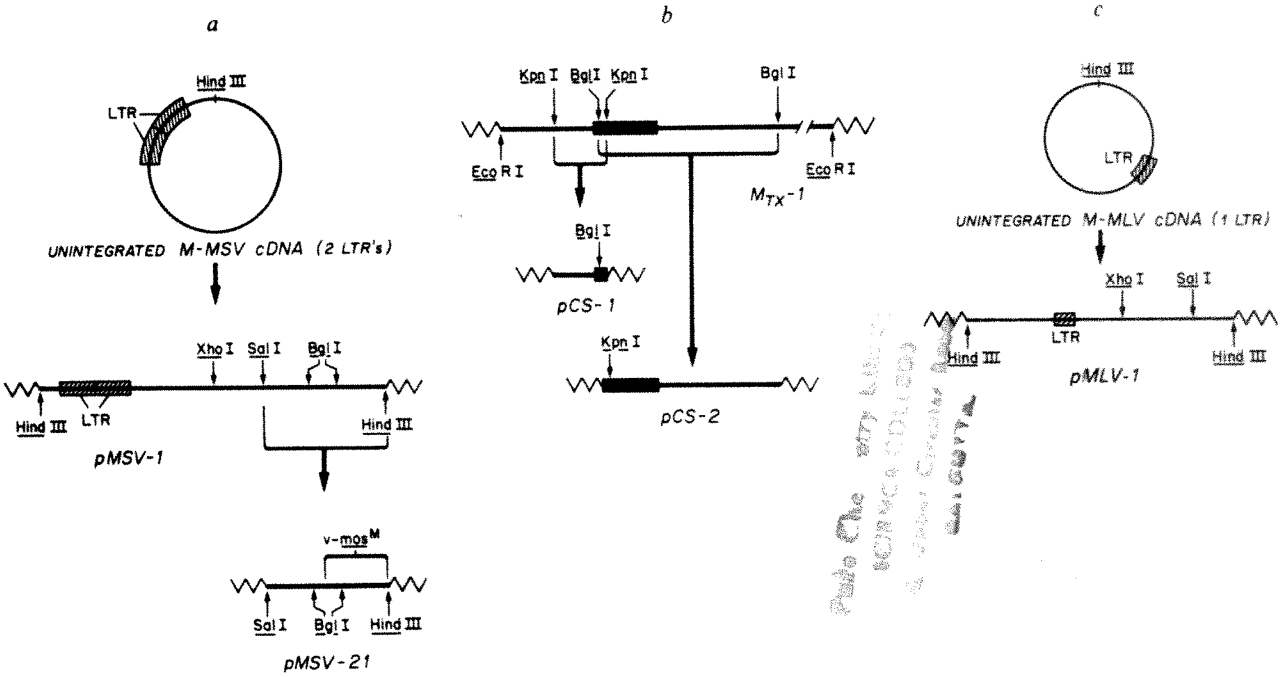

Fig. 2 Construction of plasmids. *a*, p·MSV-1 and p·MSV-21. The unintegrated circular forms of Mo-MSV DNA from freshly infected NIH/3T3 cells were isolated and cleaved at the unique *Hin*dIII site[30]. The DNA was molecularly cloned in the unique *Hin*dIII site of bacteriophage Charon 21A as described elsewhere[25]. The insert DNA containing the entire Mo-MSV DNA with two long terminal repeats was subcloned in the *Hin*dIII site of plasmid pBR322. About 1.0 μg of p·MSV-1 was cleaved with restriction endonucleases *Hin*dIII and *Sal*I and fractionated on 0.7% agarose gels. The 2.2-kilobase *Hin*dIII–*Sal*I fragment containing the v-*mos*$^{\mathrm{Mo}}$ gene was eluted from the gel and joined to *Hin*dIII- and *Sal*I- cleaved pBR322 by T4 DNA ligase as described elsewhere[25]. The recombinant plasmids were used to transform *Escherichia coli* C600SF and colonies were screened both for drug resistance ($Amp^{R}Tet^{S}$) and hybridization to Mo-MSV cDNA probes. The bracket denotes the v-*mos*$^{\mathrm{Mo}}$ sequences. *b*, p·CS-1 and p·CS-2. The 14.0-kilobase *Eco*RI fragment from uninfected NIH/3T3 cells containing the c-*mos*$^{\mathrm{Mo}}$ sequences was cloned in bacteriophage Charon 4A. The recombinant clone, $\lambda \cdot M_{TX}$-1, was analysed by restriction endonuclease[28]. The clone, $\lambda \cdot M_{TX}$-1, was cleaved with *Kpn*I which generated an expected fragment of about 1.2 kilobases, containing the 5' half of c-*mos*$^{\mathrm{Mo}}$ and adjacent cellular sequences. It was eluted from an agarose gel and a stretch of oligo(dC) residues was added using terminal transferase, as described previously[43], and cloned in the *Pst*I-cleaved [dG]-tailed pBR322. To make the plasmid p·CS-2, the recombinant clone, $\lambda \cdot M_{TX}$-1, was cleaved with *Bgl*I and a 5.5-kilobase fragment containing the 3' c-*mos*$^{\mathrm{Mo}}$ and adjacent cellular sequences was isolated from agarose gels and subcloned in the plasmid pBR322 by the [dC]-[dG]-tailing method[43]. The solid box indicates the c-*mos*$^{\mathrm{Mo}}$ sequences. *c*, p·MLV-1. The details of molecular cloning of unintegrated circular forms of Mo-MLV are described elsewhere[26]. Briefly, the Mo-MLV DNA was cleaved at an unique site with *Hin*dIII and cloned in the unique *Hin*dIII site of bacteriophage Charon 21A. The recombinant clone containing the Mo-MLV DNA was cleaved with *Hin*dIII and the insert Mo-MLV DNA further subcloned in the *Hin*dIII site of pBR322. The orientation of the insert in the plasmid was determined by restriction endonuclease analysis. The wavy lines show vector DNA.

Fig. 3 Nucleotide and predicted amino acid sequence of v-*mos*$^{\mathrm{Mo}}$ gene. The complete nucleotide sequence of Mo-MSV DNA fragment containing the v-*mos*$^{\mathrm{Mo}}$ gene is shown. The numbers in italics on the left-hand margin refer to the nucleotide numbers (1–1,547). The numbers in the figure (1–374) refer to the predicted amino acid sequence of the v-*mos*$^{\mathrm{Mo}}$ putative gene product, starting with Met as number 1 and terminating with an opal codon, TGA. The thick solid arrows under the boxed nucleotides show the recombination junctions between c-*mos*$^{\mathrm{Mo}}$ and Mo-MLV sequences; the horizontal arrows indicate the regions of the c-*mos*$^{\mathrm{Mo}}$ whose nucleotide sequence was determined; the solid triangles and the nucleotides under them denote the base alterations in the c-*mos*$^{\mathrm{Mo}}$ sequences; the amino acids in parentheses above the predicted amino acid sequences of v-*mos*$^{\mathrm{Mo}}$ gene product are the predicted changes in the c-*mos*$^{\mathrm{Mo}}$ product; the closed bar between nucleotides 184 and 187 shows the position of the 192-nucleotide Mo-MLV sequence deleted in Mo-MSV. The locations of some endo·R cleavage sites are: *Acy*I: 986; *Ava*I: 385, 426; *Bal*I: 557; *Bgl*I: 8,448; *Bgl*II: 26; *Cla*I: 1,432; *Hha*I: 208, 681; *Hin*dIII: 1,351; *Hin*fI: 353, 692, 739, 1,083, 1,326, 1,486; *Hpa*I: 844; *Hpa*II: 435, 448, 776, 979, 1,028, 1,125; *Kpn*I: 711; *Pst*I: 368, 794, 966, 1,227, 1,266; *Pvu*II: 789, 1,504; *Sst*II: 1,258; *Xba*I: 192. A complete list of endo·R restriction sites for this sequence is available on request.

Fig. 4 The 5′ and 3′ recombination junctions between Mo-MLV, Mo-MSV and $\lambda \cdot M_{TX}$-1. The 5′ and 3′ boundaries of the recombination junctions between Mo-MLV and c-mos^{Mo} leading to the formation of the v-mos^{Mo} gene sequence are shown. The open boxes denote homology whereas the hatched areas indicate non-homology. The ATG (below the arrow) indicates the position of the predicted first amino acid (Met) of the v-mos^{Mo} gene product (Fig. 3).

sequence of c-mos^{Mo} and p·MLV-1 at the 5′ and 3′ ends of the v-mos^{Mo} gene sequence. The 5′ junction of c-mos^{Mo} with Mo-MLV occurs 12 nucleotides downstream from the initiation codon of the putative v-mos^{Mo} gene product. At the 3′ end of the junction there are 19 nucleotides to the right of the *Hin*dIII site at the end of a stretch of six T residues. The N-terminus of the v-mos^{Mo} gene product extends five amino acids into the Mo-MLV genome past the c-mos^{Mo} junction. There is no direct sequence homology between Mo-MLV and c-mos^{Mo} junction sequences. However, the sequence TTCA is present immediately to the left of the 5′ junction in c-mos^{Mo}, and two nucleotides to the left of the 5′ junction in Mo-MLV (Fig. 4). This kind of sequence homology may suggest that v-mos^{Mo} originated by homologous recombination between c-mos^{Mo} and Mo-MLV sequences. The exact mechanism of recombination, however, remains obscure.

Comparison of portions of c-mos^{Mo} and v-mos^{Mo} sequences

It was of interest to determine the sequence divergence between c-mos^{Mo} and v-mos^{Mo} sequences. A cloned isolate of Mo-MLV (Mo-MLV clone 1) has been obtained[32,33]. We have propagated Mo-MSV clone 124 and Mo-MLV (clone 1) in our laboratory since 1973. Figure 3 compares the nucleotide sequence of portions of v-mos^{Mo} and c-mos^{Mo} sequences. In a stretch of about 500 nucleotides at the 5′ end there seem to be only five base changes. Similarly, in a stretch of 300 nucleotides at the 3′ end there are only eight single base substitutions. The nucleotide sequence homology between the v-mos^{Mo} and c-mos^{Mo} sequences is in complete agreement with the results obtained from nuclease S_1 analysis of hybrids formed between cloned $\lambda \cdot M_{TX}$-1 DNA (containing c-mos^{Mo} sequences, Fig. 2) and Mo-MSV genomic RNA[28]. The initiation codon ATG (at position 203 in Fig. 3) of the longest possible v-mos^{Mo} gene product is not present in the c-mos^{Mo} sequences (Fig. 4). The sequences in c-mos^{Mo} alone are not able to transform cells; however, when portions of Mo-MLV containing the long terminal repeat (LTR) are attached to it, cellular transformation can be observed (W. M. McClements and G. F. van de Woude, personal communication). Thus, it seems that the proteins encoded by v-mos^{Mo} and c-mos^{Mo} sequences are very similar.

The nucleotide sequences adjacent to the 3′ end of the v-mos^{Mo} gene in Mo-MLV and Mo-MSV are identical. However, at the 5′ end, 29 nucleotides from the 5′ junction of c-mos^{Mo} and Mo-MLV, the Mo-MSV seems to have undergone a previously undetected deletion of 192 nucleotides (shown as closed bar in Fig. 3). Analysis of the sequences on the 5′ and 3′ ends of the deletion reveals a common sequence, GACC. This small deletion was not observed in the heteroduplexes formed between Mo-MLV cDNA and Mo-MSV 124 RNA[11,15]. As there are only 29 base pairs between this deletion and the major substitution loop, it was perhaps scored as a part of the major substitution loop, β_S (ref. 11).

Fig. 5 Comparison between the proposed amino acid sequences for the v-mos^{Mo} and ASV *src* gene products. The amino acid sequences of the v-mos^{Mo} (Fig. 3) and ASV *src* (ref. 36) gene products were aligned for optimum identity as described elsewhere[37,38]. The portions of the sequences presented here include the entire v-mos^{Mo} sequence, and ASV *src* sequence from amino acid 188 to its carboxy terminus (residue 530). Areas of identity are depicted by boxes. The letter code for the amino acids is: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

The sequence in Fig. 3 was examined for features which have been implicated in RNA synthesis in other systems. Neither the v-*mos*$^{\mathrm{Mo}}$ nor the c-*mos*$^{\mathrm{Mo}}$ sequences seem to contain the canonical sequence (TATAAA, Hogness–Goldberg box) often implicated in promotion of transcription. Examination of the A+T-rich region of the sequence shown in Fig. 3 reveals a sequence, TTGTAAA, beginning at nucleotide 53, which might be used as a DNA-dependent RNA polymerase II binding site. Further sequence analysis of Mo-MLV, 5′ from nucleotide 1, reveals another potential promoter sequence (data not shown). The importance of the TATAAA sequence is uncertain, however, as it has recently been reported that removal of TATAAA sequences does not eliminate the transcription of histone genes *in vivo*[34]. To the 3′ side of the v-*mos*$^{\mathrm{Mo}}$ coding region, ~210 nucleotides from the TGA stop codon, there is the sequence AATAAA which has been associated with the addition of poly(A) tails onto eukaryotic mRNAs[35].

Comparison with other proteins

The amino acid sequence of the v-*mos*$^{\mathrm{Mo}}$ gene product, as derived from the DNA sequence, was subjected to a computer search for sequence resemblance among ~1,300 known amino acid sequences, including those for the T-antigens of polyoma and SV40. Although several sequences were found to have some marginal resemblances to portions of the v-*mos*$^{\mathrm{Mo}}$ gene product, only the recently reported oncogene product (deduced from DNA sequence studies) of avian sarcoma virus (ASV)[36] had a genuinely homologous sequence.

A very significant homology was uncovered when overlapping segments of the two proposed amino acid sequences were compared (Fig. 5). Residues 1–374 of the v-*mos*$^{\mathrm{Mo}}$ gene product were placed into optimum alignment with residues 188–530 (C-terminus) of the ASV *src* gene product using a program which has an algorithm similar to that described by Needleman and Wunsch[37,38], and which uses an empirically derived gap penalty. After an alignment score had been obtained, the two sequences were randomly jumbled, 36 comparisons of jumbled sequences executed and the alignment scores again computed. A mean value of the alignment scores was, finally, determined and the standard deviation calculated. The alignment score obtained for the two authentic sequences was about 7 s.d. above the mean of the jumbled comparisons, a highly significant result[38].

The optimum alignment of the two sequences revealed that they are about 23% identical in the region of the 371-residue overlap shown in Fig. 5. The strongest homology occurs over the stretch of the v-*mos*$^{\mathrm{Mo}}$ sequence corresponding to residues 227–309 and the ASV sequence residues 387–468. In this region there are 36 identical residues over the course of the 83-residue span, or about 45% identity. The overall degree of resemblance is approximately the same as that obtained in a comparison of mouse haemoglobin α-chain and hagfish haemoglobin[39], or of the β-chain of human haemoglobin[40] and human myoglobin[41]. The murine and avian haemoglobin α-chains, by contrast, have evolved less rapidly than have the proposed murine and avian viral proteins: the mouse haemoglobin α-chain has about 70% identity with chicken α-haemoglobin.

No detectable nucleotide sequence homology was observed when ASV *src*-specific cDNA was hybridized to viral RNA obtained from the Mo-MSV(MLV) complex[42]. This result was confirmed by a computer comparison of the nucleotide sequences of v-*mos*$^{\mathrm{Mo}}$ (Fig. 3) and the ASV *src* gene product[36]. However, the amino acid sequence homology between the oncogene products of ASV and Mo-MSV indicates that there can be little doubt that the two proteins have evolved from a common ancestor.

Conclusion

We have studied the biogenesis of the transforming gene of Mo-MSV. The Mo-MSV was isolated from sarcomas obtained after passage of Mo-MLV in mice. The Mo-MLV acquired cellular sequences, and underwent several deletions to yield a transforming but replication-defective virus. We have determined the entire nucleotide sequence of the Mo-MSV-specific sequences, referred to as the v-*mos*$^{\mathrm{Mo}}$ gene, in the Mo-MSV. Furthermore, the recombination junctions between the Mo-MLV and the cellular sequences leading to the formation of the v-*mos*$^{\mathrm{Mo}}$ gene have also been determined. The v-*mos*$^{\mathrm{Mo}}$ and c-*mos*$^{\mathrm{Mo}}$ share an uninterrupted stretch of 1,159 nucleotides with few base changes. There are no apparent structural homologies between the Mo-MLV and c-*mos*$^{\mathrm{Mo}}$ sequences at the point of recombination. However, there seems to be a small sequence homology, TTCA (Fig. 4), at the 5′ junction of Mo-MLV and c-*mos*$^{\mathrm{Mo}}$, perhaps suggesting homologous recombination. Due to the absence of specific tumour antisera, no authentic v-*mos*$^{\mathrm{Mo}}$ gene product has been identified. The 37K *in vitro* translation product[31] is specifically inhibited if the RNA is hybridized to a v-*mos*$^{\mathrm{Mo}}$ gene DNA fragment before translation (J. Papkoff, T. Hunter and I. M. V., unpublished results). The predicted amino acid sequence of the v-*mos*$^{\mathrm{Mo}}$ gene product can now be used to verify the nature of the 37K protein synthesized *in vitro*. Finally, the proposed amino acid sequence of the v-*mos*$^{\mathrm{Mo}}$ gene product has been shown to share significant homology with the ASV *src* gene product.

We thank Bart Sefton and Walter Eckhart for reading the manuscript and Carolyn Goller for preparation of it, Drs P. Czernilofsky and Hugo Martinez for help with computer programs, Dr E. P. Reddy for communicating his sequencing data on Mo-MSV^{src}-specific fragment before publication, and M. Jones and D. Murdock for help with various stages of the study. This work was supported by grants from the NCI and the American Cancer Society. D.J.D. acknowledges a Helen Hay Whitney Foundation postdoctoral fellowship.

A model from electron microscopy for the molecular structure of fibrinogen and fibrin

John W. Weisel, George N. Phillips Jr & Carolyn Cohen

Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, Massachusetts 02254

The overall architecture of the fibrinogen molecule and aspects of its packing to form fibrin have been derived from a study of electron microscope images of ordered arrays. The molecule, of length 450 Å, is seen in more detail than the Hall–Slayter model and is made up of seven globular domains connected by rod-like segments.

FIBRINOGEN is the soluble precursor of the fibrin clot in the plasma. On tissue injury, an enzymatic clotting cascade is initiated leading to thrombin cleavage of the two small pairs of highly charged peptides from fibrinogen[1,2]. The molecule then becomes highly insoluble and rapidly aggregates into the fibrin clot. This noncovalently bonded polymer is cross-linked by the fibrin-stabilizing factor enzyme and is later dissolved by cleavage with plasmin. The processes of clotting and fibrinolysis both occur continually in the normal functioning of the vascular system. The complexity of this clotting process is reflected in the complex structure of the fibrinogen molecule.

Fibrinogen has a molecular weight of 340,000 and an elongated form[3,4] but its detailed shape is unknown. Hall and Slayter[5] obtained electron micrographs of individual molecules, revealing a protein about 475 Å long consisting of a linear array of three globular domains (Fig. 1*A*). Despite considerable controversy, this 'trinodular' model is now generally accepted[5–11].

To account for the small 223 Å axial period of fibrin, Hall and Slayter invoked a 'shrinkage' of the molecule, but their proposal is inconsistent with results of X-ray diffraction studies, which show no large-scale changes in molecular structure on the conversion of fibrinogen to fibrin[12,13]. The axial period of fibrin can be accounted for most simply by a half-staggered arrangement of fibrinogen monomers[13].

Chemical studies indicate that fibrinogen is a dimer: the molecule consists of three pairs of different polypeptide chains (called Aα, Bβ and γ) linked by 29 disulphide bridges[14,15]. The complete amino acid sequence of human fibrinogen and the complex pattern of disulphide cross-links have recently been established[16–22]. Sequence analysis has also been used to locate certain regions of α-helical coiled coil[23,24] that had been predicted to connect the globular domains of the molecule[25]. However, these studies do not provide direct evidence on the overall morphology of the molecule or its packing in fibrin.

The most powerful approach to a determination of the structure of fibrinogen is X-ray crystallographic analysis. An important discovery was that microcrystals can be produced on limited cleavage of bovine fibrinogen with a bacterial protease[26] and that with further digestion, large single crystals, ordered to about 4 Å resolution, can be grown[27]. Crystallographic and chemical evidence show that the modified molecule in the crystal is only 5–10% smaller in mass than native fibrinogen[28]. Moreover, the molecules forming the crystals clot and the fibrin so produced has a band pattern in the electron microscope very similar to that of native fibrin, indicating that the modified protein is largely intact (Fig. 2*D*, *E*). (Other proteolytic enzymes have also been shown to modify fibrinogen so that microcrystals and crystals can be grown[29].)

Our strategy for determining the low resolution crystallographic structure of fibrinogen is the refinement of a model against X-ray data[30]. Here we derive a more detailed molecular model for fibrinogen than the trinodular Hall–Slayter structure and describe packing arrangements that account for electron microscope images in a variety of highly ordered arrays including fibrin.

Development of the model

It has been recognized for some time that the electron microscope band pattern of fibrin cannot be accounted for by a simple Hall–Slayter model. Within the repeat of 225 Å in negative contrast there is one bright strain-excluding band about 60 Å wide and three narrow light bands, the middle one being somewhat less prominent or variable in intensity[31–34] (Fig. 2*D*). The size and number of bands in this image show quite plainly that the globular domains in the fibrinogen molecule must be considerably smaller than those of the Hall–Slayter model (Fig. 1*A*) and that a trinodular structure cannot give rise to the details of the staining pattern.

A key to the interpretation of the fibrin band pattern can be found in the so-called 'orthogonal sheet' structure[26,28] (Fig. 2*A*). A simple, half-staggered arrangement of this highly regular array gives a band pattern closely resembling that of negatively stained fibrin[28]. An important aspect of the orthogonal sheet form is its extremely detailed substructure. The features are such that neither the Hall–Slayter model, nor, indeed, any simple arrangement of molecules running parallel to the microcrystal axis can readily account for this image. However, analysis of a variety of microcrystals of fibrinogen, including the orthogonal

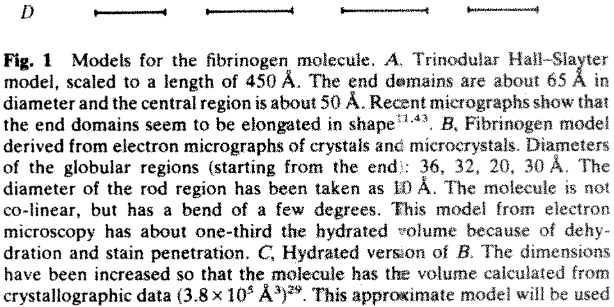

Fig. 1 Models for the fibrinogen molecule. *A*, Trinodular Hall–Slayter model, scaled to a length of 450 Å. The end domains are about 65 Å in diameter and the central region is about 50 Å. Recent micrographs show that the end domains seem to be elongated in shape[11,43]. *B*, Fibrinogen model derived from electron micrographs of crystals and microcrystals. Diameters of the globular regions (starting from the end): 36, 32, 20, 30 Å. The diameter of the rod region has been taken as 10 Å. The molecule is not co-linear, but has a bend of a few degrees. This model from electron microscopy has about one-third the hydrated volume because of dehydration and stain penetration. *C*, Hydrated version of *B*. The dimensions have been increased so that the molecule has the volume calculated from crystallographic data (3.8×10^5 Å^3)[29]. This approximate model will be used in the initial phasing of the X-ray data. *D*, Predicted α-helical coiled-coil regions based on analysis of the amino acid sequence[23,24]. The length of the region between two 'braces' of disulphide bonds is 111 residues, or about 160 Å; the coiled coil would begin at the central domain. We infer that the smallest globular domain may correspond to a region predicted to be non-helical where plasmin cleavage occurs[23] (see text).

0028–0836/81/040263—05$01.00

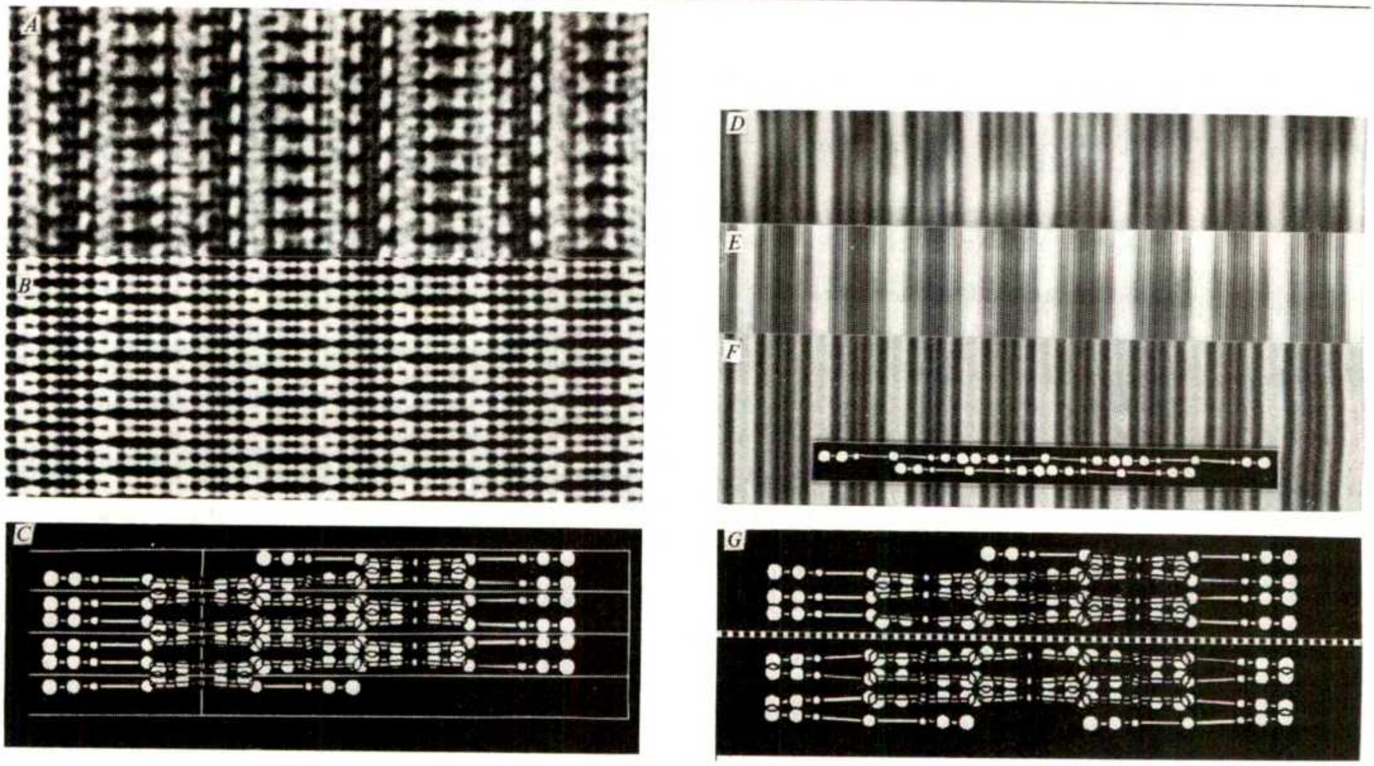

Fig. 2 Simulation of electron microscope images of the orthogonal sheet microcrystals and fibrin. *A*, Electron micrograph of a negatively contrasted microcrystal of the orthogonal sheet form[28]; the image has been optically filtered to remove background noise[44,45]. Unit cell dimensions are 900 × 90 Å. ×450,000. *B*, TV display of computer simulation of *A*, based on the model below (*C*) (as described in the text). Note that the models in *C* and *G* are drawn to a scale about 1.5 times as great as the electron micrographs above. *D*, *E*, Computer filtered electron micrographs of negatively contrasted fibrin. The axial repeat is 225 Å. In *D*, the fibrin is derived from native fibrinogen whereas in *E* the fibrin is from *Pseudomonas*-modified fibrinogen. Note that the weakest light band, which arises from the smallest globular domain, is less prominent in the modified fibrin[26,28], suggesting that the bacterial protease, like plasmin (see text), cleaves some material from this region. *F*, TV display of computer simulation of fibrin, based on the model shown in *G*. The fibrin band pattern was generated by superposition of arrays of the orthogonal sheet, shown in *A*, shifted by 225 Å (refs 26, 28). For clarity, two such layers of molecules are shown, separated by a dashed line, in the upper and lower portions of *G*. The lateral contacts in both fibrin and the orthogonal sheet form incorporate a half-stagger, where the central globular domain of one molecule fits into the 'pocket' formed by the end-to-end linkage of two molecules in an adjacent filament. A simple half-staggered array of five molecules is shown as an inset to *F* (and with the same scale) so that the relationship of the molecular shape and packing to the fibrin band pattern is apparent. The bright axial striations in both the orthogonal sheet form and fibrin arise from this juxtaposition of the end globular units of two molecules with the middle unit of a third. In the orthogonal sheet, the pairs of small bright units on either side of this feature can be seen to arise from the adjacent globular domains in these molecules. To account for the angle of the thin strands in the gap, the molecules are arrayed with a slight tilt. This arrangement generates the correct symmetry for the structure and also places the smallest globular units at the centre of the dark gap where they are seen as bright nodes.

sheet form, has indicated that all these structures seem to be made up of 450 Å-long fibrinogen molecules that bond end to end[28].

The best characterized macrocrystal form of fibrinogen is the monoclinic $P2_1$ crystal of protease-modified bovine fibrinogen[27,28]. A packing model for this crystal was established using the morphology and special features of the diffraction patterns[29,35]. Here too it was shown that the molecules are 450 Å long and bond end to end to form filaments. The general run of the molecules in the lattice was established but not their lateral relations. This knowledge of the molecular packing allowed an interpretation of electron microscope images of crystal fragments. In particular, a characteristic net or mesh form was observed that could be accounted for as the view along the unique symmetry axis (Fig. 3*A*, *D*). The strands of the mesh seen in the electron microscope were interpreted as pairs of symmetry-related molecular filaments in a distorted cell. These strands showed prominent features of macromolecular size, but again it was not possible using the Hall–Slayter model to define the lateral packing or to delineate individual molecules.

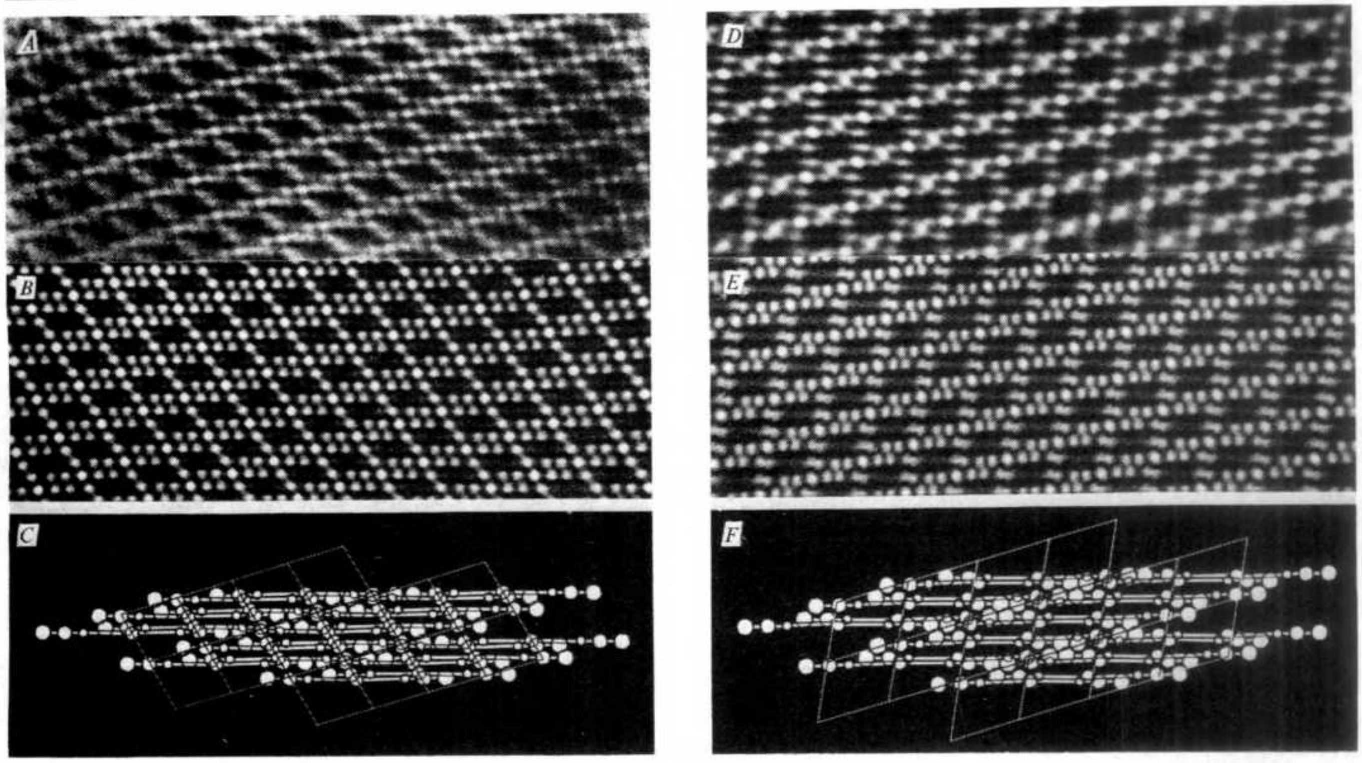
A form that we found useful in establishing the model was a 'segment' aggregate obtained from human fibrinogen modified by bacterial protease[36] (Fig. 4). The segments displayed a strikingly simple band pattern in negative staining that revealed where the molecules begin and end. Analysis of this structure showed that the molecules are in register in layers which are tilted alternately with respect to the long axis. Here again, the molecules were found to be ~450 Å long.

Because there is no molecular overlap, the packing of fibrinogen in this form yields direct information about the mass distribution along the molecule. The overall structure seems qualitatively like the Hall–Slayter model in that there are three major stain-excluding domains per molecular length. There is, however, additional fine structure in the segments. Within each major band there is another thin line of opposite contrast, which seems to define smaller domains. This evidence again suggested that the Hall–Slayter model was valid as a very low resolution image of the molecule, but that a more detailed mass distribution could be derived.

We may interpret the staining of the segments to mean that the outer domain of the Hall–Slayter model is, in fact, made up of two units, each about 30–40 Å in diameter. Close inspection of the segment images reveals an additional thin white line within the broad dark-staining region (Fig. 4). This feature indicates that another smaller globular unit may be located between the outer domain and the central nodule. This additional globular unit is, in fact, necessary to account for the detailed appearance of images of both fibrin and related forms as well as views of the crystal (see below). The molecule of length 450 Å thus appears in all the ordered aggregates as a heptad made up of seven globular domains. We show below how more precise dimensions of the globular units, as well as those of the rod-like regions connecting them, can be derived from the simulation of a variety of electron microscope images.

Simulation of electron microscope images

Using modifications of the model described above, computer simulations were carried out to develop a single molecular model whose substructure and packing could account for the negatively stained images of a variety of arrays seen in the



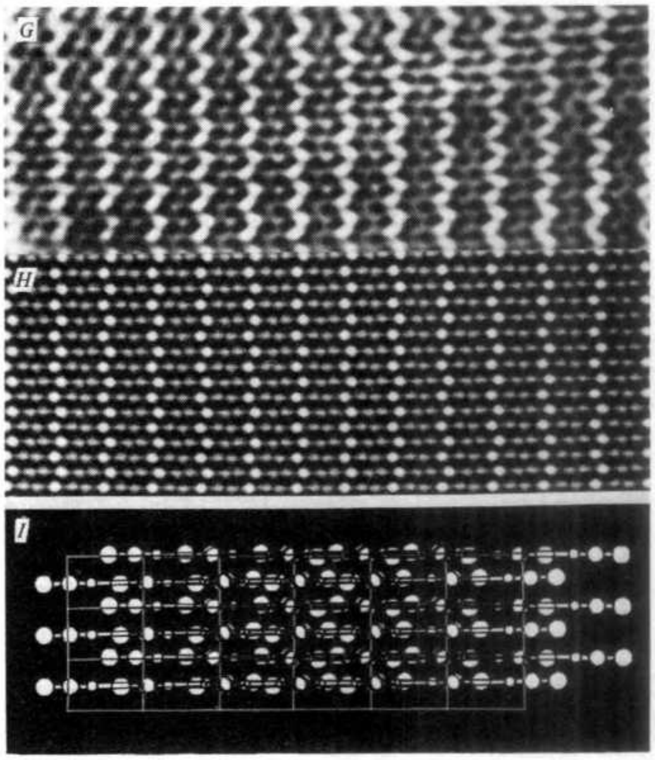


Fig. 3 Simulation of electron microscope images of the $P2_1$ crystal. *A*, *D*, *G*, Electron micrographs of negatively contrasted crystal fragments which have been filtered optically[44,45] or by computer processing of a digitized image[45,46]. *A* and *D* are two different mesh images corresponding to crystals with different amounts of shrinkage viewed along the unique axis. In both cases, the molecular strands are oriented parallel to the largest face of the crystal, which is horizontal here[29]. Unit cell parameters in *A* are: $a = 132$, $b = 97$, $c = 125$, $\beta = 105°$, whereas in *B* they are: $a = 160$, $b = 97$, $c = 130$, $\beta = 65°$. The image in *G* corresponds to the state of the crystal seen in *D* but viewed in the perpendicular direction. ×450,000. *B*, *E*, *H*, TV display of computer simulations of the models in *C*, *F*, *I* below (as described in the text). Note that the models in *C*, *F* and *I* are drawn to a scale about 1.5 times as great as the electron micrographs and simulations above so as to display the molecular packing. In the crystal, the strands correspond to the projection of filaments in different layers staggered by roughly one-third of the molecular length. In both the mesh images (*A*, *D*) the relative brightness of the different units of the motif depends on the size of the globular domains and their degree of overlap. A cluster of three overlapping globular domains corresponds to the broad light region nearest the dark gap; the very bright unit at the middle of the group corresponds to two overlapping globular regions. A small bend accounts in part for the slightly wavy appearance of the strands. The rod portion of the molecule can be visualized in some micrographs of the mesh, as in *D*.

electron microscope. Trial models for selected forms were rapidly generated with the aid of computer graphics and compared with electron micrographs. The molecule was represented as a series of seven spheres connected by rods, and the programs were written so that one set of parameters fixed the sizes and position of the spheres and rods within one molecule, and another set located a single molecule in the unit cell. Additional molecules were then generated according to the appropriate symmetry elements of the specific form under analysis. To convert these arrangements to density contours, which could then be compared with electron microscope images, the model was represented by sets of points spaced closely enough to correspond to a continuous structure at this resolution. The projected Fourier transform of this configuration was then computed, followed by the inverse transform which was displayed on a television screen. Subjective criteria were used to alter both molecular and packing parameters in comparing the simulation to filtered electron microscope images.

A range of molecular models was examined. Slight differences in the size of the globular units or slight departures of the two halves of the molecule from co-linearity were tested to achieve a good fit with a particular form. Some differences in the nature of the end-to-end molecular contacts were also tried with certain arrays. It was found that all the images could be fitted with the same heptad model (Fig. 1*B*).

The $P2_1$ crystal

Several images from $P2_1$ crystal fragments could be simulated. The net described previously and identified as the view down the unique axis of the crystal is characterized by strands having features of macromolecular size running in the horizontal direction[29] (Fig. 3*A*). The repeating unit along the strands is a group of seven stain-excluding regions of varying sizes (none larger than ~40 Å)—the middle one being particularly bright—followed by a dark-staining gap. This motif repeats every 450 Å and corresponds to the projection of two symmetry-related layers of molecular filaments in the unit cell. This form was particularly useful in establishing the size of the globular domains and their separation in the model. The small bend in the molecule accounts in part for the slightly wavy appearance of the strands. With a shift of about one-third the molecular length between filaments in the two layers the simulation shows excellent agreement with the filtered image of the electron micrograph (Fig. 3*B*, *C*).

Electron micrographs of the $P2_1$ crystal fragments show a number of states of the mesh described above. Another commonly observed form has a mesh with a different appearance (Fig. 3*D*). The motif is rather similar to that described above, although the intensities and positions of the bright units differ somewhat. Keeping the parameters of the molecular model used in the previous simulation, only a slight change in the relative stagger of the molecular filaments within each layer is required for a satisfactory fit (Fig. 3*E*, *F*).

A different view of the crystal could also be identified. Some preparations contained very thin crystals that tended to lie with the large face on the grid. This image showed a distinctive pattern of alternating rows of bright and weak zig-zags repeated 145 Å axially (Fig. 3*G*). The spacings indicated that this was the view along one of the crystal axes perpendicular to the previous view and nearly perpendicular to the large face of the crystal (see Fig. 3*D*). Using the same arrangement of molecules as before (Fig. 3*F*), and simply taking the appropriate projection (Fig. 3*I*), a very satisfactory simulation can be achieved (Fig. 3*H*).

The orthogonal sheet form and fibrin

One of the most detailed images is that of the orthogonal sheet form, related to fibrin (Fig. 2*A*). Here the motif is a very complex dumbell-shaped bright region about 400 Å long with a dark-staining gap of about 50 Å. The motifs in adjacent rows are staggered by half the lateral period so that the true axial repeat is 900 Å. Within the dark-staining gap, thin light strands seem to connect units in different rows. For the simulation, the dimensions of the molecular model as determined for the $P2_1$ crystal views were maintained, but the molecular filaments in different layers were half-staggered, as determined previously[13,26,28] (Fig. 2*C*). This arrangement accounts for the very bright axial striation which arises from juxtaposition of the end globular units of two molecules with the middle unit of a third (Fig. 2*B*). The small bright units on either side of this feature can be seen to arise from the adjacent globular domains in these molecules. To account for the angle of the thin strands in the gap, the molecules were arrayed with a slight tilt to the long axis of the unit cell. This arrangement generates the correct symmetry for the structure. The smallest globular units can be seen quite clearly as bright nodes at the centre of the dark gaps.

A half-stagger (225 Å) of this arrangement for the orthogonal sheet form then generates the fibrin image[26,28] (Fig. 2*E*, *F*, *G*). The brightest band in fibrin again arises from juxtaposition of the end globular regions of two molecules together with a centre domain of a neighbouring molecule and the narrower band on either side from the adjacent domains. Additional features of the pattern are also accounted for: the thinnest band in the period corresponds to the smallest globular domain in the molecule. In fact, this arrangement is precisely that proposed in the early half-staggered models for fibrin[13], but the size of the domains in the molecular model now yields correct dimensions for the band pattern (Fig. 2*F* inset). The relatively simple band pattern of fibrin is thus accounted for by a superposition of rather complex molecular arrays.

The molecular model

We have now obtained an improved low-resolution model for the fibrinogen molecule (Fig. 1*B*). The basic structure is closely related to the trinodular Hall–Slayter model, but we have been able to establish a precise length for the molecule of 450 Å, and a more detailed substructure. The outer globular domain, incompletely resolved by the shadowing technique used by Hall and Slayter, is now seen to consist of two regions of nearly equal size. The narrow rod-like connection between the central and outer units had not previously been visualized, and we have shown that its regular run is interrupted by a small globular region displaced towards the outer domains. There is also a slight bending of the molecule by a few degrees. We consider the evidence in favour of this model to be compelling: all the features of the model are directly visible in certain electron microscope images, and the model can account for the detailed appearance of a variety of forms, including the complex pattern of fibrin.

Fibrinogen displays different properties at different stages of clotting. As shown for other fibrous proteins[37], particular domains may be associated with each of its various functions. The central and outer globular domains of the molecule are involved in assembly of the fibrin fibre; the middle region contains the small, highly charged fibrinopeptides cleaved by thrombin[38] whereas the outer globular domains contain complementary bonding sites for fibrin formation[39,40]. Covalent cross-linking of the molecules by the fibrin-stabilizing factor has been shown to involve the outer globular domain[41]. Some of these sites may also be located in the neighbouring globular domain. The plasmin-sensitive portion of the molecule can be identified with the smallest globular domain which interrupts the regular run of the rod-like α-helical coiled-coil regions (Fig. 1*B*, *D*)[23,24]. On the basis of this oversimplified picture, we can begin to localize a number of the characteristic properties of fibrinogen in different structural domains.

These results also indicate that a modest degree of molecular 'flexing' is a necessary feature of the packing arrangements in all the forms we have examined. Hence, the molecule should not be considered as rigid, but there is no compelling reason to postulate marked departures from colinearity of the two halves of the molecule.

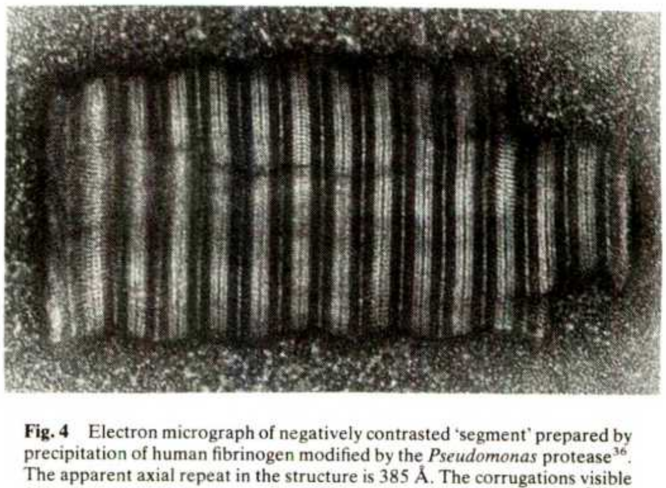

Fig. 4 Electron micrograph of negatively contrasted 'segment' prepared by precipitation of human fibrinogen modified by the *Pseudomonas* protease[36]. The apparent axial repeat in the structure is 385 Å. The corrugations visible along the upper and lower edges indicate that the true period is 770 Å and that the molecules are both tilted in layers and bent. The end of the segment on the right shows where the molecules begin. ×135,000.

The model described here represents the first stage in our approach to the detailed three-dimensional structure of fibrinogen. The dimensions used in our simulations were derived from negatively stained electron microscope images, but the approximate hydrated envelope can be calculated from the molecular volume in the crystal[29] (Fig. 1*C*). We have now completed three-dimensional X-ray data collection to about 20 Å on the $P2_1$ crystal form. To derive truer shapes of the molecular domains we are refining the hydrated version of the model against the diffraction data[42]; solvent flattening techniques may also be useful for phasing reflections at this resolution[30]. The new model will reveal in even greater detail the complex architecture of this highly evolved protein molecule.

We thank Cynthia Stauffacher and Nancy Tooney for helpful discussions, Paul Norton for electron microscopy, William Saunders for photography, David DeRosier for computer programs and Edward Swinarski for computing. Cosmic ray antiprotons and modified closed galaxy model

S. A. Stephens

Tata Institute of Fundamental Research, Homi Bhabha Road,
Bombay 400005, India

Observations suggest that a small flux of secondary antiprotons ($\bar{p}$), created in the interaction of cosmic ray nuclei with interstellar gas, should also be present in the primary cosmic radiation. Calculations based on accelerator data for the production of $\bar{p}$ and existing models for the propagation of cosmic rays, predict too small a flux of $\bar{p}$ compared with the finite flux observed recently[1]. Although the observed excess could be attributed to the existence of primary cosmic ray antimatter, the experimental upper limits[2,3] of the ratio of antinuclei to nuclei of charge $|Z| \geqslant 2$ seem to contradict this. Here we use a 'modified closed galaxy' model to attribute this excess to secondary antiprotons. In this model, ~50% of the observed cosmic ray nucleons are of recent origin and they propagate according to the 'nested leaky box' model, while the rest propagate according to 'closed galaxy' model. This model explains the observations on $\bar{p}$ and e^+, and predicts more D and ^{3}He than do the existing models.

The secondary $\bar{p}$ spectrum in cosmic rays has been calculated in the past by Gaisser and Maurer[4], and Badhwar *et al.*[5] using the extensive accelerator data available for the production of $\bar{p}$. However, these calculated spectra differ by more than a factor of two at ~10 GeV and by even larger factors at lower energies, suggesting that cross-sectional representations used by them must have been responsible for this difference. The interpretation of a finite flux of $\bar{p}$ depends crucially on the accuracy of the estimated flux of $\bar{p}$ in cosmic rays. Szabelski *et al.*[6] showed that the results of Badhwar *et al.*[5] are in error. Thereby, they questioned the 'standard leaky box' model (SLBM) for the propagation of cosmic rays. I recently obtained a more accurate parametrization[7] of the invariant cross-sections, for the production of $\bar{p}$ in inclusive reactions, and calculated the production spectrum of $\bar{p}$. This calculation confirmed the conclusions of Szabelski *et al.*[6]. The results from this calculation[7] are now used to examine the implication of the observed $\bar{p}$ in terms of cosmic ray propagation models.

The equilibrium spectrum of $\bar{p}$ has been obtained by taking into account ionization loss, annihilation of $\bar{p}$, and inelastic interactions in which $\bar{p}$ retains nearly half its energy. The resultant $\bar{p}/p$ ratio as a function of the kinetic energy of $\bar{p}$ is shown in Fig. 1 for various cosmic ray models. Curve S is the estimated $\bar{p}/p$ ratio according to SLBM, in which cosmic rays traverse 5 g cm^{-2} of interstellar gas independent of energy. This curve can be compared with other existing calculations[4–6] carried out using SLBM only. The calculations of Gaisser and Maurer[4], and Szabelski *et al.*[6] agree within 25% with curve S over the entire energy region above 2 GeV. This small deviation arises partly from the differences in the parametrization of cross-sectional data and partly due to different demodulated proton spectra used. Badhwar *et al.*[5] overestimate the $\bar{p}/p$ ratio by a factor of 2 at ~10 GeV and this difference increases with decreasing energy; however, they also agree within 25% at energies $\geqslant$50 GeV.

The SLBM has been abandoned since it was observed that the abundance ratio of secondary nuclei (like Li, Be and B) to primary nuclei (like C and O) decreased with increasing energy. This result suggested that high-energy cosmic rays traverse less amount of matter. Recent observations on the spectra of cosmic ray nuclei suggest[8] that the energy dependence of the matter traversal is approximately proportional to $(8\,\mathrm{GV}/c/R)^{1/2}$, where R is the rigidity in GV/c, for $R \geqslant 8$ GV/c and is nearly constant for $R < 8$ GV/c. This dependence has been explained in two ways. (1) The confinement of cosmic rays in the Galaxy is energy dependent[9]—'modified leaky box' model (MLBM). (2) A certain fraction, f, of the matter traversed by cosmic rays in the source regions is energy dependent—'nested leaky box' model[10] (NLBM). Curve M in Fig. 1 is the calculated $\bar{p}/p$ ratio on the basis of MLBM and the hatched region (N) is according to NLBM. The energy-dependent escape probability in NLBM from the source regions is assumed to be similar to that of MLBM, and that the median energy of interacting nucleons is ~10 times the energy of $\bar{p}$ produced; the upper and lower bounds are for $f = 0.5$ and 0.8 respectively. Figure 1 shows that

NLBM predicts too small a flux of $\bar{p}$ compared with MLBM in the energy region below a few tens of GeV.

Figure 1 plots the observed $\bar{p}/p$ ratio of $(5.2\pm1.5)\times10^{-4}$ reported by Golden *et al.*[1] in the energy region 4.7–11.6 GeV; this result was based on 28 $\bar{p}$ events of extraterrestrial origin. The correct value may be higher by ~15% because the expected flux[7] of $\bar{p}$ of atmospheric origin is smaller than that estimated by Golden *et al.* The $\bar{p}/p$ ratio obtained by Bogomolov *et al.*[11] is not plotted because it was based only on two $\bar{p}$ events, and in this experiment, splash albedo particles in the atmosphere could not be eliminated[12]. Figure 1 shows that popular models of cosmic ray propagation predict too low a flux of $\bar{p}$ by a factor ≥4 compared with the observed flux; however, the significance of this difference is only about 3σ. In the following, we examine the 'closed galaxy' model originally proposed by Rasmussen and Peters[13] to understand the apparently high flux of $\bar{p}$ observed by Golden *et al.*[1].

In the 'closed galaxy' model, cosmic rays are totally confined until they are destroyed by interaction. Curve C in Fig. 1 is the calculated $\bar{p}/p$ ratio on the basis of total confinement. The observed ratio falls short of curve C by a factor of ~2. It is therefore proposed that ~50% of the observed cosmic ray nucleons are of recent (~10^7 yr) origin, and are propagated according to either MLBM or NLBM; the remaining ones are the result of total confinement. We can now combine 50% of curve C with either curve M or hatched area N, and the resultant $\bar{p}/p$ ratio lies between the two short curves passing through the data point in Fig. 1. Thus, the 'modified closed galaxy' model (MCGM) can account for the observed flux of $\bar{p}$.

The secondary positron spectrum in cosmic rays can now be calculated using MCGM. The equilibrium spectrum of e^+ is calculated by using the recently estimated[14] production spectrum and taking into account all energy-loss processes—ionization, bremsstrahlung, synchrotron and inverse Compton scattering. For convenience, the values of mean magnetic field $\mathbf{B}_\perp$ and the radiation density are assumed to be the same for all models and are taken to be 4 μG and 0.7 eV cm^{-3} respectively.

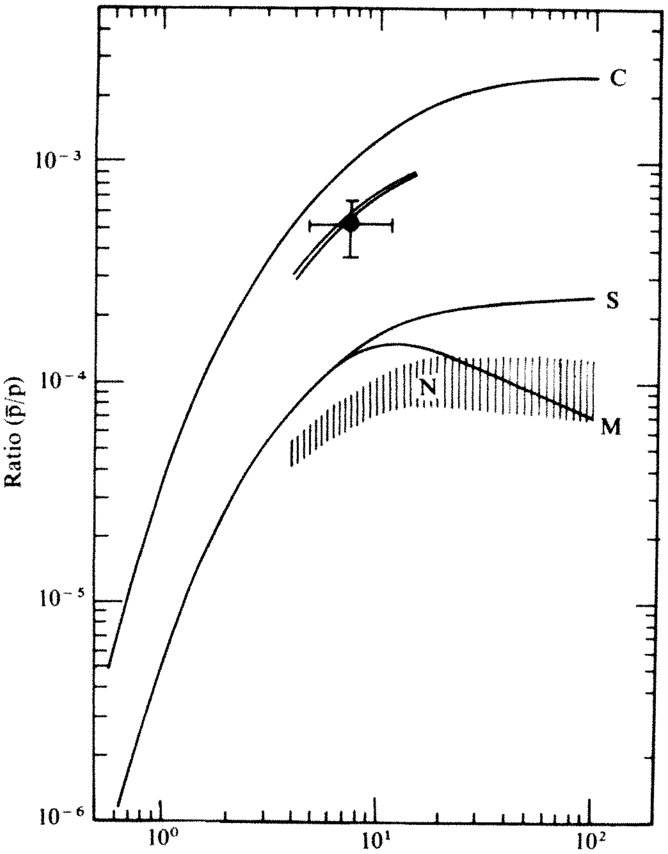

Fig. 1 The calculated $\bar{p}/p$ ratio plotted as a function of the kinetic energy of $\bar{p}$, for various models of cosmic ray propagation. The solid curves passing through the data point are the estimated ratio by summing 50% of curve C with 50% of either curve M or the lower bound of the hatched area N. ●, Data from ref. 1; S, SLBM; M, MLBM; N, NLBM; C, CGM.

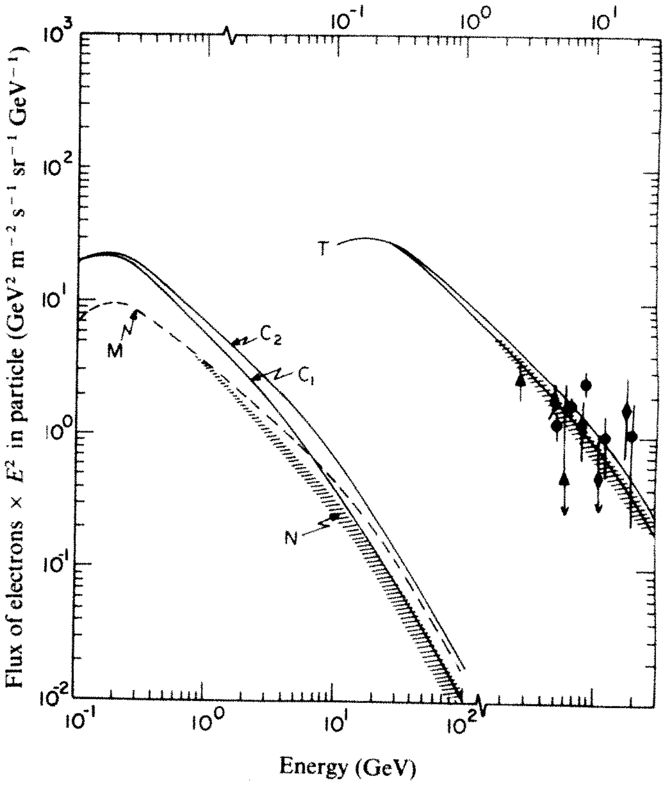

Fig. 2 The calculated energy spectra of the old and new components of secondary cosmic ray e^+ are shown in the left side, and the combined e^+ and total electron spectra on the right side; the flux values are multiplied by E^2. Symbols as in Fig. 1; curves C_1 and C_2 correspond to $n_H=0.1$ and 0.2 atom cm^{-3}, the mean hydrogen density of the interstellar gas traversed by the old component. Data are taken from: ◆, ref. 17; ●, ref. 18; ▲, ref. 19.

The calculated spectra of e^+ from the old component are shown in Fig. 2 by curves C_1 and C_2, which correspond respectively to $n_H=0.1$ and 0.2 atom cm^{-3}, where n_H is the mean hydrogen density of the interstellar gas traversed by this component. The flux values in Fig. 2 are multiplied by E^2. The flux of e^+ is proportional to n_H at high energies, where synchrotron and inverse Compton scattering losses dominate, and is independent of n_H at low energies, where ionization and bremsstrahlung losses dominate[15]. The dashed curve M is the calculated new component due to MLBM. In this calculation, the mean lifetime of cosmic rays of $R\leq8$ GV/c is assumed to be 10^7 yr, as determined by radioisotope measurements[16], and during this period they traverse 5 g cm^{-2} of interstellar gas. The recent e^+ component according to NLBM is calculated as in the case of $\bar{p}$ and is shown by the hatched area N.

The sum of the old and new components of the e^+ spectrum is shown on the right side in Fig. 2. The solid curves (T) are the sum of curves M and either C_1 or C_2, and the hatched area corresponds to the sum of the hatched area N with curve C_1 or C_2. The observed flux values of e^+ are plotted as filled data points at energies ≥3 GeV (refs 17–19), where the effect due to solar modulation is small. The band representing MCGM agrees with the observations, which have a large scatter. Note that other existing models cannot satisfactorily explain e^+ observations[6,12]. Also the value of n_H needed for the old component cannot be very much smaller than 0.1 atom cm^{-3}. This means that the effective confinement region for cosmic rays may not include regions very far away from the galactic disk, say larger than a few kpc. Also the total (e^++e^-) spectrum in interstellar space derived on the basis of curve T can be shown to be consistent with that deduced from the non-thermal radio spectrum in the Galaxy.

Half of the observed nucleons, belonging to the old component, is shared among various nuclear species approximately in proportion to the respective interaction mean-free paths. The estimated percentages of the old component among the observed p, He, (C+O), (F to Sc), (P to Cr) and (Fe Group) nuclei are respectively 58, 21, 9, 6, 4 and 3. Note that the new component constitutes $>90\%$ of the observed flux for nuclei other than p and He. Therefore, one can explain the observed energy dependence of the abundance ratio of secondary to primary nuclei using MLBM or NLBM for the new component. Further, the relative abundances of heavy nuclei of charge ≥ 6 would not differ from other models by more than a few per cent.

We now need to choose between MLBM and NLBM for the new component. According to MLBM, the energy spectrum of nucleons of recent origin above ~ 8 GV/c (~ 4 GeV/n) would be steeper than the injection spectrum by a power-law spectral index of about 0.5; the old component retains the injection spectrum. This would mean that the old component would dominate the observed flux beyond a certain energy[20]. The calculated energies at which the intensities from these two components become comparable are ~56, 460 and 1,950 GeV/n for He, (C+O) and (Fe group) respectively; protons have 58% old component even below 8 GeV. This clearly indicates that the observed similarity in the spectral shape of p and He above a few GeV/n cannot be understood, unless protons are accelerated differently. One should also expect a flattening of He spectrum beyond about 50 GeV/n, which has not been observed at least up to a few hundred GeV/n. These two inconsistencies discredit MLBM, and the natural choice is for NLBM, because the spectral shape of the new component is the same as the old.

A reliable estimate of the abundance of deuterium can be made using this model at relativistic energies. The estimated D/He ratio from this model is nearly twice as much from other models at energies ≤ 4 GeV/n and decreases slightly at high energies due to the energy-dependent confinement of the recent component in source regions. A similar enhancement is expected in the case of ^{3}He abundance. The available measurements have been restricted to energies ≤ 200 MeV/n and these results differ by a large factor[21]. However, they can be easily detected at relativistic energies using magnetic spectrometry[22]. The observation of an enhanced abundance of D would not only confirm the predictions of this model but would also reduce the difficulty in understanding the observed charge ratio of muons at sea level. Perhaps the distribution and spectral shape of high-energy γ rays, and the extended nonthermal radio emission in the Galaxy might also be explained by this model.

I thank Professors M. V. K. Apparao, R. R. Daniel and P. V. Ramana Murthy for helpful criticisms.

Expanding haloes in cometary comae

W.-H. Ip

Max-Planck-Institut fur Aeronomie, D-3411 Katlenburg-Lindau 3, FRG

Observations indicate that cometary activity can be rather violent. Flare-ups, sunward-pointing jets and periodic formation of concentric haloes expanding outwards can also be persistent features in some comets. For example, a halo structure was observed in the coma of Comet Halley during its last visit[1]. It is argued here that halo formation may be related to the propagation of shock pairs driven through the cometary atmosphere as a result of spin-modulation of the cometary outgassing rate. Even though the non-stationary process could be less dramatic than the example considered here, its effect on the chemistry and expansion of the neutral gas as well as dynamics of the cometary plasma must be significant.

Although theoretical models of cometary coma generally assume that neutral atmospheres expand spherically, symmetrically and without time variation, inhomogeneous structures have often been observed in the cometary comae. These include the formation of concentric shells (or haloes) moving outwards from the central source in succession and the appearance of fans or jets. Such non-stationary behaviour has long been thought to be related to the spin-modulation of the outgassing rate from the cometary nucleus[2,3].

There are two possiblities. If the surface composition of the cometary nucleus is uniform, the dependence of the surface temperature on the angle of insolation (θ) would mean higher gas emission rate at the point shifted from the sunlit position with $\theta = 0°$. (The exact position of the 'hot spot' is determined by the direction and period of the nuclear spin as well as thermal properties of the surface material; the resultant jet effect has been used to explain the nongravitational acceleration or deceleration of comets[2].) As the jetting of the volatile gas—though localized—is more or less constant, the expansion of the cometary atmosphere, except the persistent sunward jets, should show no marked time variation. On the other hand, if the surface of the cometary nucleus can be divided into one active hemisphere and an inactive one (say), there will be more violent ejection of the volatile gas every time the active region turns towards the Sun. In the extreme case, there will be regular outbursts at the centre with a period equal to that of the spin period leading to large spatial and temporal variations in the structure of the coma. Clearly, the formation of expanding haloes as seen in the case of Comet Donati in 1858 (ref. 4) and Comet Halley[1] must be somehow related to such periodic outbursts. (From measurements of their respective halo structures, Whipple[5,6] has determined the spin period of Comet Donati to be 4.6 h and for Comet Halley to be 10.3 h.)

To understand this phenomenon, time-dependent expansion of the gas outflow must be considered. Here it is assumed that the cometary atmosphere is an ideal gas and that the radial expansion is spherically symmetric. Furthermore, the time variation of the outgassing rate is approximated by a step function and we are basically interested in the initial propagation of the cometary neutral gas as the strong source is switched on. If ρ is the density, u the radial velocity, p the pressure and $\gamma(=5/3)$ the ratio of specific heats of the gas, then

$$\frac{\partial \rho}{\partial t}+\frac{1}{r^2}\frac{\partial}{\partial r}(r^2\rho u)=0 \tag{1}$$

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial t}=-\frac{1}{\rho}\frac{\partial p}{\partial r} \tag{2}$$

$$\frac{\partial}{\partial t}\left(\frac{p}{\rho^\gamma}\right)+u\frac{\partial}{\partial r}\left(\frac{p}{\rho^\gamma}\right)=0 \tag{3}$$

0028-0836/81/040269—03$01 00

for the hydrodynamic equations of expansion of the neutral gas from a point source. Introducing the similarity variable[7],

$$\eta = r/\alpha t \tag{4}$$

for the expansion of a piston gas with a constant speed α and defining

$$u = rV(\eta)/t, \quad \rho = \rho_0 r_0^2 \sigma(\eta)/r^2, \quad p = \rho_0 r_0^2 \pi(\eta)/t^2 \tag{5}$$

with the density distribution of the cometary coma at $t \leq 0$ given as:

$$\rho = \rho_0 r_0^2 / r^2 \tag{6}$$

(that is, $\rho = \rho_0$ at $r = r_0$ for the unperturbed flow), we can find an equivalent set of equations for V, σ and π with η as the sole variable. As discussed by Simon and Axford[8], similarity solutions of V, σ and π can be obtained for the motion of such a piston gas describing a pair of shocks (S_+ and S_-) separated by a contact surface (C). The characteristics of the strong-shock solutions are that at the contact surface with $\eta \cong 0.84$, $V = 1$, $\pi = 0$ and $\sigma \to \infty$; and that the mass efflux from the source can be expressed as

$$Q = 4\pi f \alpha \rho_0 r_0^2 \tag{7}$$

where $f \approx 0.4$ in the case of strong shocks. With V, σ and π known for $\eta \geq 0$, the physical quantities u, ρ and p can be derived in turn for various values of r and t from equation (5).

Details of the similarity solutions for a blast wave can be found in ref. 8 and numerical solution of the above adiabatic non-steady flow equations in ref. 9. For brevity, only radial variation of the mass density will be discussed here. Figure 1 shows the profile of the gas density (ρ) plotted for the case of strong forward (S_+) and reverse (S_-) shocks. As $\sigma \to \infty$ at the contact surface (C), ρ increases to a large value also. For weaker shocks, the snow-plow effect of piling up the material between S_+ and S_-, though less pronounced, should be present. The similarity solutions of the piston gas apply only to the inner coma region which is still dominated by collisional effect. For a Halley-type comet with a nuclear radius (r_n) of 3 km and a surface number density (n_0) of 3×10^{12} cm^{-3}, the nominal dimensions of such collision zone (r_c) is $\approx 1.4 \times 10^4$ km. As a result of the varying outgassing rate, r_c could be a factor of 3 larger or one-third smaller as the comet rotates around. Even with the large value of 4×10^4 km, r_c is still small compared with the radius of outer haloes ($\sim 3 \times 10^5$ km) (see ref. 1). The compression effect by the piston gas must then stop a long way inside. However, the sharp definition of the haloes may still be maintained at large distances if the temperature of the gas at the contact surface is kept sufficiently low by collisional cooling. The delineation of the haloes is also helped by the rare-fraction region just behind the reverse-shock S_-. Indeed, the density variations as shown in Fig. 1 may explain why in some cases a dark zone is observed[4] immediately behind a halo of enhanced brightness. Another effect is that the propagation speed of these haloes could be considerably lower than the value of 1 km s^{-1} generally quoted as the flow speed of the neutral gas in the inner coma close to the nucleus ($r \leq 10^{2-3}$ km) could be very small.

The dimension of these haloes as observed in the C_2-emission are limited by the scale length of these molecules ($\approx 10^5$ km at 1 AU). Furthermore, the daughter fragments of the parent molecules (such as H_2O and CO) in the compressed shells would pick up extra kinetic energy during photodissociation or ion-molecular reactions such that the corresponding thin-shell structures would be dispersed. Therefore, expanding haloes are not likely to be seen in the density distributions of H, C and O atoms, for example. We may then envisage the formation of a new spherical halo moving outwards every time the active hemisphere of the cometary nucleus faces the Sun. Partly due to the pile-up of material between the forward and reverse shocks, and partly due to the projection effect along the line-of-sight, a concentric halo will be observed progressing outwards. Note that the time variation of the outgassing rate could be anything but a step function as adopted here and the shock velocity α should have certain time variation. The dynamical process, however, is not likely to vary much as long as the active hemisphere of the comet can produce a strong driver gas. The real issue is, therefore, what is the energy source for such outbursts if they indeed are explosive.

In connection with the flare-ups of cometary activities sometimes observed, Donn and Urey[10] have suggested that explosive chemical reactions involving free radicals or unstable molecules on the nuclear surface may provide the answer. The free-radical reactions studied in the laboratory are observed to be highly exothermic, yielding a heat of reaction of approximately a few electron volts per molecule. This would mean that there are pockets of unstable chemical mixture on the surface of the active hemisphere with energetic explosions triggered by solar radiation. Another possibility suggested by Greenberg[11] in the case of interstellar grains—is simply that some of the solid grains could release free energy stored in the mantle of organic molecules and free radicals through breakup of the cometary grains. Although highly uncertain, it is, nevertheless, interesting to look into the energy budget of the coma expansion. Taking the radial speed to be 1 km s^{-1}, the kinetic energy is then only of the order of 0.1 eV per H_2O molecule and about $\dot{E} \approx 10^{28}$ eV s^{-1} in total if the gas production rate is $\approx 10^{29}$ H_2O molecules s^{-1}. An equivalent amount of chemical-energy source could be obtained if the sublimating ice contains 3% or so of the highly volatile material capable of exothermic chemical reaction. The energy budget of the halo expansion is therefore not a serious problem. In other words, even if the gas production rate were the same over one spin period, the contamination of one side with exothermic material would result in high-speed ejecta driving a shock pair periodically.

The hydrodynamics of the neutral coma in the inner region is not well understood. Various possible flow patterns including shock formation in steady-state conditions have been considered (see refs 12 and 13). The time-dependent expansion of the

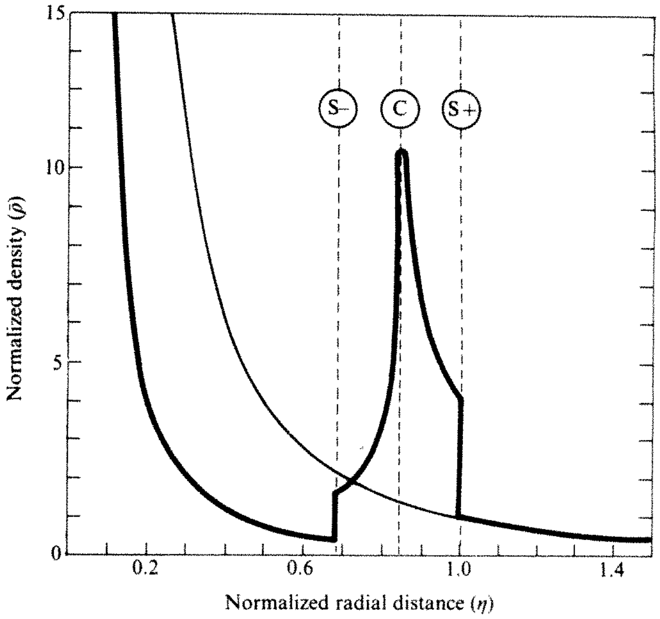

Fig. 1 The halo formation in the cometary comae through the compression effect of a piston shock. Radial variations of the density ($\bar{\rho}$) of the cometary neutral atmosphere normalized to the corresponding value at the position of the forward shock (S_+) at $\eta = 1$. Therefore $\bar{\rho} = \sigma(\eta)/\eta^2$ for $\eta = 1$ and $\bar{\rho} = 1/\eta^2$ for $\eta > 1$. The value of $\sigma(\eta)$ is obtained by taking a similarity solution to equations (1)–(6) with strong shocks (see ref. 8). The brightness enhancement in the haloes is caused by the density compression between the forward and reverse shocks. The dark zone sometimes observed immediately behind the haloes could be the manifestation of the rare-fraction region behind S_- as indicated. The density profile not modified by the shock pair is depicted by the thin curve.

cometary atmosphere should be even more complicated. Some idea can be derived from Bobrovnikoff's record of Comet Halley[1] where the expansion speed of the halo is estimated to be ≈ 0.25–$0.5\ \mathrm{km\,s^{-1}}$. Identifying this value as the propagation speed of the contact surface and using the relation that the flow speed u^* behind the reverse shock should be larger by a factor of 2.5[8], we obtain $u^* \approx 0.65$–$1.3\ \mathrm{km\,s^{-1}}$. This would mean that an additional energy source amounting to $\dot{E}^* \approx \frac{1}{2}Q(u^*)^2 \approx 10^{28}\ \mathrm{eV\,s^{-1}}$ (for $Q \approx 10^{29}$ H_2O molecules $\mathrm{s^{-1}}$) is needed to drive the piston gas. This requirement can be accommodated by introducing a small fraction of exothermic volatile material into the sublimating gas.

Whether any of these mechanisms may provide the energy required to drive a shock through the cometary atmosphere remains to be seen. But high-speed HCN jets ($u \geq 5\ \mathrm{km\,s^{-1}}$) have been detected in the coma of Comet Kohoutek (1973f) by Huebner *et al.*[14], who also favoured explosive chemical reactions as the origin of these jets. Thus the formation of shock pairs together with a compression region in between must be considered a viable explanation for the expanding haloes. For illustration and simplicity we have considered only the strong-shock case for the similarity solutions. Other types of compression processes with weaker shocks must also exist; the present interpretation, nevetheless, highlights the nature of non-steady expansion of the cometary atmosphere.

Blocking highs over Asia and monsoon droughts over India

C. R. V. Raman

MONEX, New Delhi-3, India

Y. P. Rao

B3/33 Azad Apartments, New Delhi-3, India

Severe summer droughts of the Indian subcontinent have been found to accompany prolonged 'breaks' in the south-west monsoon. Data from the years of severe drought suggest that the associated breaks were due to upper tropospheric blocking ridges over East Asia. We present here a model for the evolution of two such blocking ridges: the East Asia (EABR) and the West Asia (WABR). Apparently an intense WABR—the initiator of the monsoon break—precedes the formation of the EABR. This cycle could be a way of predicting years of intense drought or monsoon activity.

For a long time, studies of monsoon breaks were confined to changes in circulation in the monsoon area. Ramaswamy[1–3] was the first to associate breaks with the low index circulation in middle latitude westerlies and the elongation of mid-tropospheric westerly troughs into India. However, eastward-moving westerly troughs penetrating into northern India enhance monsoon activity, and Ramanathan[4] had visualized that migrating middle latitude ridges influence monsoon onset. Examining the severe droughts of 1979 (MONEX), 1972, 1966 and 1965, Raman *et al.*[5] found that the breaks in these years were associated with stagnant upper tropospheric blocking ridges over the east Asia along ~100°E, extending from 35°N to 70°N. In such situations, westerly troughs do not move beyond 80°E and instead tend to extend southwards.

Cold lows form south-west of the EABR and the lower tropospheric monsoon trough over India gets displaced northwards into the Himalayas—the most significant characteristic of breaks. We suggest that an upper trophospheric WABR along ~50°E is a necessary precursor to the development of the EABR. Also that in drought years, a well-marked surface high appears over USSR centred at 55°N and 50°E. This surface high is linked by a ridge with the Azores High over the central Atlantic. The surface high over the USSR, overlain by a ridge of up to 100 mbar, is due to the WABR. In contrast, in good monsoon years, the surface high and the associated upper ridge over the USSR are notably absent. Instead, a trough from the Aleutian low extends into Siberia with several low centres. Such a configuration is akin to the normal pattern.

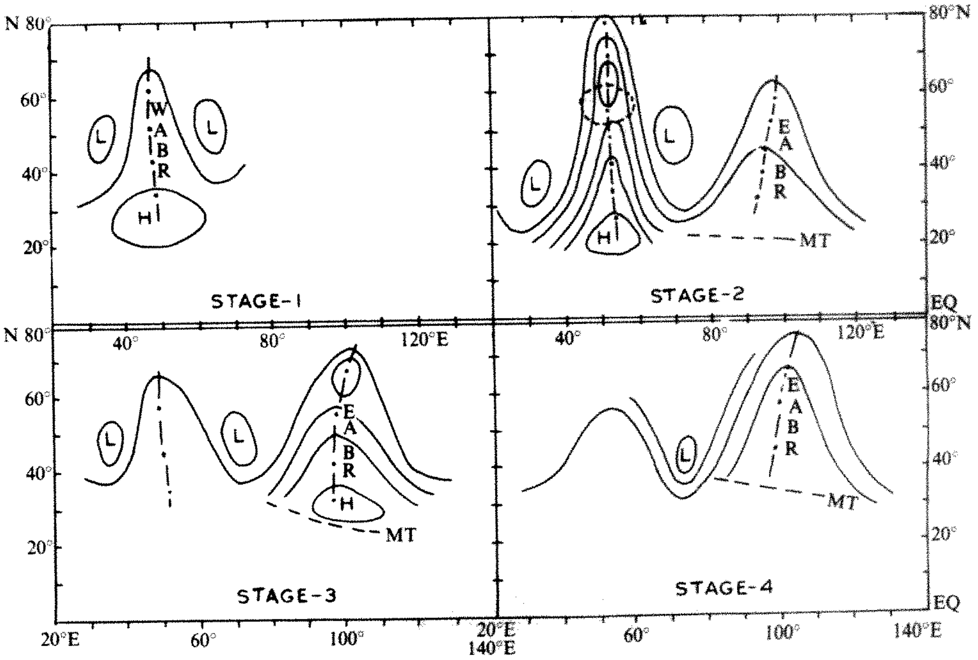

Fig. 1 Evolution of the WABR and the EABR. Solid lines denote 200-mbar contours; H, high; L, low; dashed-dotted line indicates north–south orientation of the 200-mbar blocking ridge. Stage 1, Appearance of WABR. Stage 2, Maximum phase of WABR with intense cold lows on either side. Surface high delineated by pecked isobar. EABR had commenced formation a few days earlier. Lower tropospheric Monsoon Trough (MT) in normal position. Stage 3, EABR had intensified along with weakening of WABR. Low upstream of the EABR shifts southwards. Stage 4, Monsoon trough is displaced significantly northwards leading to monsoon break.

* gpm, Geopotential metres.

The evolution of the WABR and the EABR, during drought years from 1960, was obtained from Northern Hemispherical Synoptic charts[6]. The sequence of events preceding a monsoon break starts with the appearance of a predominant ridge at 200 mbar, first in the longitudinal belt 40–70°E, extending from the subtropical high pressure cell in the monsoon regime to almost 80°N. Stagnating at times for periods of up to one to two weeks, the WABR builds up as a warm high, reaching almost to the surface in a week after appearance. At its intense phase, even a closed high develops in the whole column, with the surface pressure departing from the long term normal (1931–60) by as much as +20 mbar. Such a deep meridionally-oriented blocking ridge configuration over west Asia elongates the westerly troughs both on the upstream (west European) and the downstream (central Asian) sides. About a week after the maximum phase, the WABR begins to weaken.

The EABR generally appears in the belt 90–120°E some four days after the WABR forms, and extends from 35 to 70°N. The EABR begins to build up in a similar way to the WABR, generally when the latter starts to shrink in meridional extent and weaken. During this phase of the build up of the EABR, the westerly trough over central Asia between the WABR and the EABR further elongates to more southern latitudes. (The temperatures in this trough are ~5–8 °C below normal in the mid-troposphere but warmer than the surrounding at 200 mbar and 100 mbar.) The superposition of this elongated cold upper trough/low at southern latitudes is manifested as the displace-

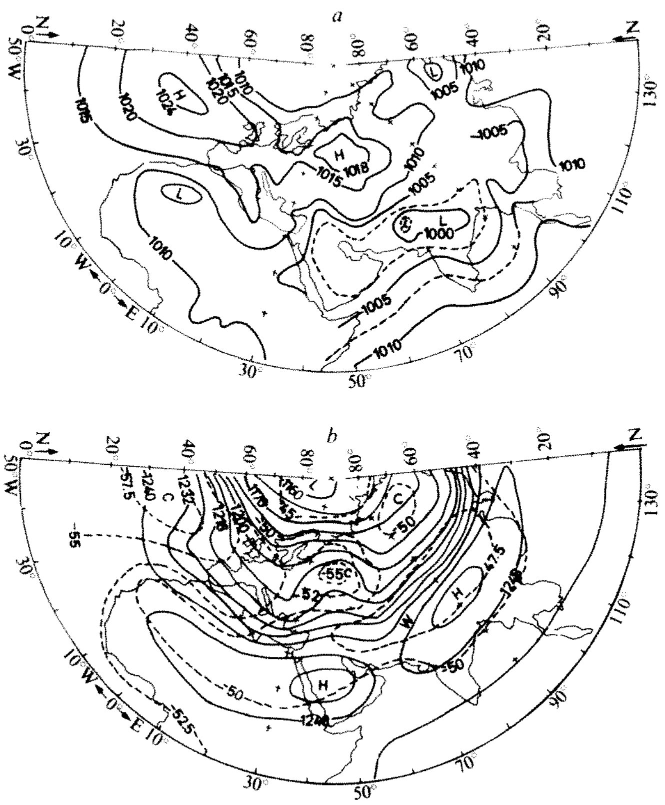

Fig. 2 Mean conditions in August 1972, a year of severe monsoon drought. *a*, Surface isobars. Note marked high centre at 55°N 50°E and the associated ridge linking with the Azores High over the central Atlantic. The ridge extends to 90°E across Eurasia. *b*, 200 mbar. Solid lines denote contours and dashed lines represent temperature (°C). C, cold; W, warm. Note markedly cold upper tropospheric ridge along 50°E, above the surface high over USSR.

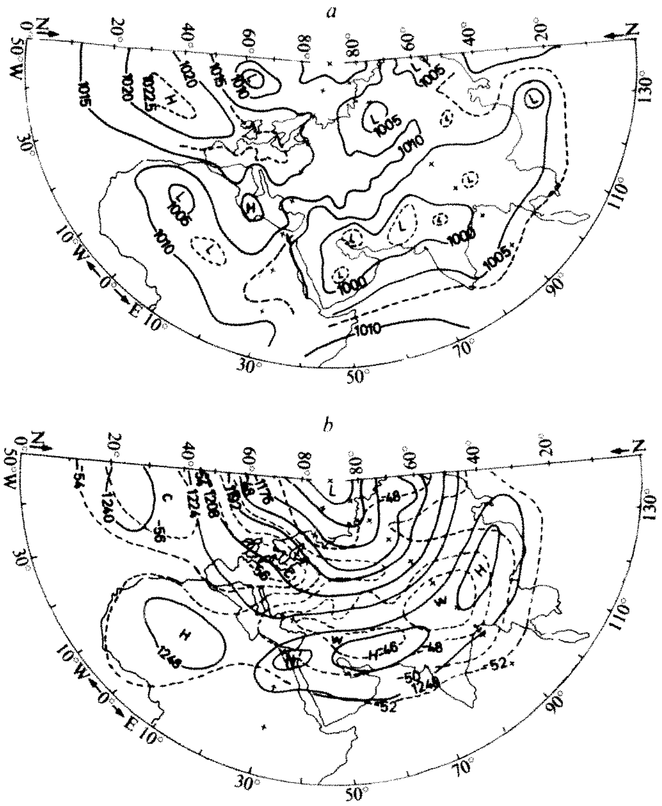

Fig. 3 Mean conditions during August 1975, a year of good monsoon rains. *a*, Surface isobars. Note the absence of a high centre over the USSR. Instead, a trough from the Aleutian low extends into Siberia with several low centres. Note that the monsoon low over India and neighbourhood is more intense than in Fig. 2*a* (1972). *b*, 200 mbar. Solid lines denote contours and dashed lines represent temperature (°C). Note the circumpolar flow and absence of ridges along 50°E.

ment of the lower tropospheric monsoon trough (MT) to the north into the Himalayas—symptomatic of the monsoon break. The build-up of an intense WABR seems essential for creating the EABR, which brings about the monsoon break. This cycle of the WABR building up well before the break could be useful in predicting monsoon breaks and consequent droughts. The sequence of evolution is presented in Fig. 1. A few examples of the cycle are given in Table 1.

Certain broad features of the WABR and the EABR are striking even in the monthly mean charts of 1972, a severe drought year. Figures 2 and 3 present the surface and upper air circulation features during August 1972 and 1975 respectively. In 1972, the WABR had started to build-up by the beginning of June and continued during the first half of July 1972. The subsequent build up of the EABR coincided with the pronounced break over India during the second half of July. The WABR/EABR configuration continued in August 1972, when the monsoon rains failed. The WABR prominent in Fig. 2*b* at 200 mbar, is associated with cold temperatures along ~50°E. The surface high vertically below this 200 mbar ridge is quite prominent (Fig. 2*a*). The EABR is less marked in the monthly mean chart (Fig. 2*b*), although it is seen markedly in decadal mean charts covering break occurrences in this and other years. In the good monsoon year of 1975, the circulation at 200 mbar (Fig. 3*b*) is more circumpolar with a weak trough in the location of the 1972 WABR (50°E). The contrasts between the good and bad monsoon years described above in the surface pressure distribution and the upper air features from the eastern Atlantic to east Asia are shown by other years during the past two decades.

Negative temperature anomalies are noticed at 200 mbar and above in WABR and EABR, with positive anomalies in the troposphere. The tropospheric warmth seems to be associated with the subsidence characteristic of high pressure. The stratospheric cooling must be due to the ascent, and maintains the high. Hoskins and Simmons have revived interest in downstream development as an important atmospheric scale phenomenon. It might be useful to apply this study to monsoon variability over India.

Possible role for metals in stratospheric chlorine chemistry

Edmond Murad & William Swider

Massachusetts 01731

Sidney W. Benson

Department of Chemistry, University of Southern California,
Los Angeles, California 90007

Meteoroids ablate largely in the Earth's ionosphere (at altitudes between 80 and 120 km) and the products are seen mostly as atomic ions[1–3]. Atomic neutral atoms have also been observed and studied optically, but the data are not extensive for elements other than sodium[4,5]. The processes responsible for maintaining the equilibrium of metallic atoms and ions in the ionosphere are understood generally[6–9]. Below 80 km, the metal ions are largely neutralized. The chemistry which occurs during the subsequent transport of the metals to the ground is uncertain; aerosols collected in the lower stratosphere have been reported to contain chlorides and sulphates of metals (some of which occur in meteors)[10–12] while aerosols collected in the troposphere have been found to contain many metals among which are meteor metals[13–16]. It has been suggested that ions of the type $Na^+ \cdot (H_2O)_n$ may be present in the upper stratosphere[17], their presence being plausible in view of a meteor sodium model which indicated that large amounts of NaOH (almost 10^6 cm^{-3}) would be present at 40 km (ref. 18). This latter conclusion was questioned[19] in view of thermochemical data which indicated that NaOH, once formed, should be removed quickly by reaction with Cl, ClO and HCl. We consider here reactions of meteor, and other, metals with Cl, ClO and HCl to assess the impact of halocarbons on ozone. Release of 1,000 tonne of sodium (or similar metal) may significantly reduce the harmful effects of halocarbons on ozone for several years.

Although sodium comprises only about 2% by weight of the total metal concentration in meteors[20], its reaction with Cl, ClO and HCl may represent a class of reactions which could be important in the chemical maintenance of these species in the stratosphere (the condensation of Ga, Ge and Sb in nebulae has been suggested to proceed through the respective metal hydroxide and metal chloride intermediates[21]). The other major metallic constituents of meteors are (by weight): Al(1.7%), Ca(1%), Fe(11.5%), Mg(12.5%), Ni(1.5%) and Si(20%). Here Si is included in the term 'metallics'. Other, less abundant metals (such as Ti, Cr, Mn) have been observed in micrometeorites collected in the stratosphere[22].

We now consider chemical reactions involving these metals or their intermediates with Cl, ClO and HCl, even though a quantitative evaluation of these reactions is not possible because of the lack of kinetic and thermochemical data. Cl, ClO and HCl have significant concentrations at altitudes between 15 and 50 km (refs 23, 24). Sodium will probably be in the form of NaOH (ref. 18) and/or $NaHCO_3$ by the time it has descended to 50 km (refs 19, 25). Similar compounds will be formed in the case of the other metals. The basic mechanism for the formation of the metal hydroxides (MOH) and the bicarbonates ($MHCO_3$) seems to be:

$$MO + H_2O \rightarrow MOH + OH \quad (M = \text{Na and, possibly, Al}) \qquad (1)$$

$$MO + CH_4 \rightarrow MOH + CH_3 \quad (M = \text{Na, Al}) \qquad (2)$$

$$MO + H_2 \rightarrow MOH + H \quad (M = \text{Na, Al}) \qquad (3)$$

$$MOH + CO_2 + X \rightarrow MHCO_3 + X \quad (\text{for all MOH}) \qquad (4)$$

where M is any meteor metal and X is any third-body. Metal chlorides, MCl, may then be formed by the reactions:

$$MOH + Cl \rightarrow MCl + OH \quad (M = \text{Na}) \qquad (5)$$

$$MOH + ClO \rightarrow MCl + HO_2 \quad (\text{all M}) \qquad (6)$$

$$MOH + HCl \rightarrow MCl + H_2O \quad (\text{all M}) \qquad (7)$$

$$MHCO_3 + HCl \rightarrow MCl + (H_2CO_3 \text{ or } H_2O + CO_2) \quad (\text{all M}) \qquad (8)$$

Reactions (7) and (8) are expected to proceed with large rate coefficients (~10^{-9} cm^3 molecule^{-1} s^{-1}) and can deplete HCl significantly relative to the reaction

$$HCl + OH \rightarrow H_2O + Cl \qquad (9)$$

which is an important step in the chain reaction leading to the depletion of ozone[26]. Reaction (9) has a rate coefficient[27] of 6.6×10^{-13} cm^3 molecule^{-1} s^{-1} so that even if $k_7 + k_8$ [rate coefficients for reactions (7) and (8)] were a factor of 1,000 less than estimated (that is ~10^{-12} cm^3 molecule^{-1} s^{-1}), they would still be important competition for reaction (9) for [OH]~[MOH]+[$MHCO_3$]; the data of refs 18 and 23 indicate this to be true at ~20 km. Of the meteor metals, sodium and aluminium

0028–0836/81/040273—02$01.00

can readily form chlorides through reactions (7) and (8). The possibility of forming hydroxides of other metals (Fe, Mg and Ca) by three-body reactions or by reactions of the monoxides with minor constituents (such as HO_2) should not be discounted.

Silicon is likely to enter the stratosphere as SiO_2 as the large dissociation energy of the monoxide, $D^\circ_0(\text{Si–O}) = 190 \pm 2\ \text{kcal mol}^{-1}$ (ref. 28), precludes its reduction by O atoms. SiO_2 might also form weakly bonded compounds with Cl, ClO and HCl; photochemical studies indicate that solid SiO_2 catalyses the rate of photochemical decomposition of halocarbons[29]. Reactions leading to the formation of MOCl may also be possible, perhaps through

$$\text{MO} + \text{ClO} \rightarrow \text{MOCl} + \text{O} \qquad (10)$$

Thermochemical data are available only for AlOCl, and these indicate that the dissociation energy of AlOCl, $D^\circ_0(\text{AlO–Cl})$ is greater than $D^\circ_0(\text{Cl–O})$ or $D^\circ_0(\text{H–Cl})$ (ref. 30). Indeed, analysis of the high-temperature reactions among the constituents of solid-fuel rocket engines predicts large amounts of AlOH and AlOCl at the expense of Al_2O_3 and HCl (ref. 31) (note that the engine of the space shuttle releases considerable amounts of Al_2O_3, Fe and $FeCl_2$ (ref. 32)).

A quantitative assessment of the importance of reactions (1)–(8) will have to await the availability of their rate coefficients. However, the strongly ionic character of many of these metals suggests that reactions of the above type will be fast. For example, Ca and ClO_2 react to yield both CaO and CaCl and the total reaction cross-section has been estimated to be $10^{-14}\ \text{cm}^2$ at thermal energies[33], which corresponds to a rate coefficient of $10^{-9}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$. Taking $k_7 + k_8$ to be $10^{-11}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$ (which is a conservative estimate) and using $[\text{MHCO}_3] + [\text{MOH}] \sim 2 \times 10^6\ \text{cm}^{-3}$ for M = Al + Na at 40 km [this is equivalent to twice the calculated total sodium compound concentration at 40 km (ref. 18)], then the time constant for reactions 7 + 8 is 5×10^4 s. On the other hand, reaction (9), the dominant process for the removal of HCl not involving metals, has a time constant of $\sim 2 \times 10^6$ s because $[\text{OH}] \sim 10^6\ \text{cm}^{-3}$ and $k_9 = 6.6 \times 10^{-13}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$ (ref. 27). This shows that reactions such as (7) and (8) may be important.

The metal chlorides, particularly NaCl, are very stable in the stratosphere, and would be expected to act as nucleating agents, eventually being incorporated in aerosols. (Rocket exhaust which contains metals such as aluminium has been found to enhance ice nucleation[34].) Observations indicate the presence of Cl (refs 10–12, 16, 35), and Na in some aerosols. At high temperatures both condensed and gaseous Na_2SO_4, a possible aerosol constituent, reacts[36,37] with HCl to yield NaCl. NaCl will, of course, polymerize readily. The condensation of NaCl will probably be in the form of heterogeneous nucleation of monomer, dimer or trimer NaCl with other constituents such as water molecules or sulphur dioxide. A cluster containing 100 molecules, only 1–3 of which are NaCl, will have a concentration of $\sim 10^6\ \text{cm}^{-3}$ and its sodium would be undetectable. On the other hand, a cluster of NaCl, $(\text{NaCl})_n$ with $n = 100$, would have a concentration of $\sim 10^4\ \text{cm}^{-3}$ and would again be undetectable in the atmosphere.

How much metal is deposited by meteors and how does this compare with the total amount of halocarbons deposited in the atmosphere? Parkin and Tilles[38] estimated the total meteor influx to the Earth to be from $3.6 \times 10^{10}\ \text{g yr}^{-1}$ to $3.6 \times 10^{11}\ \text{g yr}^{-1}$. Gadsden[7] estimated the total meteor influx to be $9 \times 10^{10}\ \text{g yr}^{-1}$ (9×10^4 tonnes per yr), corresponding to a total metal atom influx of 2×10^6 metal atoms $\text{cm}^{-2}\ \text{s}^{-1}$. Hughes[39] quoted values in the range 3×10^8–$5 \times 10^{13}\ \text{g yr}^{-1}$ with a recommended estimate of $5 \times 10^8\ \text{g yr}^{-1}$. Later, Hughes[40] reviewed the data and estimated the total amount of meteors deposited into the Earth to be $1.6 \times 10^{10}\ \text{g yr}^{-1}$. Hunten *et al.*[41] analysed this problem from the point of view of smoke and dust particles deposited in the Earth's mesosphere and stratosphere by meteoroids and preferred the value given by Hughes[40], although the possibility of a higher value was noted, and suggested[41] a meteoric origin for the condensation nuclei of sulphate aerosols. The total weight of halocarbons deposited in the atmosphere has been estimated to be $\sim 7 \times 10^5$ tonnes yr^{-1}. If Gadsden's estimate[7] is correct, then meteor metals may be important in the chemistry and fate of the halocarbons in the stratosphere.

High-flying aircraft provide two additional sources of metals in the stratosphere through the combustion of jet fuels and the erosion of engine parts (the latter being orders of magnitude greater than the former[42]). The principal metal contaminants in the fuels are iron, copper, calcium, vanadium and sodium, and these may be released in amounts varying between 100 and 1,000 tonnes yr^{-1} depending on the type of fuel and on the frequency of flights[43]. Engine erosion elements include predominantly aluminium, manganese and chromium.

An intentional or an unintentional release (such as, jet fuels and engine erosion) in the stratosphere of $\sim 10^3$ tonnes of Na and, possibly, Al might reduce [Cl] and [ClO] by a factor of two. It would require several years for the diffusion cycle to re-establish those concentrations if the release occurred above 30 km. Finally, although the above discussion is speculative, it may help explain recent controversial results obtained by Anderson *et al.*[44], who were the first to measure [Cl], [ClO] and $[O_3]$ simultaneously. Their results indicate some difficulties in current chemical models used to predict the effect of these species on $[O_3]$.

We thank Dr R. S. Narcisi for helpful comments.
